The **Superior Epigastric Artery** (*a. epigastrica superior*) continues in the original direction of the internal mammary; it descends through the interval between the costal and sternal attachments of the Diaphragma, and enters the sheath of the Rectus abdominis, at first lying behind the muscle, and then perforating and supplying it, and anastomosing with the inferior epigastric artery from the external iliac. Branches perforate the anterior wall of the sheath of the Rectus, and supply the muscles of the abdomen and the integument, and a small branch passes in front of the xiphoid process and anastomoses with the artery of the opposite side. It also gives some twigs to the Diaphragma, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

Applied Anatomy.—The internal mammary artery is liable to be wounded in stabs of the chest wall and in the operation of paracentesis pericardii (p. 603). It is most easily reached by a transverse incision in the second intercostal space.

4. The **costocervical trunk** (*truncus costocervicalis; superior intercostal artery*) (Fig. 590) arises from the upper and back part of the subclavian artery, behind the Scalenus anterior on the right side, and medial to that muscle on the left side. Passing backward, it gives off the **profunda cervicalis**, and, continuing as the **highest intercostal artery**, descends behind the pleura in front of the necks of the first and second ribs, and anastomoses with the first aortic intercostal. As it crosses the neck of the first rib it lies medial to the anterior division of the first thoracic nerve, and lateral to the first thoracic ganglion of the sympathetic trunk.

In the first intercostal space, it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the highest aortic intercostal artery. This branch is not constant, but is more commonly found on the right side; when absent, its place is supplied by an intercostal branch from the aorta. Each intercostal gives off a posterior branch which goes to the posterior vertebral muscles, and sends a small spinal branch through the corresponding intervertebral foramen to the medulla spinalis and its membranes.

The **Profunda Cervicalis** (*a. cervicalis profunda; deep cervical branch*) arises, in most cases, from the costocervical trunk, and is analogous to the posterior branch of an aortic intercostal artery: occasionally it is a separate branch from the subclavian artery. Passing backward, above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the neck of the first rib, it runs up the back of the neck, between the Semispinales capitis and colli, as high as the axis vertebra, supplying these and adjacent muscles, and anastomosing with the deep division of the descending branch of the occipital, and with branches of the vertebral. It gives off a spinal twig which enters the canal through the intervertebral foramen between the seventh cervical and first thoracic vertebræ.

THE AXILLA.

The axilla is a pyramidal space, situated between the upper lateral part of the chest and the medial side of the arm.

Boundaries.—The *apex*, which is directed upward toward the root of the neck, corresponds to the interval between the outer border of the first rib, the superior border of the scapula, and the posterior surface of the clavicle, and through it the axillary vessels and nerves pass. The *base*, directed downward, is broad at the chest but narrow and pointed at the arm; it is formed by the integument and a thick layer of fascia, the **axillary fascia**, extending between the lower border of the Pectoralis major in front, and the lower border of the Latissimus dorsi behind. The *anterior wall* is formed by the Pectorales major and minor, the former covering the whole of this wall, the latter only its central part. The space between the upper border of the Pectoralis minor and the clavicle is occupied by the coracoclavicular fascia. The *posterior wall*, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *medial side* are the first four ribs with their corresponding Intercostales, and part of the Serratus anterior. On the *lateral side*, where the anterior and posterior walls converge, the space is narrow, and bounded by the humerus, the Coracobrachialis, and the Biceps brachii.

Contents.—It contains the axillary vessels, and the brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymph glands, together with a quantity of fat and loose areolar tissue. The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the lateral boundary of the axilla, from its apex to its base, and are placed much nearer to the anterior than to the posterior wall, the vein lying to the thoracic side of the artery and partially concealing it. At the forepart of the axilla, in contact with the Pectorales, are the thoracic branches of the axillary artery, and along the lower margin of the Pectoralis minor the lateral thoracic artery extends to the side of the chest. At the back part, in contact with the lower margin of the Subscapularis, are the subscapular vessels and nerves; winding around the lateral border of this muscle are the scapular circumflex vessels; and, close to the neck of the humerus, the posterior humeral circumflex vessels and the axillary nerve curve backward to the shoulder. Along the medial or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the highest thoracic artery. There are some important nerves, however, in this situation, viz., the long thoracic nerve, descending on the surface of the Serratus anterior, to which it is distributed; and the intercostobrachial nerve, perforating the upper and anterior part of this wall, and passing across the axilla to the medial side of the arm.

The position and arrangement of the lymph glands are described on pages 780 and 781.

Applied Anatomy.—The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease; it contains numerous lymph glands which may require removal; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or inflammatory exudation; and it may be the seat of rapidly growing tumors. Moreover, it is covered at its base by thin skin, which is largely supplied with sebaceous and sweat glands, and is frequently the seat of small cutaneous abscesses and boils.

Penetrating wounds in the axilla are sometimes accompanied by extensive hemorrhage, either from wounds of the main vessels, or of one of the large branches of the axillary artery, *e. g.*, the lateral thoracic or the subscapular. Where the blood cannot find an easy exit externally, it collects in the axillary space and forms a large swelling which projects in the floor of the axilla and also bulges forward the Pectoralis major. The treatment consists in freely opening up the cavity and searching for and securing the bleeding vessel.

When suppuration occurs in the axilla, the arrangement of the fasciæ plays a very important part in the direction which the pus takes. As described on page 528, the coracoclavicular fascia, after covering in the space between the clavicle and the upper border of the Pectoralis minor splits to enclose this muscle, and, reblending at its lower border, becomes incorporated with the axillary fascia at the anterior fold of the axilla. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the Pectorales or behind the Pectoralis minor; in the former case, the abscess would point either at the anterior border of the axillary fold, or in the groove between the Deltoideus and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves, and ascend into the neck, that being the direction in which there is least resistance. Its progress toward the surface is prevented by the axillary fascia; its progress backward, by the insertion of the Serratus anterior; forward, by the coracoclavicular fascia; medialward, by the wall of the thorax; and lateralward, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinal cavity. Instances have been recorded where the pus found its way along the course of the vessels into the upper arm.

When opening an axillary abscess, the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. After an incision has been made through the skin and fascia it is well to use a director and dressing forceps in the manner directed by Hilton.

The relations of the vessels and nerves in the several parts of the axilla are important, for it is the almost universal plan, in the present day, to remove the glands from the axilla in operating for cancer of the breast. In performing such an operation, it is necessary to proceed with much caution in the direction of the lateral wall and apex of the space, as here the axillary vessels are in danger of being wounded. The subscapular, scapular circumflex, and posterior humeral circumflex vessels on the posterior wall and the thoracic branches along the anterior wall must be avoided. In clearing out the axilla, the axillary vein should be first defined and traced up to the apex of the space by means of a director. The Pectoralis major is retracted by an assistant; or, as is more commonly the practice in the present day, the sternocostal origin of this muscle is first removed. This proceeding not only lessens the chance of recurrence of the disease, but also enables the surgeon to clear out the axillary cavity more thoroughly. When the apex of the space is reached all fat and glands must be carefully removed and the whole axilla cleared by separating the tissues along the medial and posterior walls, so that when the proceeding is completed the axilla is emptied of all its contents except the main vessels and nerves.

The Axillary Artery (A. Axillaris) (Fig. 599).

The **axillary artery**, the continuation of the subclavian, commences at the outer border of the first rib, and ends at the lower border of the tendon of the Teres major, where it takes the name of brachial. Its direction varies with the position of the limb; thus the vessel is nearly straight when the arm is directed at right angles with the trunk, concave upward when the arm is elevated above this, and convex upward and lateralward when the arm lies by the side. At its origin the artery is very deeply situated, but near its termination is superficial, being covered only by the skin and fascia. To facilitate the description of the vessel it is divided into three portions; the first part lies above, the second behind, and the third below the Pectoralis minor.

Relations.—The **first portion** of the axillary artery is covered *anteriorly* by the clavicular portion of the Pectoralis major and the coracoclavicular fascia, and is crossed by the lateral anterior thoracic nerve, and the thoracoacromial and cephalic veins; *posterior* to it are the first intercostal space, the corresponding Intercostalis externus, the first and second digitations of the Serratus anterior, and the long thoracic and medial anterior thoracic nerves, and the medial cord of the brachial plexus; on its *lateral side* is the brachial plexus, from which it is separated by a little areolar tissue; on its *medial*, or thoracic side, is the axillary vein which overlaps the artery. It is enclosed, together with the axillary vein and the brachial plexus, in a fibrous sheath—the **axillary sheath**—continuous above with the deep cervical fascia.

The **second portion** of the axillary artery is covered, *anteriorly*, by the Pectorales major and minor; posterior to it are the posterior cord of the brachial plexus, and some areolar tissue which intervenes between it and the Subscapularis; on the *medial side* is the axillary vein, separated from the artery by the medial cord of the brachial plexus and the medial anterior thoracic nerve; on the *lateral side* is the lateral cord of the brachial plexus. The brachial plexus thus surrounds the artery on three sides, and separates it from direct contact with the vein and adjacent muscles.

The **third portion** of the axillary artery extends from the lower border of the Pectoralis minor to the lower border of the tendon of the Teres major. *In front*, it is covered by the lower part

of the Pectoralis major above, but only by the integument and fascia below; *behind*, it is in relation with the lower part of the Subscapularis, and the tendons of the Latissimus dorsi and Teres major; on its *lateral side* is the Coracobrachialis, and on its *medial* or thoracic side, the axillary vein. The nerves of the brachial plexus bear the following relations to this part of the artery: on the *lateral side* are the lateral head and the trunk of the median, and the musculocutaneous for a short distance; on the *medial side* the ulnar (between the vein and artery) and medial brachial cutaneous (to the medial side of the vein); *in front* are the medial head of the median and the medial antibrachial cutaneous, and *behind*, the radial and axillary, the latter only as far as the lower border of the Subscapularis.

A
Au
circ

FIG. 599.—The axillary artery and its branches.

Applied Anatomy.—*Compression* of the vessel may be required in the removal of tumors, or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing it against the humerus in this situation, the circulation may be effectually arrested.

With the exception of the popliteal, the axillary artery is perhaps more frequently lacerated than any other artery in the body by violent movements, especially in those cases where its coats are diseased. It has occasionally been ruptured in attempts to reduce old dislocations of the shoulder-joint. This lesion is most likely to occur during the preliminary breaking down of adhesions, in cases where the artery has become fixed to the capsule of the joint. Aneurism of the axillary artery sometimes occurs; a large number of the cases are traumatic in their origin, due to the injuries to which the artery is exposed in the varied, extensive, and often violent movements of the limb.

The *application of a ligature to the axillary artery* may be required in cases of aneurism of the upper part of the brachial, or as a distal operation for aneurism of the subclavian; and there are only two situations in which it can be secured, viz., in the first and in the third parts of its course; for the second part of the artery is so deeply seated, and so closely surrounded with large nerve trunks, that the application of a ligature to it there would be almost impracticable.

In the *third part* of its course the operation is simple, and may be performed in the following manner. The arm is separated from the side, with the hand supinated, and an incision about 5 cm. in length is made through the integument forming the floor of the axilla, a little nearer to the anterior than to the posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the nerve is displaced to the

lateral, and the vein to the medial side of the arm, the elbow being at the same time bent so as to relax the structures and facilitate their separation; the ligature may be passed around the artery from the ulnar to the radial side. This portion of the artery is occasionally crossed by a muscular slip, the **axillary arch** (p. 524), derived from the *Latissimus dorsi*.

The *first portion* of the axillary artery may be tied in cases of aneurism encroaching so far upward that a ligature cannot be applied to the lower part of the artery. Notwithstanding that this operation has been performed in some few patients with success, its performance is attended with much difficulty and danger. The student will remark that, in this situation, it would be necessary to divide a thick muscle, and, after incising the coracoclavicular fascia, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to it particularly hazardous. Under such circumstances, it is an easier and, at the same time, more advisable operation, to tie the third part of the subclavian artery. The first part of the axillary can be best secured by a curved incision with the convexity downward from a point 1.25 cm. lateral to the sternoclavicular joint to a point 1.25 cm. on the medial side of the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and the incision carried through the superficial structures, care being taken of the cephalic vein at the lateral angle of the incision. The clavicular origin of the *Pectoralis major* is then divided in the whole extent of the wound. The arm is now brought to the side, and the upper edge of the *Pectoralis minor* defined and drawn downward. The coracoclavicular fascia is carefully divided on a director, close to the coracoid process, and the axillary sheath exposed; this is to be opened with special care on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

Collateral Circulation after Ligature of the Axillary Artery.—If the artery be tied above the origin of the thoracoacromial, the collateral circulation will be carried on by the same branches as after the ligature of the third part of the subclavian (p. 658); if at a lower point, between the thoracoacromial and the subscapular, the latter vessel, by its free anastomosis with the transverse scapular and transverse cervical branches of the subclavian, will become the chief agent in carrying on the circulation; the lateral thoracic, if it be below the ligature, will materially contribute by its anastomoses with the intercostal and internal mammary arteries. If the point included in the ligature is below the origin of the subscapular artery, it will most probably also be below the origins of the two humeral circumflex arteries. The chief agents in restoring the circulation will then be the subscapular and the two humeral circumflex arteries anastomosing with the *a. profunda brachii*.

Branches.—The branches of the axillary are:

<i>From first part</i> , Highest Thoracic.	<i>From second part</i> { Thoracoacromial. Lateral Thoracic.
<i>From third part</i> { Subscapular. Posterior Humeral Circumflex. Anterior Humeral Circumflex.	

1. The **highest thoracic artery** (*a. thoracalis suprema; superior thoracic artery*) is a small vessel, which may arise from the thoracoacromial. Running forward and medialward along the upper border of the *Pectoralis minor*, it passes between it and the *Pectoralis major* to the side of the chest. It supplies branches to these muscles, and to the parietes of the thorax, and anastomoses with the internal mammary and intercostal arteries.

2. The **thoracoacromial artery** (*a. thoracoacromialis; acromiothoracic artery; thoracic axis*) is a short trunk, which arises from the forepart of the axillary artery, its origin being generally overlapped by the upper edge of the *Pectoralis minor*. Projecting forward to the upper border of this muscle, it pierces the coracoclavicular fascia and divides into four branches—pectoral, acromial, clavicular, and deltoid. The **pectoral branch** descends between the two *Pectorales*, and is distributed to them and to the mamma, anastomosing with the intercostal branches of the internal mammary and with the lateral thoracic. The **acromial branch** runs lateralward over the coracoid process and under the *Deltoides*, to which it gives branches; it then pierces that muscle and ends on the acromion in an arterial network formed by branches from the transverse scapular, thoracoacromial, and posterior humeral circumflex arteries. The **clavicular branch** runs upward and medialward to the sternoclavicular joint, supplying this articulation, and the *Subclavius*. The

deltoid (humeral) branch, often arising with the acromial, crosses over the Pectoralis minor and passes in the same groove as the cephalic vein, between the Pectoralis major and Deltoideus, and gives branches to both muscles.

3. The **lateral thoracic artery** (*a. thoracalis lateralis*; *long thoracic artery*; *external mammary artery*) follows the lower border of the Pectoralis minor to the side of the chest, supplying the Serratus anterior and the Pectoralis, and sending branches across the axilla to the axillary glands and Subscapularis; it anastomoses with the internal mammary, subscapular, and intercostal arteries, and with the pectoral branch of the thoracoacromial. In the female it supplies an **external mammary branch** which turns round the free edge of the Pectoralis major and supplies the mamma.

4. The **subscapular artery** (*a. subscapularis*) the largest branch of the axillary artery, *arises* at the lower border of the Subscapularis, which it follows to the inferior angle of the scapula, where it anastomoses with the lateral thoracic and intercostal arteries and with the descending branch of the transverse cervical, and ends in the neighboring muscles. About 4 cm. from its origin it gives off a branch, the **scapular circumflex artery**.

The **Scapular Circumflex Artery** (*a. circumflexa scapulae*; *dorsalis scapulae artery*) is generally larger than the continuation of the subscapular. It curves around the axillary border of the scapula, traversing the space between the Subscapularis above, the Teres major below, and the long head of the Triceps laterally (Fig. 600); it enters the infraspinatus fossa under cover of the Teres minor, and anastomoses with the transverse scapular artery and the descending branch of the transverse cervical. In its course it gives off two branches: one (*infrascapular*) enters the subscapular fossa beneath the Subscapularis, which it supplies, anastomosing with the transverse scapular artery and the descending branch of the transverse cervical; the other is continued along the axillary border of the scapula, between the Teretes major and minor, and at the dorsal surface of the inferior angle anastomoses with the descending branch of the transverse cervical. In addition to these, small branches are distributed to the back part of the Deltoideus and the long head of the Triceps brachii, anastomosing with an ascending branch of the a. profunda brachii.

5. The **posterior humeral circumflex artery** (*a. circumflexa humeri posterior*; *posterior circumflex artery*) (Fig. 600) *arises* from the axillary artery at the lower border of the Subscapularis, and runs backward with the axillary nerve through the quadrangular space bounded by the Subscapularis and Teres minor above, the Teres major below, the long head of the Triceps brachii medially, and the surgical neck of the humerus laterally. It winds around the neck of the humerus and is distributed to the Deltoideus and shoulder-joint, anastomosing with the anterior humeral circumflex and profunda brachii.

FIG. 600.—The scapular and circumflex arteries.

6. The **anterior humeral circumflex artery** (*a. circumflexa humeri anterior; anterior circumflex artery*) (Fig. 600), considerably smaller than the posterior, *arises* nearly opposite it, from the lateral side of the axillary artery. It runs horizontally, beneath the Coracobrachialis and short head of the Biceps brachii, in front of the neck of the humerus. On reaching the intertubercular sulcus, it gives off a branch which ascends in the sulcus to supply the head of the humerus and the shoulder-joint. The trunk of the vessel is then continued onward beneath the long head of the Biceps brachii and the Deltoideus, and anastomoses with the posterior humeral circumflex artery.

Peculiarities.—The branches of the axillary artery vary considerably in different subjects. Occasionally the subscapular, humeral circumflex, and profunda arteries arise from a common trunk, and when this occurs the branches of the brachial plexus surround this trunk instead of the main vessel. Sometimes the axillary artery divides into the radial and ulnar arteries, and occasionally it gives origin to the volar interosseous artery of the forearm.

The Brachial Artery (A. Brachialis) (Fig. 601).

The **brachial artery** commences at the lower margin of the tendon of the Teres major, and, passing down the arm, ends about 1 cm. below the bend of the elbow, where it divides into the **radial** and **ulnar arteries**. At first the brachial artery lies medial to the humerus; but as it runs down the arm it gradually gets in front of the bone, and at the bend of the elbow it lies midway between its two epicondyles.

Relations.—The artery is superficial throughout its entire extent, being covered, *in front*, by the integument and the superficial and deep fasciæ; the *lacertus fibrosus* (*bicipital fascia*) lies in front of it opposite the elbow and separates it from the *vena mediana cubiti*; the median nerve crosses from its lateral to its medial side opposite the insertion of the Coracobrachialis. *Behind*, it is separated from the long head of the Triceps brachii by the radial nerve and a *profunda* of the Coracobrachialis, and lastly on the Brachialis. *Laterally*, it is in relation above with the median nerve and the Coracobrachialis, below with the Biceps brachii, the two muscles overlapping the artery to a considerable extent. *Medially*, its upper half is in relation with the medial antibrachial cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on its medial side, but is separated from it in the lower part of the arm by the deep fascia. The artery is accompanied by two *venæ comitantes*, which lie in close contact with it, and are connected together at intervals by short transverse branches.

The **Anticubital Fossa**.—At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the **anticubital fossa**. The base of the triangle is directed upward, and is represented by a line connecting the two epicondyles of the humerus; the sides are formed by the medial edge of the Brachioradialis and the lateral margin of the Pronator teres; the floor is formed by the Brachialis and Supinator. This space contains the brachial artery, with its accompanying veins; the radial and ulnar arteries; the median and radial nerves; and the tendon of the Biceps brachii. The brachial artery occupies the middle of the space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the integument, the superficial fascia, and the *vena mediana cubiti*, the last being separated from the artery by the *lacertus fibrosus*. *Behind* it is the Brachialis which separates it from the elbow-joint. The median nerve lies close to the medial side of the artery, above, but is separated from it below by the ulnar head of the Pronator teres. The tendon of the Biceps brachii lies to the lateral side of the artery; the radial nerve is situated upon the Supinator, and concealed by the Brachioradialis.

Peculiarities of the Brachial Artery as Regards its Course.—The brachial artery, accompanied by the median nerve, may leave the medial border of the Biceps brachii, and descend toward the medial epicondyle of the humerus; in such cases it usually passes behind the *supracondylar process* of the humerus, from which a fibrous arch is in most cases thrown over the artery; it then runs beneath or through the substance of the Pronator teres, to the bend of the elbow.

This variation bears considerable analogy with the normal condition of the artery in some of the carnivora; it has been referred to in the description of the humerus (p. 312).

As Regards its Division.—Occasionally, the artery is divided for a short distance at its upper part into two trunks, which are united below. Frequently the artery divides at a higher level than usual, and the vessels concerned in this high division are three, viz., radial, ulnar, and interosseous. Most frequently the radial is given off high up, the other limb of the bifurcation consisting of the ulnar and interosseous; in some instances the ulnar arises above the ordinary level, and the radial and interosseous form the other limb of the division; occasionally the interosseous arises high up.

Sometimes, long slender vessels, *vasa aberrantia*, connect the brachial or the axillary artery with one of the arteries of the forearm, or branches from them. These vessels usually join the radial.

Varieties in Muscular Relations.—The brachial artery is occasionally concealed, in some part of its course, by muscular or tendinous slips derived from the Coracobrachialis, Biceps brachii, Brachialis, or Pronator teres.

Applied Anatomy.—In spite of the fact that the brachial artery is very superficial and but little protected by surrounding tissues, it is seldom wounded. This, no doubt, is due to its situation on the medial side of the arm, which is little exposed to injury. Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm, and may be effected in almost any part of the course of the artery. If pressure be made in the upper part of the limb, it should be directed lateralward; if in the lower part, backward, as the artery lies on the medial side of the humerus above, and in front of it below. The most favorable situation is about the middle of the arm, where the artery lies on the tendon of the Coracobrachialis on the medial surface of the humerus.

The application of a ligature to the brachial artery may be required in cases of wound of the vessel, and in some cases of wound of the volar arch. It is also sometimes necessary in cases of aneurism of the brachial, radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the medial margins of the Coracobrachialis and Biceps brachii, and the known course of the vessel; its pulsation should be carefully felt for before any

operation is performed, as the vessel occasionally deviates from its usual position. It is essential in applying a ligature to this vessel that the arm should be held away from the side, and supported only from the elbow, for if the arm be allowed to rest on any firm structure the Triceps brachii is pressed forward and overlaps the vessel, thus making the operation much more difficult.

In the upper third of the arm the artery may be exposed in the following manner. The patient being placed supine upon a table, the affected limb should be raised from the side, and the hand supinated. An incision about 5 cm. in length is made on the medial side of the Coracobrachialis, and the subjacent fascia cautiously divided, so as to avoid wounding the medial antibrachial cutaneous nerve or basilic vein, as the latter sometimes runs on the surface of the artery as high as the axilla. The fascia having been divided, it should be remembered that the ulnar nerve and the medial antibrachial cutaneous nerve lie on the medial side of the artery, the median nerve

artery

FIG. 601. —The brachial artery.

on the lateral side but occasionally superficial to the artery in this situation, and that the venæ comitantes are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed around the artery from the medial side.

In the case of a high division, the two arteries are usually placed side by side; and if they are exposed in an operation, the surgeon should endeavor to ascertain, by alternately pressing on each vessel, which is connected with the wound or aneurism, when a ligature may be applied accordingly; if pulsation or hemorrhage ceases only when both vessels are compressed, both must be tied.

In the middle of the arm the brachial artery may be exposed by making an incision along the medial margin of the Biceps brachii. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and the fascia carefully divided, when the median nerve will be exposed lying upon (sometimes behind) the artery; the nerve being drawn medialward and the muscle lateralward, the artery should be separated from its accompanying veins and secured. In this situation the superior ulnar collateral (*inferior profunda*) may be mistaken for the main trunk, especially if enlarged from the collateral circulation having become established; this may be avoided by directing the incision toward the Biceps brachii, rather than toward the Triceps brachii.

The lower part of the brachial artery is of interest from a surgical point of view, on account of the relation which it bears to the veins most commonly opened in venesection. Of these vessels, the vena mediana cubiti (*median basilic vein*) is the largest and most prominent, and, consequently, the one usually selected for the operation. This vein runs parallel with the brachial artery, from which it is separated by the lacertus fibrosus (*bicipital fascia*), and care should be taken, in opening the vein, not to carry the incision too deep, so as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the humeral circumflex and subscapular arteries anastomosing with ascending branches from the profunda brachii. If the artery be tied *below* the origin of the profunda brachii and superior ulnar collateral, the circulation is maintained by the branches of these two arteries anastomosing with the inferior ulnar collateral, the radial and ulnar recurrents, and the dorsal interosseous.

Branches.—The branches of the brachial artery are:

Profunda Brachii.	Superior Ulnar Collateral.
Nutrient.	Inferior Ulnar Collateral.
	Muscular.

1. The **arteria profunda brachii** (*superior profunda artery*) is a large vessel which arises from the medial and back part of the brachial, just below the lower border of the Teres major. It follows closely the radial nerve, running at first backward between the medial and lateral heads of the Triceps brachii, then along the groove for the radial nerve, where it is covered by the lateral head of the Triceps brachii, to the lateral side of the arm; there it pierces the lateral intermuscular septum, and, descending between the Brachioradialis and the Brachialis to the front of the lateral epicondyle of the humerus, ends by anastomosing with the radial recurrent artery. It gives branches to the Deltoideus and to the muscles between which it lies; it supplies an occasional **nutrient artery** which enters the humerus behind the deltoid tuberosity. A branch ascends between the long and lateral heads of the Triceps brachii to anastomose with the posterior humeral circumflex artery; a **middle collateral branch** descends in the middle head of the Triceps brachii and assists in forming the anastomosis above the olecranon; and, lastly, a **radial collateral branch** runs down behind the lateral intermuscular septum to the back of the lateral epicondyle of the humerus, where it anastomoses with the interosseous recurrent and the inferior ulnar collateral arteries.

2. The **nutrient artery** (*a. nutritia humeri*) of the body of the humerus arises about the middle of the arm and enters the nutrient canal near the insertion of the Coracobrachialis.

3. The **superior ulnar collateral artery** (*a. collateralis ulnaris superior; inferior profunda artery*), of small size, arises from the brachial a little below the middle of the arm; it frequently springs from the upper part of the a. profunda brachii. It pierces the medial intermuscular septum, and descends on the surface of the medial head of the Triceps brachii to the space between the medial epicondyle and

olecranon, accompanied by the ulnar nerve, and ends under the Flexor carpi ulnaris by anastomosing with the posterior ulnar recurrent, and inferior ulnar collateral. It sometimes sends a branch in front of the medial epicondyle, to anastomose with the anterior ulnar recurrent.

4. The **inferior ulnar collateral artery** (*a. collateralis ulnaris inferior; anastomotica magna artery*) arises about 5 cm. above the elbow. It passes medialward upon the Brachialis, and piercing the medial intermuscular septum, winds around the back of the humerus between the Triceps brachii and the bone, forming, by its junction with the profunda brachii, an arch above the olecranon fossa. As the vessel lies on the Brachialis, it gives off branches which ascend to join the superior ulnar collateral: others descend in front of the medial epicondyle, to anastomose with the anterior ulnar recurrent. Behind the medial epicondyle a branch anastomoses with the superior ulnar collateral and posterior ulnar recurrent arteries.

5. The **muscular branches** (*rami musculares*) three or four in number, are distributed to the Coracobrachialis, Biceps brachii, and Brachialis.

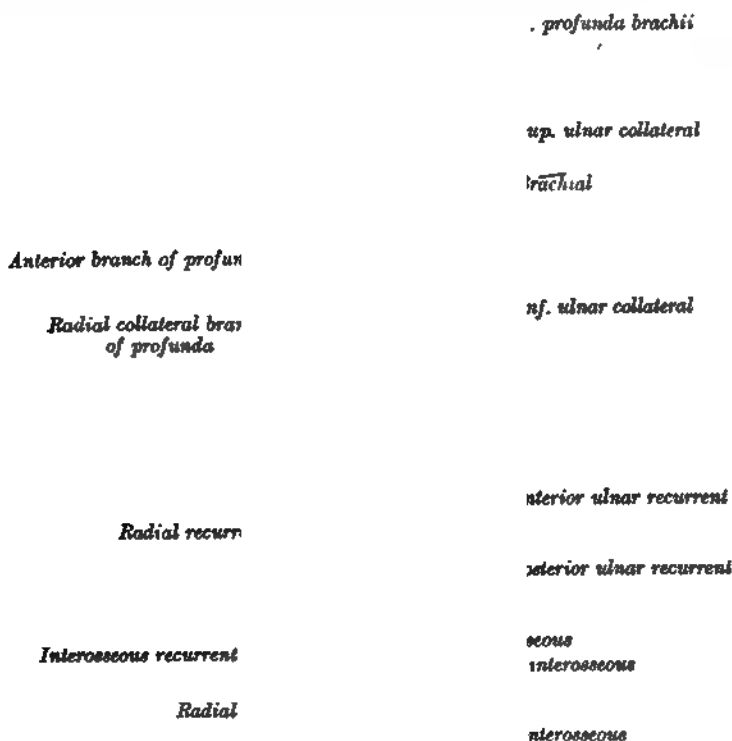

FIG. 802.—Diagram of the anastomosis around the elbow-joint.

The Anastomosis Around the Elbow-joint (Fig. 602).—The vessels engaged in this anastomosis may be conveniently divided into those situated *in front* of and those *behind* the medial and lateral epicondyles of the humerus. The branches anastomosing *in front* of the medial epicondyle are: the anterior branch of the inferior ulnar collateral, the anterior ulnar recurrent, and the anterior branch of the superior ulnar collateral. Those *behind* the medial epicondyle are: the inferior ulnar collateral, the posterior ulnar recurrent, and the posterior branch of the superior ulnar collateral. The branches anastomosing *in front* of the lateral epicondyle are: the radial recurrent and the terminal part of the profunda brachii. Those *behind* the lateral epicondyle (perhaps more properly described as being situated

between the lateral epicondyle and the olecranon) are: the inferior ulnar collateral, the interosseous recurrent, and the radial collateral branch of the profunda brachii. There is also an arch of anastomosis above the olecranon, formed by the interosseous recurrent joining with the inferior ulnar collateral and posterior ulnar recurrent (Fig. 605).

The Radial Artery (A. Radialis) (Fig. 603).

The radial artery appears, from its direction, to be the continuation of the brachial, but it is smaller in calibre than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist. It then winds backward, around the lateral side of the carpus, beneath the tendons of the Abductor pollicis longus and Extensores pollicis longus and brevis to the upper end of the space between the metacarpal bones of the thumb and index finger. Finally it passes forward between the two heads of the first Interosseous dorsalis, into the palm of the hand, where it crosses the metacarpal bones and at the ulnar side of the hand unites with the deep volar branch of the ulnar artery to form the deep volar arch. The radial artery therefore consists of three portions, one in the forearm, a second at the back of the wrist, and a third in the hand.

Relations.—(a) *In the forearm* the artery extends from the neck of the radius to the forepart of the styloid process, being placed to the medial side of the body of the bone above, and in front of it below. Its upper part is overlapped by the fleshy belly of the Brachioradialis; the rest of the artery is superficial, being covered by the integument and the superficial and deep fasciæ. In its course downward, it lies upon the tendon of the Biceps brachii, the Supinator, the Pronator teres, the radial origin of the Flexor digitorum sublimis, the Flexor pollicis longus, the Pronator quadratus, and the lower end of the radius. In the upper third of its course it lies between the Brachioradialis and the Pronator teres; in the lower two-thirds, between the tendons of the Brachioradialis and Flexor carpi radialis. The superficial branch of the radial nerve is close to the lateral side of the artery in the middle third of its course; and some filaments of the lateral antibrachial cutaneous nerve run along the lower part of the artery as it winds around the wrist. The vessel is accompanied by a pair of venæ comitantes throughout its whole course.

(b) *At the wrist* the artery reaches the back of the carpus by passing between the radial collateral ligament of the wrist and the tendons of the Abductor pollicis longus and Extensor pollicis brevis. It then descends on the navicular and greater multangular bones, and before disappearing between the heads of the first Interosseous dorsalis is crossed by the tendon of the Extensor pollicis longus. In the interval between the two Extensores pollicis it is crossed by the digital rami of the superficial branch of the radial nerve which go to the thumb and index finger.

(c) *In the hand*, it passes from the upper end of the first interosseous space, between the heads of the first Interosseous dorsalis, transversely across the palm between the Adductor pollicis obliquus and Adductor pollicis transversus, but sometimes piercing the latter muscle, to the base of the metacarpal bone of the little finger, where it anastomoses with the deep volar branch from the ulnar artery, completing the **deep volar arch** (Fig. 604).

Peculiarities.—The origin of the radial artery is, in nearly one case in eight, higher than usual; more often it arises from the axillary or upper part of the brachial than from the lower part of the latter vessel. In the forearm it deviates less frequently from its normal position than the ulnar. It has been found lying on the deep fascia instead of beneath it. It has also been observed on the surface of the Brachioradialis, instead of under its medial border; and in turning around the wrist, it has been seen lying on, instead of beneath, the Extensor tendons of the thumb.

Applied Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded by the hand being driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, etc. The injury may be followed by a traumatic aneurism, for which the operation of laying open the sac and securing the vessel above and below is necessary.

The operation of tying the radial artery is required in cases of wounds either of its trunk, or of some of its branches, or for aneurism; and the vessel may be exposed in any part of its course through the forearm without the division of any muscular fibres. The operation in the middle or distal third of the forearm is easily performed; but in the proximal third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel, and from its being overlapped by the Brachioradialis.

To tie the artery in the proximal third, an incision 7 or 8 cm. in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided,

and the Brachioradialis drawn aside, the artery will be exposed. The venae comitantes should be carefully separated from the vessel and the ligature passed from the radial to the ulnar side.

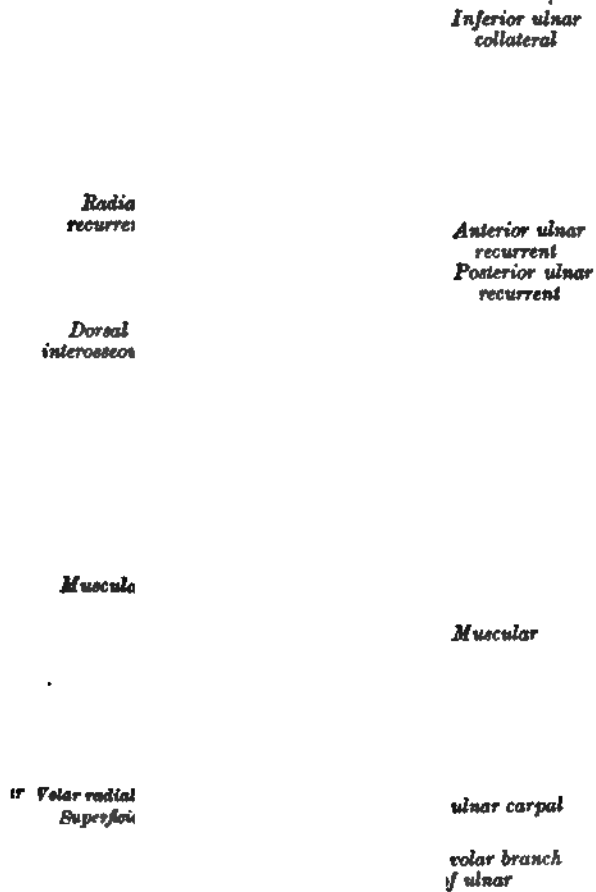

FIG. 603.—The radial and ulnar arteries.

FIG. 604.—Ulnar and radial arteries. Deep view.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the medial border of the Brachioradialis. In this situation, the superficial part of the

radial nerve lies in close relation with the lateral side of the artery, and should, as well as the veins, be carefully avoided.

In the distal third, the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Brachioradialis and Flexor carpi radialis.

Branches.—The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

<i>In the Forearm.</i>	<i>At the Wrist.</i>	<i>In the Hand.</i>
Radial Recurrent.	Dorsal Carpal.	Princeps Pollicis.
Muscular.	First Dorsal Metacarpal.	Volaris Indicis Radialis.
Volar Carpal.		Volar Metacarpal.
Superficial Volar.		Perforating.
		Recurrent.

The **radial recurrent artery** (*a. recurrens radialis*) arises immediately below the elbow. It ascends between the branches of the radial nerve, lying on the Supinator and then between the Brachioradialis and Brachialis, supplying these muscles and the elbow-joint, and anastomosing with the terminal part of the profunda brachii.

The **muscular branches** (*rami musculares*) are distributed to the muscles on the radial side of the forearm.

The **volar carpal branch** (*ramus carpeus volaris; anterior radial carpal artery*) is a small vessel which arises near the lower border of the Pronator quadratus, and, running across the front of the carpus, anastomoses with the volar carpal branch of the ulnar artery. This anastomosis is joined by a branch from the volar interosseous above, and by recurrent branches from the deep volar arch below, thus forming a **volar carpal net-work** which supplies the articulations of the wrist and carpus.

The **superficial volar branch** (*ramus volaris superficialis; superficialis volae artery*) arises from the radial artery, just where this vessel is about to wind around the lateral side of the wrist. Running forward, it passes through, occasionally over, the muscles of the ball of the thumb, which it supplies, and sometimes anastomoses with the terminal portion of the ulnar artery, completing the **superficial volar arch**. This vessel varies considerably in size: usually it is very small, and ends in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The **dorsal carpal branch** (*ramus carpeus dorsalis; posterior radial carpal artery*) is a small vessel which arises beneath the Extensor tendons of the thumb; crossing the carpus transversely toward the medial border of the hand, it anastomoses with the dorsal carpal branch of the ulnar and with the volar and dorsal interosseous arteries to form a **dorsal carpal network**. From this network are given off three slender **dorsal metacarpal arteries**, which run downward on the second, third, and fourth Interossei dorsales and bifurcate into the dorsal digital branches for the supply of the adjacent sides of the middle, ring, and little fingers respectively, communicating with the proper volar digital branches of the superficial volar arch. Near their origins they anastomose with the deep volar arch by the **superior perforating arteries**, and near their points of bifurcation with the common volar digital vessels of the superficial volar arch by the **inferior perforating arteries**.

The **first dorsal metacarpal** arises just before the radial artery passes between the two heads of the first Interosseous dorsalis and divides almost immediately into two branches which supply the adjacent sides of the thumb and index finger; the radial side of the thumb receives a branch directly from the radial artery.

The **arteria princeps pollicis** arises from the radial just as it turns medialward to the deep part of the hand; it descends between the first Interosseus dorsalis and Adductor pollicis obliquus, along the ulnar side of the metacarpal bone of the thumb to the base of the first phalanx, where it lies beneath the tendon of the

Flexor pollicis longus and divides into two branches. These make their appearance between the medial and lateral insertions of the Adductor pollicis obliquus, and run along the sides of the thumb, forming on the volar surface of the last phalanx an arch, from which branches are distributed to the integument and subcutaneous tissue of the thumb.

The **arteria volaris indicis radialis** (*radialis indicis artery*) arises close to the preceding, descends between the first Interosseus dorsalis and Adductor pollicis transversus, and runs along the radial side of the index finger to its extremity, where it anastomoses with the proper digital artery, supplying the ulnar side of the finger. At the lower border of the Adductor pollicis transversus this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial volar arch. The a. princeps pollicis and a. volaris indicis radialis may spring from a common trunk termed the **first volar metacarpal artery**.

The **deep volar arch** (*arcus volaris profundus; deep palmar arch*) (Fig. 604) is formed by the anastomosis of the terminal part of the radial artery with the deep volar branch of the ulnar. It lies upon the carpal extremities of the metacarpal bones and on the Interossei, being covered by the Adductor pollicis obliquus, the Flexor tendons of the fingers, and the Lumbricales. Alongside of it, but running in the opposite direction—that is to say, toward the radial side of the hand—is the deep branch of the ulnar nerve.

The **volar metacarpal arteries** (*aa. metacarpeae volares; palmar interosseous arteries*), three or four in number, arise from the convexity of the deep volar arch; they run distally upon the Interossei, and anastomose at the clefts of the fingers with the common digital branches of the superficial volar arch.

The **perforating branches** (*rami perforantes*), three in number, pass backward from the deep volar arch, through the second, third, and fourth interosseous spaces and between the heads of the corresponding Interossei dorsalis, to anastomose with the dorsal metacarpal arteries.

The **recurrent branches** arise from the concavity of the deep volar arch. They ascend in front of the wrist, supply the intercarpal articulations, and end in the volar carpal network.

The Ulnar Artery (A. Ulnaris) (Fig. 604).

The **ulnar artery**, the larger of the two terminal branches of the brachial, begins a little below the bend of the elbow, and, passing obliquely downward, reaches the ulnar side of the forearm at a point about midway between the elbow and the wrist. It then runs along the ulnar border to the wrist, crosses the transverse carpal ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches, which enter into the formation of the superficial and deep volar arches.

Relations.—(a) *In the forearm.*—In its upper half, it is deeply seated, being covered by the Pronator teres, Flexor carpi radialis, Palmaris longus, and Flexor digitorum sublimis; it lies upon the Brachialis and Flexor digitorum profundus. The median nerve is in relation with the medial side of the artery for about 2.5 cm. and then crosses the vessel, being separated from it by the ulnar head of the Pronator teres. In the lower half of the forearm it lies upon the Flexor digitorum profundus, being covered by the integument and the superficial and deep fasciæ, and placed between the Flexor carpi ulnaris and Flexor digitorum sublimis. It is accompanied by two venæ comitantes, and is overlapped in its middle third by the Flexor carpi ulnaris; the ulnar nerve lies on the medial side of the lower two-thirds of the artery, and the palmar cutaneous branch of the nerve descends on the lower part of the vessel to the palm of the hand.

(b) *At the wrist* (Fig. 603) the ulnar artery is covered by the integument and the volar carpal ligament, and lies upon the transverse carpal ligament. On its medial side is the pisiform bone, and, somewhat behind the artery, the ulnar nerve.

Peculiarities.—The ulnar artery varies in its origin in the proportion of about one in thirteen cases; it may arise about 5 to 7 cm. below the elbow, but more frequently higher, the brachial

being more often the source of origin than the axillary. Variations in the position of this vessel are more common than in the radial. When its origin is normal, the course of the vessel is rarely changed. When it arises high up, it is almost invariably superficial to the Flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases, its position was subcutaneous in the upper part of the forearm, and subaponeurotic in the lower part.

Applied Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery, or of its branches, or in consequence of aneurism. In the upper half of the forearm the artery is deeply seated beneath the superficial Flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the medial epicondyle of the humerus to the lateral side of the pisiform bone, so that the centre of the incision is three fingers' breadth below the medial epicondyle. The skin and superficial fascia having been divided, and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other Flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed lying on the Flexor digitorum profundus, and must be drawn aside. The artery will be found accompanied by its venae comitantes, and may be ligatured as it lies to the lateral side of the nerve. In the middle and lower thirds of the forearm, this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris; when the deep fascia is divided, and the tendon separated from the Flexor sublimis, the vessel will be exposed, accompanied by its venae comitantes, the ulnar nerve lying on its medial side.

Branches.—The branches of the ulnar artery may be arranged in the following groups:

<i>In the Forearm</i>	Anterior Recurrent.	<i>At the Wrist</i>	Volar Carpal.
	Posterior Recurrent.		Dorsal Carpal.
	Common Interosseous.	<i>In the Hand</i>	Deep Volar.
	Muscular.		Superficial Volar Arch.

The **anterior ulnar recurrent artery** (*a. recurrentes ulnaris anterior*) arises immediately below the elbow-joint, runs upward between the Brachialis and Pronator teres, supplies twigs to those muscles, and, in front of the medial epicondyle, anastomoses with the superior and inferior ulnar collateral arteries.

The **posterior ulnar recurrent artery** (*a. recurrentes ulnaris posterior*) is much larger, and arises somewhat lower than the preceding. It passes backward and medialward on the Flexor digitorum profundus, behind the Flexor digitorum sublimis, and ascends behind the medial epicondyle of the humerus. In the interval between this process and the olecranon, it lies beneath the Flexor carpi ulnaris, and ascending between the heads of that muscle, in relation with the ulnar nerve, it supplies the neighboring muscles and the elbow-joint, and anastomoses with the superior and inferior ulnar collateral and the interosseous recurrent arteries (Fig. 605).

The **common interosseous artery** (*a. interossea communis*) (Fig. 604), about 1 cm. in length, arises immediately below the tuberosity of the radius, and, passing backward to the upper border of the interosseous membrane, divides into two branches, the **volar and dorsal interosseous arteries**.

The **Volar Interosseous Artery** (*a. interossea volaris; anterior interosseous artery*) (Fig. 604), passes down the forearm on the volar surface of the interosseous membrane. It is accompanied by the volar interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor digitorum profundus and Flexor pollicis longus, giving off in this situation **muscular branches**, and the **nutrient arteries** of the radius and ulna. At the upper border of the Pronator quadratus it pierces the interosseous membrane and reaches the back of the forearm, where it anastomoses with the dorsal interosseous artery (Fig. 605). It then descends, in company with the terminal portion of the dorsal interosseous nerve, to the back of the wrist to join the dorsal carpal net-work. The volar interosseous artery gives off a slender branch, the **arteria mediana**, which accompanies the median nerve, and gives offsets to its substance; this artery is sometimes much enlarged, and runs

with the nerve into the palm of the hand. Before it pierces the interosseous membrane the volar interosseous sends a branch downward behind the Pronator quadratus to join the volar carpal network.

FIG. 605.—Arteries of the back of the forearm and hand.

The **Dorsal Interosseous** Artery (*a. interossea dorsalis*; *posterior interosseous artery*) (Fig. 605) passes backward between the oblique cord and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator and the Abductor pollicis longus, and runs down the back of the forearm between

the superficial and deep layers of muscles, to both of which it distributes branches. Where it lies upon the Abductor pollicis longus and the Extensor pollicis brevis, it is accompanied by the dorsal interosseous nerve. At the lower part of the forearm it anastomoses with the termination of the volar interosseous artery, and with the dorsal carpal network. It gives off, near its origin, the **interosseous recurrent artery**, which ascends to the interval between the lateral epicondyle and olecranon, on or through the fibres of the Supinator, but beneath the Anconeus, and anastomoses with the radial collateral branch of the profunda brachii, the posterior ulnar recurrent and the inferior ulnar collateral.

The **muscular branches** (*rami musculares*) are distributed to the muscles along the ulnar side of the forearm.

The **volar carpal branch** (*ramus carpeus volares; anterior ulnar carpal artery*) is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor digitorum profundus, and anastomoses with the corresponding branch of the radial artery.

The **dorsal carpal branch** (*ramus carpeus dorsalis; posterior ulnar carpal artery*) arises immediately above the pisiform bone, and winds backward beneath the tendon of the Flexor carpi ulnaris; it passes across the dorsal surface of the carpus beneath the Extensor tendons, to anastomose with a corresponding branch of the radial artery. Immediately after its origin, it gives off a small branch, which runs along the ulnar side of the fifth metacarpal bone, and supplies the ulnar side of the dorsal surface of the little finger.

The **deep volar branch** (*ramus volaris profundus; profunda branch*) (Fig. 604) passes between the Abductor digiti quinti and Flexor digiti quinti brevis and through the origin of the Opponens digiti quinti; it anastomoses with the radial artery, and completes the deep volar arch.

The **superficial volar arch** (*arcus volaris superficialis; superficial palmar arch*) (Fig. 603) is formed by the ulnar artery, and is usually completed by a branch from the a. volaris indicis radialis, but sometimes by the superficial volar or by a branch from the a. princeps pollicis of the radial artery. The arch passes across the palm, describing a curve, with its convexity downward.

Relations.—The superficial volar arch is covered by the skin, the Palmaris brevis, and the palmar aponeurosis. It lies upon the transverse carpal ligament, the Flexor digiti quinti brevis and Opponens digiti quinti, the tendons of the Flexor digitorum sublimis, the Lumbricales, and the divisions of the median and ulnar nerves.

Three Common Volar Digital Arteries (*aa. digitales volares communes; palmar digital arteries*) (Fig. 603) arise from the convexity of the arch and proceed downward on the second, third, and fourth Lumbricales. Each receives the corresponding volar metacarpal artery and then divides into a pair of **proper volar digital arteries** (*aa. digitales volares propriae; collateral digital arteries*) which run along the contiguous sides of the index, middle, ring, and little fingers, behind the corresponding digital nerves; they anastomose freely in the subcutaneous tissue of the finger tips and by smaller branches near the interphalangeal joints. Each gives off a couple of dorsal branches which anastomose with the dorsal digital arteries, and supply the soft parts on the back of the second and third phalanges, including the matrix of the finger-nail. The proper volar digital artery for medial side of the little finger springs from the ulnar artery under cover of the Palmaris brevis.

Applied Anatomy.—Wounds of the volar arches are of special interest, and are always difficult to deal with. When the superficial arch is involved it is generally possible (enlarging the wound when necessary) to secure the vessel and tie it on both sides of the bleeding point; or in cases where it is found impossible to encircle the vessel with a ligature, a pair of hemostatic forceps may be applied and left on for twenty-four or forty-eight hours. Failing this, the wound may be plugged with gauze and an outside dressing carefully bandaged on. The plug should be allowed to remain untouched for three or four days. It is useless in these cases to ligature one of the arteries of the forearm alone, and indeed simultaneous ligature of both radial and ulnar arteries

above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, upon the failure of pressure to arrest hemorrhage, it is expedient to apply a ligature to the brachial artery. When an incision for deep-seated suppuration in the tendon sheath is required, the situation of the superficial arch must always be borne in mind, and the incisions placed either above or below it. The position of the common digital branches of the artery must also be remembered, and incisions must be made opposite the heads of the metacarpal bones and not between them.

THE ARTERIES OF THE TRUNK.

THE DESCENDING AORTA.

The descending aorta is divided into two portions, the **thoracic** and **abdominal**, in correspondence with the two great cavities of the trunk in which it is situated.

The Thoracic Aorta (*Aorta Thoracalis*) (Fig. 606).

The **thoracic aorta** is contained in the posterior mediastinal cavity. It begins at the lower border of the fourth thoracic vertebra where it is continuous with the aortic arch, and ends in front of the lower border of the twelfth at the aortic hiatus in the Diaphragma. At its commencement, it is situated on the left of the vertebral column; it approaches the median line as it descends; and, at its termination, lies directly in front of the column. The vessel describes a curve which is concave forward, and as the branches given off from it are small, its diminution in size is inconsiderable.

Relations.—It is in relation, *anteriorly*, from above downward, with the root of the left lung, the pericardium, the cesophagus, and the Diaphragma; *posteriorly*, with the vertebral column and the hemiazygos veins; on the *right side*, with the azygos vein and thoracic duct; on the *left side*, with the left pleura and lung. The cesophagus, with its accompanying plexus of nerves, lies on the right side of the aorta above; but at the lower part of the thorax it is placed in front of the aorta, and, close to the Diaphragma, is situated on its left side.

Peculiarities.—The aorta is occasionally found to be obliterated at the junction of the arch with the thoracic aorta, just below the ductus arteriosus. Whether this is the result of disease, or of congenital malformation, is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation. The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the *Pathological Transactions*, vols. viii and x. In the former, Sydney Jones thus sums up the detailed description of the anastomosing vessels: The principal communications by which the circulation was carried on were: (1) The internal mammary, anastomosing with the intercostal arteries, with the inferior phrenic of the abdominal aorta by means of the musculophrenic and pericardiophrenic, and largely with the inferior epigastric. (2) The costocervical trunk, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. (3) The inferior thyroid, by means of a branch about the size of an ordinary radial, forming a communication with the first aortic intercostal. (4) The transverse cervical, by means of very large communications with the posterior branches of the intercostals. (5) The branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals. In the second case Wood describes the anastomoses in a somewhat similar manner, adding the remark that "the blood which was brought into the aorta through the anastomosis of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis; while the supply to the lower extremities had passed through the internal mammary and epigastrics."

In a few cases an apparently double descending thoracic aorta has been found, the two vessels lying side by side, and eventually fusing to form a single tube in the lower part of the thorax or in the abdomen. One of them is the aorta, the other represents a dissecting aortic aneurism which has become canalized; opening above and below into the true aorta, and at first sight presenting the appearances of a proper bloodvessel.

Applied Anatomy.—The effects likely to be produced by aneurism of the thoracic aorta, a disease of common occurrence, must now be considered. When the great depth of the vessel from the surface and the number of important structures which surround it are remembered, it may easily be conceived what a variety of obscure symptoms are likely to arise from disease

of this part of the arterial system, and how they may be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backward, along the left side of the vertebral column, producing absorption of the bodies of the vertebræ, with curvature of the column; while the irritation or pressure on the medulla spinalis will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumor may project backward on either side of the vertebral column, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased

1
des
a

FIG. 606.—The thoracic aorta, viewed from the left side.

bone; or it may displace the œsophagus and compress the lungs on one or the other side. If the tumor extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; it may displace or compress the œsophagus, causing pain and difficulty of swallowing; and ultimately even open into it by ulceration, producing fatal hemorrhage. If the disease extend to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity, or into the trachea or lung; and lastly, it may open into the posterior mediastinal cavity. Pressure on one of the bronchi, usually the left, will cause cough, and in time set up bronchiectasis; pressure on the left pulmonary plexus has been said

to give rise to asthmatic attacks. Of late years, the diagnosis of thoracic aneurism has been much facilitated by the employment of the x-rays, by means of which the outline of the sac may be demonstrated.

Branches of the Thoracic Aorta.—

<i>Visceral</i>	{	Pericardial.	<i>Parietal.</i>	{	Intercostal.
		Bronchial.			Subcostal.
		Œsophageal.			Superior Phrenic.
		Mediastinal.			

The **pericardial branches** (*rami pericardiaci*) consist of a few small vessels which are distributed to the posterior surface of the pericardium.

The **bronchial arteries** (*aa. bronchiales*) vary in number, size, and origin. There is as a rule only one **right bronchial artery**, which *arises* from the first aortic intercostal, or from the upper left bronchial artery. The **left bronchial arteries** are usually two in number, and *arise* from the thoracic aorta. The upper left bronchial arises opposite the fifth thoracic vertebra, the lower just below the level of the left bronchus. Each vessel runs on the back part of its bronchus, dividing and subdividing along the bronchial tubes, supplying them, the areolar tissue of the lungs, the bronchial lymph glands, and the œsophagus.

The **œsophageal arteries** (*aa. œsophageae*) four or five in number, *arise* from the front of the aorta, and pass obliquely downward to the œsophagus, forming a chain of anastomoses along that tube, anastomosing with the œsophageal branches of the inferior thyroid arteries above, and with ascending branches from the left inferior phrenic and left gastric arteries below.

The **mediastinal branches** (*rami mediastinales*) are numerous small vessels which supply the lymph glands and loose areolar tissue in the posterior mediastinal cavity.

Intercostal Arteries (*aa. intercostales*).—There are usually nine pairs of aortic intercostal arteries. They *arise* from the back of the aorta, and are redistributed to the lower nine intercostal spaces, the first two spaces being supplied by the highest intercostal artery, a branch of the costocervical trunk of the subclavian. The **right** aortic intercostals are longer than the left, on account of the position of the aorta on the left side of the vertebral column; they pass across the bodies of the vertebræ behind the œsophagus, thoracic duct, and vena azygos, and are covered by the right lung and pleura. The **left** aortic intercostals run backward on the sides of the vertebræ and are covered by the left lung and pleura; the upper two vessels are crossed by the highest left intercostal vein, the lower vessels by the hemiazygos veins. The further course of the intercostal arteries is practically the same on both sides. Opposite the heads of the ribs the sympathetic trunk passes downward in front of them, and the splanchnic nerves also descend in front by the lower arteries. Each artery then divides into an **anterior** and a **posterior ramus**.

The **Anterior Ramus** crosses the corresponding intercostal space obliquely toward the angle of the upper rib, and thence is continued forward in the costal groove. It is placed at first between the pleura and the posterior intercostal membrane, then it pierces this membrane, and lies between it and the *Intercostalis externus* as far as the angle of the rib; from this onward it runs between the *Intercostales externus* and *internus*, and anastomoses in front with the intercostal branch of the internal mammary or musculophrenic. Each artery is accompanied by a vein and a nerve, the former being above and the latter below the artery, except in the upper spaces, where the nerve is at first above the artery. The first aortic intercostal artery anastomoses with the intercostal branch of the costocervical trunk, and may form the chief supply of the second intercostal space. The lower two intercostal arteries

are continued anteriorly from the intercostal spaces into the abdominal wall, and anastomose with the subcostal, superior epigastric, and lumbar arteries.

Branches.—The anterior rami give off the following branches:

Collateral Intercostal.	Lateral Cutaneous.
Muscular.	Mammary.

The **collateral intercostal branch** comes off from the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with the intercostal branch of the internal mammary.

Muscular branches are given to the Intercostales and Pectorales and to the Serratus anterior; they anastomose with the highest and lateral thoracic branches of the axillary artery.

The **lateral cutaneous branches** accompany the lateral cutaneous branches of the thoracic nerves.

Mammary branches are given off by the vessels in the third, fourth, and fifth spaces. They supply the mamma, and increase considerably in size during the period of lactation.

The **Posterior Ramus** runs backward through a space which is bounded above and below by the necks of the ribs, medially by the body of a vertebra, and laterally by an anterior costotransverse ligament. It gives off a **spinal branch** which enters the vertebral canal through the intervertebral foramen and is distributed to the medulla spinalis and its membranes and the vertebræ. It then courses over the transverse process with the posterior division of the thoracic nerve, supplies branches to the muscles of the back and cutaneous branches which accompany the corresponding cutaneous branches of the posterior division of the nerve.

Applied Anatomy.—The position of the anterior rami of the intercostal vessels should be borne in mind in performing the operation of paracentesis thoracis. The puncture should never be made nearer the middle line posteriorly than the angle of the rib, as the artery crosses the space medial to this point. In the lateral portion of the chest, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The **subcostal arteries**, so named because they lie below the last ribs, constitute the lowest pair of branches derived from the thoracic aorta, and are in series with the intercostal arteries. Each passes along the lower border of the twelfth rib behind the kidney and in front of the Quadratus lumborum muscle, and is accompanied by the twelfth thoracic nerve. It then pierces the posterior aponeurosis of the Transversus abdominis, and, passing forward between this muscle and the Obliquus internus, anastomoses with the superior epigastric, lower intercostal, and lumbar arteries. Each subcostal artery gives off a posterior branch which has a similar distribution to the posterior ramus of an intercostal artery.

The **superior phrenic branches** are small and arise from the lower part of the thoracic aorta; they are distributed to the posterior part of the upper surface of the Diaphragma, and anastomose with the musculophrenic and pericardiophrenic arteries.

A small **aberrant artery** is sometimes found arising from the right side of the thoracic aorta near the origin of the right bronchial. It passes upward and to the right behind the trachea and the œsophagus, and may anastomose with the highest right intercostal artery. It represents the remains of the right dorsal aorta, and in a small proportion of cases is enlarged to form the first part of the right subclavian artery.

The Abdominal Aorta (Aorta Abdominalis) (Fig. 607).

The **abdominal aorta** begins at the aortic hiatus of the Diaphragma, in front of the lower border of the body of the last thoracic vertebra, and, descending in

front of the vertebral column, ends on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line,¹ by dividing into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebræ, the curve which it describes is convex forward, the summit of the convexity corresponding to the third lumbar vertebra.

DIAPHRAGMA

Inferior phrenic arteries

1

FIG. 607.—The abdominal aorta and its branches.

Relations.—The abdominal aorta is covered, *anteriorly*, by the lesser omentum and stomach, behind which are the branches of the celiac artery and the celiac plexus; below these, by the renal vein, the pancreas, the left renal vein, the inferior part of the duodenum, the mesentery, and aortic plexus. *Posteriorly*, it is separated from the lumbar vertebræ and intervertebral fibrocartilages by the anterior longitudinal ligament and left lumbar veins. On the *right side* it is in relation above with the azygos vein, cisterna chyli, thoracic duct, and the right crus of the Diaphragma—the last separating it from the upper part of the inferior vena cava, and from the right celiac ganglion; the inferior vena cava is in contact with the aorta below. On the *left side* are the left crus of the Diaphragma, the left celiac ganglion, the ascending part of the duodenum, and some coils of the small intestine.

Applied Anatomy.—The abdominal aorta may be the seat of an aneurism either at its upper part, close to and often involving the celiac artery, or at its lower part, near the bifurcation.

¹ Lord Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it "either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less to the left, and in 2 was slightly to the right." *System of Surgery*, edited by T. Holmes, 2d ed., v. 652.

Occasionally aneurisms are met with on some of the branches of the aorta, the mesenteric or lienal, quite independent of the main trunk.

When an aneurismal sac is connected with the posterior part of the abdominal aorta, it usually produces absorption of the bodies of the vertebræ. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumor pressing on or displacing the branches of the celiac plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumor; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (generally of the left side). This form of aneurism usually bursts into or behind the peritoneal cavity.

When an aneurismal sac is connected with the front of the aorta near the celiac artery, it forms a pulsating tumor in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the digestive tube, as sickness, dyspepsia, or constipation, and accompanied by pain, which is constant, but nearly always fixed, in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity, behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it rarely extends backward so as to affect the vertebral column.

Occlusion of the abdominal aorta by thrombosis or embolism is rare, but produces very severe symptoms when it does occur. The patient complains of intense pain in the legs; pallor of the legs, followed by coldness, lividity, paresis, paralysis, and finally gangrene, are likely to succeed, death usually supervening within a fortnight.

The abdominal aorta has been tied in several cases, and although none of the patients permanently recovered, still, as one case lived forty-eight days, the possibility of the reestablishment of the circulation may be considered to be proved.

Collateral Circulation.—The collateral circulation would be carried on by the anastomoses between the internal mammary and the inferior epigastric; by the free communication between the superior and inferior mesenterics, if the ligature were placed between these vessels; or by the anastomosis between the inferior mesenteric and the internal pudendal, when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the hypogastric.

Branches.—The branches of the abdominal aorta may be divided into three sets: visceral, parietal, and terminal.

Visceral Branches.

Celiac.
Superior Mesenteric.
Inferior Mesenteric.
Middle Suprarenals.
Renals.
Internal Spermaties.
Ovarian (in the female).

Parietal Branches.

Inferior Phrenics.
Lumbers.
Middle Sacral.

Terminal Branches.

Common Iliacs.

Of the visceral branches, the celiac artery and the superior and inferior mesenteric arteries are unpaired, while the suprarenals, renals, internal spermatics, and ovarian are paired. Of the parietal branches the inferior phrenics and lumbers are paired; the middle sacral is unpaired. The terminal branches are paired.

The **celiac artery** (*a. coeliaca; celiac axis*) (Figs. 608, 609) is a short thick trunk, about 1.25 cm. in length, which *arises* from the front of the aorta, just below the aortic hiatus of the Diaphragma, and, passing nearly horizontally forward, divides into three large branches, the **left gastric**, the **hepatic**, and the **splenic**; it occasionally gives off one of the inferior phrenic arteries.

Relations.—The celiac artery is covered by the lesser omentum. On the *right side* it is in relation with the right celiac ganglion and the caudate process of the liver; on the *left side*, with the left celiac ganglion and the cardiac end of the stomach. *Below*, it is in relation to the upper border of the pancreas, and the lienal vein.

1. The **Left Gastric Artery** (*a. gastrica sinistra; gastric or coronary artery*), the smallest of the three branches of the celiac artery, passes upward and to the left, posterior to the omental bursa, to the cardiac orifice of the stomach. Here it distributes branches to the œsophagus, which anastomose with the aortic œsophageal

arteries; others supply the cardiac part of the stomach, anastomosing with branches of the lienal artery. It then runs from left to right, along the lesser curvature of the stomach to the pylorus, between the layers of the lesser omentum; it gives branches to both surfaces of the stomach and anastomoses with the right gastric artery.

2. The **Hepatic Artery** (*a. hepatica*) in the adult is intermediate in size between the left gastric and lienal; in the fetus, it is the largest of the three branches of the coeliac artery. It is first directed forward and to the right, to the upper margin of the superior part of the duodenum, forming the lower boundary of the epiploic foramen (*foramen of Winslow*). It then crosses the portal vein anteriorly and ascends between the layers of the lesser omentum, and in front of the epiploic foramen, to the porta hepatis, where it divides into two branches, right and left, which

Cystic art

Probe passed through epiploic foramen

FIG. 608.—The coeliac artery and its branches; the liver has been raised, and the lesser omentum and anterior layer of the greater omentum removed.

supply the corresponding lobes of the liver, accompanying the ramifications of the portal vein and hepatic ducts. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the common bile-duct and portal vein, the duct lying to the right of the artery, and the vein behind.

Its branches are:

Right Gastric.

Gastroduodenal { Right Gastroepiploic.
Superior Pancreaticoduodenal.

Cystic.

The **right gastric artery** (*a. gastrica dextra; pyloric artery*) arises from the hepatic, above the pylorus, descends to the pyloric end of the stomach, and passes from

right to left along its lesser curvature, supplying it with branches, and anastomosing with the left gastric artery.

The **gastroduodenal artery** (*a. gastroduodenalis*) (Fig. 609) is a short but large branch, which descends, near the pylorus, between the superior part of the duodenum and the neck of the pancreas, and divides at the lower border of the duodenum into two branches, the **right gastroepiploic** and the **superior pancreaticoduodenal**. Previous to its division it gives off two or three small branches to the pyloric end of the stomach and to the pancreas.

Branches to greater omentum

FIG. 609.—The coeliac artery and its branches; the stomach has been raised and the peritoneum removed.

The **right gastroepiploic artery** (*a. gastroepiploica dextra*) runs from right to left along the greater curvature of the stomach, between the layers of the greater omentum, anastomosing with the left gastroepiploic branch of the lienal artery. Except at the pylorus, where it is in contact with the stomach, it lies about a finger's breadth from the greater curvature. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, while others descend to supply the greater omentum and anastomose with branches of the middle colic.

The **superior pancreaticoduodenal artery** (*a. pancreaticoduodenalis superior*) descends between the contiguous margins of the duodenum and pancreas. It supplies both these organs, and anastomoses with the inferior pancreaticoduodenal branch of the superior mesenteric artery, and with the pancreatic branches of the lienal artery.

The **cystic artery** (*a. cystica*) (Fig. 608), usually a branch of the right hepatic, passes downward and forward along the neck of the gall-bladder, and divides into two branches, one of which ramifies on the free surface, the other on the attached surface of the gall-bladder.

3. The **Lienal or Splenic Artery** (*a. lienalis*), the largest branch of the coeliac artery, is remarkable for the tortuosity of its course. It passes horizontally to the left side, behind the stomach and the omental bursa of the peritoneum, and along the upper border of the pancreas, accompanied by the lienal vein, which lies below it; it crosses in front of the upper part of the left kidney, and, on arriving near the spleen, divides into branches, some of which enter the hilus of that organ between the two layers of the phrenicolienal ligament to be distributed to the tissues of the spleen; some are given to the pancreas, while others pass to the greater curvature of the stomach between the layers of the gastrolial ligament. Its branches are:

Pancreatic.

Short Gastric.

Left Gastroepiploic.

The **pancreatic branches** (*rami pancreatici*) are numerous small vessels derived from the lienal as it runs behind the upper border of the pancreas, supplying its body and tail. One of these, larger than the rest, is sometimes given off near the tail of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the **arteria pancreatica magna**. These vessels anastomose with the pancreatic branches of the pancreaticoduodenal and superior mesenteric arteries.

The **short gastric arteries** (*aa. gastricae breves; vasa brevia*) consist of from five to seven small branches, which arise from the end of the lienal artery, and from its terminal divisions. They pass from left to right, between the layers of the gastrolial ligament, and are distributed to the greater curvature of the stomach, anastomosing with branches of the left gastric and left gastroepiploic arteries.

The **left gastroepiploic artery** (*a. gastroepiploica sinistra*) the largest branch of the lienal, runs from left to right about a finger's breadth or more from the greater curvature of the stomach, between the layers of the greater omentum, and anastomoses with the right gastroepiploic. In its course it distributes several ascending branches to both surfaces of the stomach; others descend to supply the greater omentum and anastomose with branches of the middle colic.

Applied Anatomy.—Embolism of branches of the lienal artery is tolerably common in heart disease, the embolus coming from the left side of the heart. It is characterized by the occurrence of a sudden sharp pain or "stitch" in the splenic region, with subsequent local enlargement of the spleen from the formation of an infarct in its substance.

The **superior mesenteric artery** (*a. mesenterica superior*) (Fig. 610) is a large vessel which supplies the whole length of the small intestine, except the superior part of the duodenum; it also supplies the cecum and the ascending part of the colon and about one-half of the transverse part of the colon. It arises from the front of the aorta, about 1.25 cm. below the coeliac artery, and is crossed at its origin by the lienal vein and the neck of the pancreas. It passes downward and forward, anterior to the processus uncinatus of the head of the pancreas and inferior part of the duodenum, and descends between the layers of the mesentery to the right iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches, viz., the ileocolic. In its course it crosses in front of the inferior vena cava, the right ureter and Psoas major, and forms an arch, the convexity of which is directed forward and downward to the left side, the concavity backward and upward to the right. It is accompanied by the superior mesenteric vein, which lies to its right side, and it is surrounded by the superior mesenteric plexus of nerves.

Dissection.—In order to expose the superior mesenteric artery raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse mesocolon and mesentery join; the artery will then be exposed just as it issues from over the processus uncinatus of the head of the pancreas.

m
ic

FIG. 610.—The superior mesenteric artery and its branches.

Branches.—Its branches are:

Inferior Pancreaticoduodenal.	Ileocolic.
Intestinal.	Right Colic.
Middle Colic.	

The **Inferior Pancreaticoduodenal Artery** (*a. pancreaticoduodenalis inferior*) is given off from the superior mesenteric or from its first intestinal branch, opposite the upper border of the inferior part of the duodenum. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreaticoduodenal artery. It distributes branches to the head of the pancreas and to the descending and inferior parts of the duodenum.

The **Intestinal Arteries** (*aa. intestinales; vasa intestini tenuis*) arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum and ileum. They run nearly parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with adjacent branches, forming a series of arches, the

convexities of which are directed toward the intestine (Fig. 611). From this first set of arches branches arise, which unite with similar branches from above and below and thus a second series of arches is formed; from the lower branches of the artery, a third, a fourth, or even a fifth series of arches may be formed, diminishing in size the nearer they approach the intestine. In the short, upper part of the mesentery only one set of arches exists, but as the depth of the mesentery increases, second, third, fourth, or even fifth groups are developed. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying between its coats. From the intestinal arteries small branches are given off to the lymph glands and other structures between the layers of the mesentery.

11a
and
10a

FIG. 611.—Loop of small intestine showing distribution of intestinal arteries. (From a preparation by Mr. Hamilton Drummond.) The vessels were injected while the gut was in situ; the gut was then removed, and an x-ray photograph taken.

The **Ileocolic Artery** (*a. ileocolica*) is the lowest branch arising from the concavity of the superior mesenteric artery. It passes downward and to the right behind the peritoneum toward the right iliac fossa, where it divides into a superior and an inferior branch; the inferior anastomoses with the end of the superior mesenteric artery, the superior with the right colic artery.

The inferior branch of the ileocolic runs toward the upper border of the ileocolic junction and supplies the following branches (Fig. 612):

(a) **colic**, which pass upward on the ascending colon; (b) **anterior and posterior cecal**, which are distributed to the front and back of the cecum; (c) an **appendicular artery**, which descends behind the termination of the ileum and enters the mesenteriole of the vermiform process; it runs near the free margin of this mesenteriole and ends in branches which supply the vermiform process; and (d) **ileal**, which run

upward and to the left on the lower part of the ileum, and anastomose with the termination of the superior mesenteric.

The **Right Colic Artery** (*a. colica dextra*) arises from about the middle of the concavity of the superior mesenteric artery, or from a stem common to it and the ileocolic. It passes to the right behind the peritoneum, and in front of the right internal spermatic or ovarian vessels, the right ureter and the Psoas major, toward the middle of the ascending colon; sometimes the vessel lies at a higher level, and crosses the descending part of the duodenum and the lower end of the right kidney. At the colon it divides into a descending branch, which anastomoses with the ileocolic, and an ascending branch, which anastomoses with the middle colic. These branches form arches, from the convexity of which vessels are distributed to the ascending colon.

idicular
'y

FIG. 612.—Arteries of cecum and vermiform process.

The **Middle Colic Artery** (*a. colica media*) arises from the superior mesenteric just below the pancreas and, passing downward and forward between the layers of the transverse mesocolon, divides into two branches, right and left; the former anastomoses with the right colic; the latter with the left colic, a branch of the inferior mesenteric. The arches thus formed are placed about two fingers' breadth from the transverse colon, to which they distribute branches.

The **inferior mesenteric artery** (*a. mesenterica inferior*) (Fig. 613) supplies the left half of the transverse part of the colon, the whole of the descending and iliac parts of the colon, the sigmoid colon, and the greater part of the rectum. It is smaller than the superior mesenteric, and arises from the aorta, about 3 or 4 cm. above its division into the common iliacs and close to the lower border of the inferior part of the duodenum. It passes downward posterior to the peritoneum, lying at first anterior to and then on the left side of the aorta. It crosses the left common iliac artery and is continued into the lesser pelvis under the name of the **superior hemorrhoidal artery**, which descends between the two layers of the sigmoid mesocolon and ends on the upper part of the rectum.

Dissection.—In order to expose the inferior mesenteric artery draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon toward the thorax, and divide the peritoneum covering the front of the aorta.

FIG. 613.—The inferior mesenteric artery and its branches.

Branches.—Its branches are:

Left Colic.

Sigmoid.

Superior Hemorrhoidal.

The **Left Colic Artery** (*a. colica sinistra*) runs to the left behind the peritoneum and in front of the Psoas major, and after a short, but variable, course divides into an ascending and a descending branch; the stem of the artery or its branches cross the left ureter and left internal spermatic vessels. The ascending branch crosses in front of the left kidney and ends, between the two layers of the transverse mesocolon, by anastomosing with the middle colic artery; the descending branch anastomoses with the highest sigmoid artery. From the arches formed by these anastomoses branches are distributed to the descending colon and the left part of the transverse colon.

The **Sigmoid Arteries** (*aa. sigmoideae*) (Fig. 614), two or three in number, run obliquely downward and to the left behind the peritoneum and in front of the Psoas major, ureter, and internal spermatic vessels. Their branches supply the lower part of the descending colon, the iliac colon, and the sigmoid or pelvic colon; anastomosing above with the left colic, and below with the superior hemorrhoidal artery.

The **Superior Hemorrhoidal Artery** (*a. hæmorrhoidalis superior*) (Fig. 614), the continuation of the inferior mesenteric, descends into the pelvis between the layers of the mesentery of the sigmoid colon, crossing, in its course, the left common iliac vessels. It divides, opposite the third sacral vertebra, into two branches, which descend one on either side of the rectum, and about 10 or 12 cm. from the anus break up into several small branches. These pierce the muscular coat of the bowel and run downward, as straight vessels, placed at regular intervals from each other in the wall of the gut between its muscular and mucous coats, to the level of the Sphincter ani internus; here they form a series of loops around the lower end of the rectum, and communicate with the middle hemorrhoidal branches of the hypogastric, and with the inferior hemorrhoidal branches of the internal pudendal.

FIG. 614.—Sigmoid colon and rectum, showing distribution of branches of inferior mesenteric artery and their anastomoses. (From a preparation by Mr. Hamilton Drummond.) Prepared in same manner as Fig. 611.

Applied Anatomy.—Embolism of the mesenteric arteries produces acute and severe symptoms, of which the chief are abdominal pain and tenderness, nausea and vomiting, diarrhoea or constipation; blood is found in the stools of nearly half the patients. In many cases the symptoms closely resemble those of intestinal obstruction.

The **middle suprarenal arteries** (*aa. suprarenales mediae*; *middle capsular arteries*; *suprarenal arteries*) are two small vessels which arise, one from either side of the aorta, opposite the superior mesenteric artery. They pass lateralward and slightly upward, over the crura of the Diaphragma, to the suprarenal glands, where they anastomose with suprarenal branches of the inferior phrenic and renal arteries. In the fetus these arteries are of large size.

The **renal arteries** (*aa. renales*) (Fig. 607), are two large trunks, which arise from the side of the aorta, immediately below the superior mesenteric artery.

Each is directed across the crus of the Diaphragma, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava, the right renal vein, the head of the pancreas, and the descending part of the duodenum. The left is somewhat higher than the right; it lies behind the left renal vein, the body of the pancreas and the lienal vein, and is crossed by the inferior mesenteric vein. Before reaching the hilus of the kidney, each artery divides into four or five branches; the greater number of these lie between the renal vein and ureter, the vein being in front, the ureter behind, but one or more branches are usually situated behind the ureter. Each vessel gives off some small **inferior suprarenal branches** to the suprarenal gland, the ureter, and the surrounding cellular tissue and muscles. One or two accessory renal arteries are frequently found, more especially on the left side they usually arise from the aorta, and may come off above or below the main artery, the former being the more common position. Instead of entering the kidney at the hilus, they usually pierce the upper or lower part of the gland.

The **internal spermatic arteries** (*aa. spermaticae internae; spermatic arteries*) (Fig. 607) are distributed to the testes. They are two slender vessels of considerable length, and *arise* from the front of the aorta a little below the renal arteries. Each passes obliquely downward and lateralward behind the peritoneum, resting on the Psoas major, the right spermatic lying in front of the inferior vena cava and behind the middle colic and ileocolic arteries and the terminal part of the ileum, the left behind the left colic and sigmoid arteries and the iliac colon. Each crosses obliquely over the ureter and the lower part of the external iliac artery to reach the abdominal inguinal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous, and divides into several branches. Two or three of these accompany the ductus deferens, and supply the epididymis, anastomosing with the artery of the ductus deferens; others pierce the back part of the tunica albuginea, and supply the substance of the testis. The internal spermatic artery supplies one or two small branches to the ureter, and in the inguinal canal gives one or two twigs to the Cremaster.

The **ovarian arteries** (*aa. ovaricae*) are the corresponding arteries in the female to the internal spermatic in the male. They supply the ovaries, are shorter than the internal spermatics, and do not pass out of the abdominal cavity. The origin and course of the first part of each artery are the same as those of the internal spermatic, but on arriving at the upper opening of the lesser pelvis the ovarian artery passes inward, between the two layers of the ovario pelvic ligament and of the broad ligament of the uterus, to be distributed to the ovary. Small branches are given to the ureter and the uterine tube, and one passes on to the side of the uterus, and unites with the uterine artery. Other offsets are continued on the round ligament of the uterus, through the inguinal canal, to the integument of the labium majus and groin.

At an early period of fetal life, when the testes or ovaries lie by the side of the vertebral column, below the kidneys, the internal spermatic or ovarian arteries are short; but with the descent of these organs into the scrotum or lesser pelvis, the arteries are gradually lengthened.

The **inferior phrenic arteries** (*aa. phrenicae inferiores*) (Fig. 607) are two small vessels, which supply the Diaphragma but present much variety in their origin. They may *arise* separately from the front of the aorta, immediately above the coeliac artery, or by a common trunk, which may spring either from the aorta or from the coeliac artery. Sometimes one is derived from the aorta, and the other from one of the renal arteries; they rarely arise as separate vessels from the aorta. They diverge from one another across the crura of the Diaphragma, and then run obliquely upward and lateralward upon its under surface. The left phrenic passes

behind the œsophagus, and runs forward on the left side of the œsophageal hiatus. The right phrenic passes behind the inferior vena cava, and along the right side of the foramen which transmits that vein. Near the back part of the central tendon each vessel divides into a medial and a lateral branch. The **medial branch** curves forward, and anastomoses with its fellow of the opposite side, and with the musculophrenic and pericardiophrenic arteries. The **lateral branch** passes toward the side of the thorax, and anastomoses with the lower intercostal arteries, and with the musculophrenic. The lateral branch of the right phrenic gives off a few vessels to the inferior vena cava; and the left one, some branches to the œsophagus. Each vessel gives off **superior suprarenal branches** to the suprarenal gland of its own side. The spleen and the liver also receive a few twigs from the left and right vessels respectively.

The **lumbar arteries** (*aa. lumbales*) are in series with the intercostals. They are usually four in number on either side, and *arise* from the back of the aorta, opposite the bodies of the upper four lumbar vertebræ. A fifth pair, small in size, is occasionally present: they *arise* from the middle sacral artery. They run lateralward and backward on the bodies of the lumbar vertebræ, behind the sympathetic trunk, to the intervals between the adjacent transverse processes, and are then continued into the abdominal wall. The arteries of the right side pass behind the inferior vena cava, and the upper two on each side run behind the corresponding crus of the Diaphragma. The arteries of both sides pass beneath the tendinous arches which give origin to the Psoas major, and are then continued behind this muscle and the lumbar plexus. They now cross the Quadratus lumborum, the upper three arteries running behind, the last usually in front of the muscle. At the lateral border of the Quadratus lumborum they pierce the posterior aponeurosis of the Transversus abdominis and are carried forward between this muscle and the Obliquus internus. They anastomose with the lower intercostal, the subcostal, the iliolumbar, the deep iliac circumflex, and the inferior epigastric arteries.

Branches.—In the interval between the adjacent transverse processes each lumbar artery gives off a **posterior ramus** which is continued backward between the transverse processes and is distributed to the muscles and skin of the back; it furnishes a **spinal branch** which enters the vertebral canal and is distributed in a manner similar to the spinal branches of the posterior rami of the intercostal arteries (page 686). **Muscular branches** are supplied from each lumbar artery and from its posterior ramus to the neighboring muscles.

The **middle sacral artery** (*a. sacralis media*) (Fig. 607) is a small vessel, which *arises* from the back of the aorta, a little above its bifurcation. It descends in the middle line in front of the fourth and fifth lumbar vertebræ, the sacrum and coccyx, and ends in the glomus coccygeum (*coccygeal gland*). From it, minute branches are said to pass to the posterior surface of the rectum. On the last lumbar vertebra it anastomoses with the lumbar branch of the iliolumbar artery; in front of the sacrum it anastomoses with the lateral sacral arteries, and sends offsets into the anterior sacral foramina. It is crossed by the left common iliac vein, and is accompanied by a pair of venae comitantes; these unite to form a single vessel, which opens into the left common iliac vein.

THE COMMON ILIAC ARTERIES (AA. ILIACAE COMMUNES) (Figs. 607, 615).

The abdominal aorta divides, on the left side of the body of the fourth lumbar vertebra, into the two **common iliac arteries**. Each is about 5 cm. in length. They diverge from the termination of the aorta, pass downward and lateralward, and divide, opposite the intervertebral fibrocartilage between the last lumbar vertebra and the sacrum, into two branches, the **external iliac** and **hypogastric arteries**;

the former supplies the lower extremity; the latter, the viscera and parietes of the pelvis.

The **right common iliac artery** (Fig. 615) is somewhat longer than the left, and passes more obliquely across the body of the last lumbar vertebra. *In front* of it are the peritoneum, the small intestines, branches of the sympathetic nerves, and, at its point of division, the ureter. *Behind*, it is separated from the bodies of the fourth and fifth lumbar vertebræ, and the intervening fibrocartilage, by the terminations of the two common iliac veins and the commencement of the inferior vena cava. *Laterally*, it is in relation, above, with the inferior vena cava and the right common iliac vein; and, below, with the Psoas major. *Medial* to it, above, is the left common iliac vein.

FIG. 615.—The arteries of the pelvis.

The **left common iliac artery** is in relation, *in front*, with the peritoneum, the small intestines, branches of the sympathetic nerves, and the superior hemorrhoidal artery; and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebræ, and the intervening fibrocartilage. The left common iliac vein lies partly *medial* to, and partly behind the artery; *laterally*, the artery is in relation with the Psoas major.

Branches.—The common iliac arteries give off small branches to the peritoneum, Psoas major, ureters, and the surrounding areolar tissue, and occasionally give origin to the iliolumbar, or accessory renal arteries.

Peculiarities.—The *point of origin* varies according to the bifurcation of the aorta. In three-fourths of a large number of cases, the aorta bifurcated either upon the fourth lumbar vertebra, or upon the fibrocartilage between it and the fifth; the bifurcation being, in one case out of nine, below, and in one out of eleven, above this point. In about 80 per cent. of the cases the aorta bifurcated within 1.25 cm. above or below the level of the crest of the ilium; more frequently below than above.

The *point of division* is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum; being above that point in one case out of eight, and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The *relative lengths*, also, of the two common iliac arteries vary. The right common iliac was the longer in sixty-three cases; the left in fifty-two; while they were equal in fifty-three. The length of the arteries varied, in five-sevenths of the cases examined, from 3.5 to 7.5 cm.; in about half of the remaining cases the artery was longer, and in the other half, shorter; the minimum length being less than 1.25 cm., the maximum, 11 cm. In rare instances, the right common iliac has been found wanting, the external iliac and hypogastric arising directly from the aorta.

Applied Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurism or hemorrhage, implicating the external iliac or hypogastric. The easiest and best method of tying the artery is by a transperitoneal route. The abdomen is opened, the intestines are drawn aside and the peritoneum covering the artery divided; the sheath is then opened and the needle passed from the medial to the lateral side. On the right side great care must be exercised in passing the needle, since both the common iliac veins lie behind the artery. After the vessel has been tied, the incision in the peritoneum over the artery should be sutured. Formerly there were different methods by which the common iliac artery was tied, without opening the peritoneal cavity, but these have now been discarded.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are: the anastomoses of the hemorrhoidal branches of the hypogastric with the superior hemorrhoidal from the inferior mesenteric; of the uterine, ovarian, and vesical arteries of the opposite sides; of the lateral sacral with the middle sacral artery; of the inferior epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the deep iliac circumflex with the lumbar arteries; of the iliolumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the inferior epigastric.

The Hypogastric Artery (A. Hypogastrica; Internal Iliac Artery) (Fig. 615).

The **hypogastric artery** supplies the walls and viscera of the pelvis, the buttock, the generative organs, and the medial side of the thigh. It is a short, thick vessel, smaller than the external iliac, and about 4 cm. in length. It *arises* at the bifurcation of the common iliac, opposite the lumbosacral articulation, and, passing downward to the upper margin of the greater sciatic foramen, divides into two large trunks, an **anterior** and a **posterior**.

Relations.—It is in relation *in front* with the ureter; *behind*, with the internal iliac vein, the lumbosacral trunk, and the Piriformis muscle; *laterally*, near its origin, with the external iliac vein, which lies between it and the Psoas major muscle; lower down, with the obturator nerve.

In the fetus, the hypogastric artery is twice as large as the external iliac, and is the direct continuation of the common iliac. It ascends along the side of the bladder, and runs upward on the back of the anterior wall of the abdomen to the umbilicus, converging toward its fellow of the opposite side. Having passed through the umbilical opening, the two arteries, now termed **umbilical**, enter the umbilical cord, where they are coiled around the umbilical vein, and ultimately **ramify** in the placenta.

At birth, when the placental circulation ceases, the pelvic portion only of the artery remains patent and constitutes the hypogastric and the first part of the superior vesical artery of the adult; the remainder of the vessel is converted into a solid fibrous cord, the **lateral umbilical ligament** (*obliterated hypogastric artery*) which extends from the pelvis to the umbilicus.

Peculiarities as Regards Length.—In two-thirds of a large number of cases, the length of the hypogastric varied between 2.25 and 3.4 cm.; in the remaining third it was more frequently longer than shorter, the maximum length being about 7 cm. the minimum about 1 cm.

The lengths of the common iliac and hypogastric arteries bear an inverse proportion to each other, the hypogastric artery being long when the common iliac is short, and *vice versa*.

As Regards its Place of Division.—The place of division of the hypogastric varies between the upper margin of the sacrum and the upper border of the greater sciatic foramen.

The right and left hypogastric arteries in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Applied Anatomy.—The application of a ligature to the hypogastric artery may be required in cases of aneurism or hemorrhage affecting one of its branches. The vessel may be best secured by an abdominal section in the median line, and reaching the vessel through the peritoneal cavity. It should be remembered that the vein lies behind, and, on the right side, a little lateral to the artery, and in close contact with it; the ureter, which lies in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon its length. It has been seen that, in the great majority of the cases examined, the artery was short, varying from 2 to 4 cm.; in these cases, the artery is deeply seated in the pelvis; when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery be very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac.

Collateral Circulation.—The circulation after ligature of the hypogastric artery is carried on by the anastomoses of the uterine and ovarian arteries; of the vesical arteries of the two sides; of the hemorrhoidal branches of the hypogastric with those from the inferior mesenteric; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side, and with the inferior epigastric and medial femoral circumflex; of the circumflex and perforating branches of the profunda femoris with the inferior gluteal; of the superior gluteal with the posterior branches of the lateral sacral arteries; of the iliolumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the iliac circumflex with the iliolumbar and superior gluteal.¹

Branches.—The branches of the hypogastric artery are:

From the Anterior Trunk.

From the Posterior Trunk.

Superior Vesical.

Iliolumbar.

Middle Vesical.

Lateral Sacral.

Inferior Vesical.

Superior Gluteal.

Middle Hemorrhoidal.

Obturator.

Internal Pudendal.

Inferior Gluteal.

Uterine } *In the Female.*
Vaginal }

The **superior vesical artery** (*a. vesicalis superior*) supplies numerous branches to the upper part of the bladder. From one of these a slender vessel, the **artery to the ductus deferens**, takes origin and accompanies the duct in its course to the testis, where it anastomoses with the internal spermatic artery. Other branches supply the ureter. The first part of the superior vesical artery represents the terminal section of the pervious portion of the fetal hypogastric artery.

The **middle vesical artery** (*a. vesicalis medialis*), usually a branch of the superior, is distributed to the fundus of the bladder and the vesiculæ seminales.

The **inferior vesical artery** (*a. vesicalis inferior*) frequently arises in common with the middle hemorrhoidal, and is distributed to the fundus of the bladder, the prostate, and the vesiculæ seminales. The branches to the prostate communicate with the corresponding vessels of the opposite side.

The **middle hemorrhoidal artery** (*a. haemorrhoidalis media*) usually arises with the preceding vessel. It is distributed to the rectum, anastomosing with the inferior vesical and with the superior and inferior hemorrhoidal arteries. It gives offsets to the vesiculæ seminales and prostate.

The **uterine artery** (*a. uterina*) (Fig. 616) springs from the anterior division of the hypogastric and runs medialward on the Levator ani and toward the cervix uteri; about 2 cm. from the cervix it crosses above and in front of the ureter, to which it supplies a small branch. Reaching the side of the uterus it ascends in a tortuous manner between the two layers of the broad ligament to the junction

¹ For a description of a case in which Owen made a dissection ten years after ligature of the hypogastric artery, see *Med.-Chir. Trans.*, vol. xvi.

The **anterior branch** runs forward on the outer surface of the obturator membrane and then curves downward along the anterior margin of the foramen. It distributes branches to the Obturator externus, Pectineus, Adductores, and Gracilis, and anastomoses with the posterior branch and with the medial femoral circumflex artery.

The **posterior branch** follows the posterior margin of the foramen and turns forward on the inferior ramus of the ischium, where it anastomoses with the anterior branch. It gives twigs to the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal. It also supplies an articular branch which enters the hip-joint through the acetabular notch, ramifies in the fat at the bottom of the acetabulum and sends a twig along the ligamentum teres to the head of the femur.

Peculiarities.—The obturator artery sometimes arises from the main stem or from the posterior trunk of the hypogastric, or it may spring from the superior gluteal artery; occasionally it arises from the external iliac. In about two out of every seven cases it springs from the inferior epigastric and descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein, and on the lateral side of the femoral ring (Fig. 617 A); in such cases it would not be endangered in the operation for strangulated femoral hernia. Occasionally, however, it curves along the free margin of the lacunar ligament (Fig. 617 B), and if in such circumstances a femoral hernia occurred, the vessel would almost completely encircle the neck of the hernial sac, and would be in great danger of being wounded if an operation were performed for strangulation.

A

B

FIG. 617.—Variations in origin and course of obturator artery.

The **internal pudendal artery** (*a. pudenda interna; internal pudic artery*) is the smaller of the two terminal branches of the anterior trunk of the hypogastric, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The **internal pudendal artery in the male** passes downward and outward to the lower border of the greater sciatic foramen, and emerges from the pelvis between the Piriformis and Coccygeus; it then crosses the ischial spine, and enters the perineum through the lesser sciatic foramen. The artery now crosses the Obturator internus, along the lateral wall of the ischiorectal fossa, being situated about 4 cm. above the lower margin of the ischial tuberosity. It gradually approaches the margin of the inferior ramus of the ischium and passes forward between the two layers of the fascia of the urogenital diaphragm; it then runs forward along the medial margin of the inferior ramus of the pubis, and about 1.25 cm. behind the pubic arcuate ligament it pierces the inferior fascia of the urogenital diaphragm and divides into the dorsal and deep arteries of the penis.

Relations.—Within the pelvis, it lies in front of the Piriformis muscle, the sacral plexus of nerves, and the inferior gluteal artery. As it crosses the ischial spine, it is covered by the Gluteus maximus and overlapped by the sacrotuberous ligament. Here the pudendal nerve lies to the medial side and the nerve to the Obturator internus to the lateral side of the vessel. In the perineum it lies on the lateral wall of the ischiorectal fossa, in a canal (*Alcock's canal*) formed by the

splitting of the obturator fascia. It is accompanied by a pair of *venae comitantes* and the pudendal nerve.

Peculiarities.—The internal pudendal artery is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the **accessory pudendal**, which generally arises from the internal pudendal artery before its exit from the greater sciatic foramen. It passes forward along the lower part of the bladder and across the side of the prostate to the root of the penis, where it perforates the urogenital diaphragm, and gives off the branches usually derived from the internal pudendal artery. The deficiency most frequently met with is that in which the internal pudendal ends as the artery of the urethral bulb, the dorsal and deep arteries of the penis being derived from the accessory pudendal. The internal pudendal artery may also end as the perineal, the artery of the urethral bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudendal artery is derived from one of the other branches of the hypogastric artery, most frequently the inferior vesical or the obturator.

Branches.—The branches of the internal pudendal artery (Figs. 618, 619) are:

Muscular.	Artery of the Urethral Bulb.
Inferior Hemorrhoidal.	Urethral.
Perineal.	Deep Artery of the Penis.
	Dorsal Artery of the Penis.

*Sacrospinous
ligament*

*Posterior scrotal arteries
Posterior scrotal nerves
Pudendal nerve
Internal pudendal artery*

FIG. 618.—The superficial branches of the internal pudendal artery.

The **Muscular Branches** consist of two sets: one given off in the pelvis; the other, as the vessel crosses the ischial spine. The former consists of several small offsets which supply the Levator ani, the Obturator internus, the Piriformis, and the Coccygeus. The branches given off outside the pelvis are distributed to the adjacent parts of the Gluteus maximus and external rotator muscles. They anastomose with branches of the inferior gluteal artery.

The **Inferior Hemorrhoidal Artery** (*a. haemorrhoidalis inferior*) arises from the internal pudendal as it passes above the ischial tuberosity. Piercing the wall of Alcock's canal it divides into two or three branches which cross the ischiorectal fossa, and are distributed to the muscles and integument of the anal region, and

send offshoots around the lower edge of the Glutaeus maximus to the skin of the buttock. They anastomose with the corresponding vessels of the opposite side, with the superior and middle hemorrhoidal, and with the perineal artery.

The **Perineal Artery** (*a. perinei*; *superficial perineal artery*) arises from the internal pudendal, in front of the preceding branches, and turns upward, crossing, either over or under the Transversus perinaei superficialis, and runs forward, parallel to the pubic arch, in the interspace between the Bulbocavernosus and Ischiocavernosus, both of which it supplies, and finally divides into several **posterior scrotal branches** which are distributed to the skin and dartos tunic of the scrotum. As it crosses the Transversus perinaei superficialis it gives off the **transverse perineal artery** which runs transversely on the cutaneous surface of the muscle, and anastomoses with the corresponding vessel of the opposite side and with the perineal and inferior hemorrhoidal arteries. It supplies the Transversus perinaei superficialis and the structures between the anus and the urethral bulb.

Deep artery
Dorsal artery

Artery of urethral bulb
Internal pudendal artery
Bulbo-urethral gland

FIG. 619. —The deeper branches of the internal pudendal artery

The **Artery of the Urethral Bulb** (*a. bulbi urethrae*) is a short vessel of large calibre which arises from the internal pudendal between the two layers of fascia of the urogenital diaphragm; it passes medialward, pierces the inferior fascia of the urogenital diaphragm, and gives off branches which ramify in the bulb of the urethra and in the posterior part of the corpus cavernosum urethrae. It gives off a small branch to the bulbo-urethral gland.

The **Urethral Artery** (*a. urethralis*) arises a short distance in front of the artery of the urethral bulb. It runs forward and medialward, pierces the inferior fascia of the urogenital diaphragm and enters the corpus cavernosum urethrae, in which it is continued forward to the glans penis.

The **Deep Artery of the Penis** (*a. profunda penis*; *artery to the corpus cavernosum*), one of the terminal branches of the internal pudendal, arises from that vessel while it is situated between the two fasciae of the urogenital diaphragm; it pierces the inferior fascia, and, entering the crus penis obliquely, runs forward in the centre of the corpus cavernosum penis, to which its branches are distributed.

The **Dorsal Artery of the Penis** (*a. dorsalis penis*) ascends between the crus penis and the pubic symphysis, and, piercing the inferior fascia of the urogenital diaphragm, passes between the two layers of the suspensory ligament of the penis, and runs forward on the dorsum of the penis to the glans, where it divides into two branches, which supply the glans and prepuce. On the penis, it lies between the dorsal nerve and deep dorsal vein, the former being on its lateral side. It supplies the integument and fibrous sheath of the corpus cavernosum penis, sending branches through the sheath to anastomose with the preceding vessel.

The **internal pudendal artery in the female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The perineal artery supplies the labia pudendi; the artery of the bulb supplies the bulbus vestibuli and the erectile tissue of the vagina; the deep artery of the clitoris supplies the corpus cavernosum clitoridis; and the dorsal artery of the clitoris supplies the dorsum of that organ, and ends in the glans and prepuce of the clitoris.

The **inferior gluteal artery** (*a. glutea inferior; sciatic artery*) (Fig. 620), the larger of the two terminal branches of the anterior trunk of the hypogastric, is distributed chiefly to the buttock and back of the thigh. It passes down on the sacral plexus of nerves and the Piriformis, behind the internal pudendal artery, to the lower part of the greater sciatic foramen, through which it escapes from the pelvis between the Piriformis and Coccygeus. It then descends in the interval between the greater trochanter of the femur and tuberosity of the ischium, accompanied by the sciatic and posterior femoral cutaneous nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh, supplying the skin, and anastomosing with branches of the perforating arteries.

Inside the pelvis it distributes branches to the Piriformis, Coccygeus, and Levator ani; some branches which supply the fat around the rectum, and occasionally take the place of the middle hemorrhoidal artery; and vesical branches to the fundus of the bladder, vesiculæ seminales, and prostate. *Outside the pelvis* it gives off the following branches:

Muscular.	Anastomotic.
Coccygeal.	Articular.
Comitans Nervi Ischiadici.	Cutaneous.

The **Muscular Branches** supply the Gluteus maximus, anastomosing with the superior gluteal artery in the substance of the muscle; the external rotators, anastomosing with the internal pudendal artery; and the muscles attached to the tuberosity of the ischium, anastomosing with the posterior branch of the obturator and the medial femoral circumflex arteries.

The **Coccygeal Branches** run medialward, pierce the sacrotuberous ligament, and supply the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The **Arteria Comitans Nervi Ischiadici** is a long, slender vessel, which accompanies the sciatic nerve for a short distance; it then penetrates it, and runs in its substance to the lower part of the thigh.

The **Anastomotic** is directed downward across the external rotators, and assists in forming the so-called **crucial anastomosis** by joining with the first perforating and medial and lateral femoral circumflex arteries.

The **Articular Branch**, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

The **Cutaneous Branches** are distributed to the skin of the buttock and back of the thigh.

The **iliolumbar artery** (*a. iliolumbalis*) a branch of the posterior trunk of the hypogastric, turns upward behind the obturator nerve and the external iliac vessels

to the medial border of the Psoas major, behind which it divides into a lumbar and an iliac branch.

The **Lumbar Branch** (*ramus lumbalis*) supplies the Psoas major and Quadratus lumborum, anastomoses with the last lumbar artery, and sends a small **spinal branch** through the intervertebral foramen between the last lumbar vertebra and the sacrum, into the vertebral canal, to supply the cauda equina.

The **Iliac Branch** (*ramus iliacus*) descends to supply the Iliacus; some offsets, running between the muscle and the bone, anastomose with the iliac branches of the obturator; one of these enters an oblique canal to supply the bone, while others run along the crest of the ilium, distributing branches to the gluteal and abdominal muscles, and anastomosing in their course with the superior gluteal, iliac circumflex, and lateral femoral circumflex arteries.

The **lateral sacral arteries** (*aa. sacrales laterales*) (Fig. 615) arise from the posterior division of the hypogastric; there are usually two, a **superior** and an **inferior**.

The **superior**, of large size, passes medialward, and, after anastomosing with branches from the middle sacral, enters the first or second anterior sacral foramen, supplies branches to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, is distributed to the skin and muscles on the dorsum of the sacrum, anastomosing with the superior gluteal.

The **inferior** runs obliquely across the front of the Piriformis and the sacral nerves to the medial side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the middle sacral and opposite lateral sacral artery. In its course it gives off branches, which enter the anterior sacral foramina; these, after supplying the contents of the sacral canal, escapes by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal arteries.

The **superior gluteal artery** (*a. glutea superior; gluteal artery*) (Fig. 620) is the largest branch of the hypogastric, and appears to be the continuation of the posterior division of that vessel. It is a short artery which runs backward between

FIG. 620.—The arteries of the gluteal and posterior femoral regions.

the lumbosacral trunk and the first sacral nerve, and, passing out of the pelvis above the upper border of the Piriformis, immediately divides into a **superficial** and a **deep branch**. Within the pelvis it gives off a few branches to the Iliacus, Piriformis, and Obturator internus, and just previous to quitting that cavity, a nutrient artery which enters the ilium.

The **superficial branch** enters the deep surface of the Glutaeus maximus, and divides into numerous branches, some of which supply the muscle and anastomose with the inferior gluteal, while others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the lateral sacral arteries.

The **deep branch** lies under the Glutaeus medius and almost immediately subdivides into two. Of these, the **superior division**, continuing the original course of the vessel, passes along the upper border of the Glutaeus minimus to the anterior superior spine of the ilium, anastomosing with the deep iliac circumflex artery and the ascending branch of the lateral femoral circumflex artery. The **inferior division** crosses the Glutaeus minimus obliquely to the greater trochanter, distributing branches to the Glutaei and anastomoses with the lateral femoral circumflex artery. Some branches pierce the Glutaeus minimus and supply the hip-joint.

Applied Anatomy.—Any of these three vessels may require to be ligatured for a wound, or for aneurism which is generally traumatic. The *superior gluteal* artery is ligatured by turning the patient two-thirds over on to his face and making an incision from the posterior superior spine of the ilium to the upper and posterior angle of the greater trochanter. This must expose the Glutaeus maximus, and its fibres are to be separated through the whole thickness of the muscle and pulled apart with retractors. The contiguous margins of the Glutaeus medius and Piriformis are now to be separated from each other, and the artery will be exposed emerging from the greater sciatic foramen. In ligature of the *inferior gluteal* artery, the incision should be made parallel with that for ligature of the superior gluteal but 4 cm. lower down. After the fibres of the Glutaeus maximus have been separated, the vessel is to be sought for at the lower border of the Piriformis; the sciatic nerve, which lies just above it, forms the chief guide to the artery.

The External Iliac Artery (A. Iliaca Externa) (Fig. 615).

The **external iliac artery** is larger than the hypogastric, and passes obliquely downward and lateralward along the medial border of the Psoas major, from the bifurcation of the common iliac to a point beneath the inguinal ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, where it enters the thigh and becomes the femoral artery.

Relations.—*In front and medially*, the artery is in relation with the peritoneum, subperitoneal areolar tissue, the termination of the ileum and frequently the vermiform process on the right side, and the sigmoid colon on the left, and a thin layer of fascia, derived from the iliac fascia, which surrounds the artery and vein. At its origin it is crossed by the ovarian vessels in the female, and occasionally by the ureter. The internal spermatic vessels lie for some distance upon it near its termination, and it is crossed in this situation by the external spermatic branch of the genitofemoral nerve and the deep iliac circumflex vein; the ductus deferens in the male, and the round ligament of the uterus in the female, curve down across its medial side. *Behind*, it is in relation with the medial border of the Psoas major, from which it is separated by the iliac fascia. At the upper part of its course, the external iliac vein lies partly behind it, but lower down lies entirely to its medial side. *Laterally*, it rests against the Psoas major, from which it is separated by the iliac fascia. Numerous lymphatic vessels and lymph glands lie on the front and on the medial side of the vessel.

Applied Anatomy.—The application of a ligature to the external iliac may be required in cases of aneurism of the femoral artery, iliofemoral aneurism, or for a wound of the artery. The vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the hypogastric, and near its lower end, which should also be avoided on account of the proximity of the inferior epigastric and deep iliac circumflex vessels. The operation may be performed by opening the abdomen and incising the peritoneum over the artery (*transperitoneal*); or by an incision in the iliac region, dividing all the structures down to the peritoneum, which is then reflected medialward unopened from the iliac fossa until the artery is reached (*retroperitoneal*).

The transperitoneal ligature requires an incision through the abdominal wall into the peritoneal cavity. The intestines are then pushed upward and held out of the way by a broad abdominal retractor, and an incision made through the peritoneum at the margin of the pelvis in the course of the artery; the vessel is secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be, that if it is found necessary, the common iliac artery can be ligatured instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligatured without in any way interfering with the sac of an aneurism.

The retroperitoneal ligature may be performed by an incision above and parallel to the lateral half of the inguinal ligament. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised toward the pelvis; and on introducing the finger to the bottom of the wound, the artery may be felt pulsating along the medial border of the Psoas major. The external iliac vein is generally found on the medial side of the artery, and must be cautiously separated from it, and the aneurism needle should be introduced on the medial side, between the artery and vein.

Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are: the iliolumbar with the iliac circumflex; the superior gluteal with the lateral femoral circumflex; the obturator with the medial femoral circumflex; the inferior gluteal with the first perforating and circumflex branches of the profunda artery; and the internal pudendal with the external pudendal. When the obturator arises from the inferior epigastric, it is supplied with blood by branches, from either the hypogastric, the lateral sacral, or the internal pudendal. The inferior epigastric receives its supply from the internal mammary and lower intercostal arteries, and from the hypogastric by the anastomoses of its branches with the obturator.¹

Branches.—Besides several small branches to the Psoas major and the neighboring lymph glands, the external iliac gives off two branches of considerable size:

Inferior Epigastric.

Deep Iliac Circumflex.

The **inferior epigastric artery** (*a. epigastrica inferior; deep epigastric artery*) (Fig. 623) arises from the external iliac, immediately above the inguinal ligament. It curves forward in the subperitoneal tissue, and then ascends obliquely along the medial margin of the abdominal inguinal ring; continuing its course upward, it pierces the transversalis fascia, and, passing in front of the linea semicircularis, ascends between the Rectus abdominis and the posterior lamella of its sheath. It finally divides into numerous branches, which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary and with the lower intercostal arteries (Fig. 598). As the inferior epigastric artery passes obliquely upward from its origin it lies along the lower and medial margins of the abdominal inguinal ring, and behind the commencement of the spermatic cord. The ductus deferens, as it leaves the spermatic cord in the male, and the round ligament of the uterus in the female, winds around the lateral and posterior aspects of the artery.

Branches.—The branches of the vessel are: the **external spermatic artery** (*cremasteric artery*), which accompanies the spermatic cord, and supplies the Cremaster and other coverings of the cord, anastomosing with the internal spermatic artery (in the female it is very small and accompanies the round ligament); a **pubic branch** which runs along the inguinal ligament, and then descends along the medial margin of the femoral ring to the back of the pubis, and there anastomoses with the pubic branch of the obturator artery; **muscular branches**, some of which are distributed to the abdominal muscles and peritoneum, anastomosing with the iliac circumflex and lumbar arteries; branches which perforate the tendon of the Obliquus externus, and supply the integument, anastomosing with branches of the superficial epigastric.

Peculiarities.—The origin of the inferior epigastric may take place from any part of the external iliac between the inguinal ligament and a point 6 cm. above it; or it may arise below this ligament, from the femoral. It frequently springs from the external iliac, by a common trunk with the obturator. Sometimes it arises from the obturator, the latter vessel being furnished by the

¹ Sir Astley Cooper describes in Guy's Hospital Reports, vol. i, the dissection of a limb eighteen years after successful ligature of the external iliac artery.

hypogastric, or it may be formed of two branches, one derived from the external iliac, the other from the hypogastric.

Applied Anatomy.—The inferior epigastric artery has important surgical relations, and is one of the principal means, through its anastomosis with the internal mammary, of establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the abdominal inguinal ring, and is therefore *medial* to an oblique inguinal hernia, but *lateral* to a direct inguinal hernia, as these emerge from the abdomen. It forms the lateral boundary of Hesselbach's triangle, and is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The ductus deferens hooks around its lateral side.

The **deep iliac circumflex artery** (*a. circumflexa ilium profunda*) arises from the lateral aspect of the external iliac nearly opposite the inferior epigastric artery. It ascends obliquely lateralward behind the inguinal ligament, contained in a fibrous sheath formed by the junction of the transversalis fascia and iliac fascia, to the anterior superior iliac spine, where it anastomoses with the ascending branch of the lateral femoral circumflex artery. It then pierces the transversalis fascia and passes along the inner lip of the crest of the ilium to about its middle, where it perforates the Transversus, and runs backward between that muscle and the Obliquus internus, to anastomose with the iliolumbar and superior gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch, which ascends between the Obliquus internus and Transversus muscles, supplying them, and anastomosing with the lumbar and inferior epigastric arteries.

THE ARTERIES OF THE LOWER EXTREMITY.

The artery which supplies the greater part of the lower extremity is the direct continuation of the external iliac. It runs as a single trunk from the inguinal ligament to the lower border of the Popliteus, where it divides into two branches, the **anterior** and **posterior tibial**. The upper part of the main trunk is named the **femoral**, the lower part the **popliteal**.

THE FEMORAL ARTERY (A. FEMORALIS) (Figs. 624, 625).

The **femoral artery** begins immediately behind the inguinal ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and passes down the front and medial side of the thigh. It ends at the junction of the middle with the lower third of the thigh, where it passes through an opening in the Adductor magnus to become the popliteal artery. The vessel, at the upper part of the thigh, lies in front of the hip-joint; in the lower part of its course it lies to the medial side of the body of the femur, and between these two parts, where it crosses the angle between the head and body, the vessel is some distance from the bone. The first 4 cm. of the vessel is enclosed, together with the femoral vein, in a fibrous sheath—the **femoral sheath**. In the upper third of the thigh the femoral artery is contained in the **femoral triangle** (*Scarpa's triangle*), and in the middle third of the thigh, in the **adductor canal** (*Hunter's canal*).

The **femoral sheath** (*crural sheath*) (Figs. 621, 622) is formed by a prolongation downward, behind the inguinal ligament, of the fasciæ which line the abdomen, the transversalis fascia being continued down in front of the femoral vessels and the iliac fascia behind them. The sheath assumes the form of a short funnel, the wide end of which is directed upward, while the lower, narrow end fuses with the fascial investment of the vessels, about 4 cm. below the inguinal ligament. It is strengthened in front by a band termed the **deep crural arch** (page 509). The lateral wall of the sheath is vertical and is perforated by the lumboinguinal nerve; the medial wall is directed obliquely downward and lateralward, and is pierced by the

FIG. 621 —Femoral sheath laid open to show its three compartments.

FIG. 622.—Structures passing behind the inguinal ligament.

ANGIOLOGY

us vein and by some lymphatic vessels. The sheath is divided by partitions which stretch between its anterior and posterior walls. The upper compartment contains the femoral artery, and the intermediate the femoral vein, while the medial and smallest compartment is named the **femoral canal** and contains some lymphatic vessels and a lymph gland imbedded in a small amount of areolar tissue. The femoral canal is conical and measures about 1.25 cm.

Its base, directed upward and named the **femoral ring**, is oval in shape and its diameter being directed transversely and measuring about 1.25 cm. (Figs. 622, 623) is bounded in *front* by the inguinal ligament, *superiorly* by the Pectineus covered by the pectineal fascia, *medially* by the crescentic crural ligament, and *laterally* by the fibrous septum on the medial side of the femoral vein. The spermatic cord in the male and the round ligament in the female lie immediately above the anterior margin of the ring, and the superior epigastric vessels are close to its upper and lateral angle. The femoral sheath is closed by a somewhat condensed portion of the extraperitoneal layer named the **septum femorale** (*crural septum*), the abdominal surface of which is

Fig. 622. Relations of the femoral and abdominal inguinal rings, seen from within the abdomen. Right side.

ports a small lymph gland and is covered by the parietal layer of the peritoneum. The septum femorale is pierced by numerous lymphatic vessels, and the deep inguinal to the external iliac lymph glands, and the parietal layer of the peritoneum immediately above it presents a slight depression named the **femoral**

triangle (*trigonum femorale*; *Scarpa's triangle*) (Fig. 624) corresponding to the depression seen immediately below the fold of the groin. Its apex is directed downward, and the sides are formed laterally by the medial margin of the Adductor longus, and above by the medial margin of the Adductor longus, and above by the inguinal ligament. The floor of the space is formed from its lateral to its medial side by the Iliacus, Psoas major, Pectineus, in some cases a small part of the Psoas brevis, and the Adductor longus; and it is divided into two nearly equal parts by the femoral vessels, which extend from near the middle of its base to its apex. The femoral artery giving off in this situation its superficial and profunda branches, and the femoral vein receiving the deep femoral and great saphenous tributaries. The lateral side of the femoral artery is the femoral nerve dividing into its

branches. Besides the vessels and nerves, this space contains some fat and lymphatics.

The **adductor canal** (*canalis adductorius*; *Hunter's canal*) is an aponeurotic tunnel in the middle third of the thigh, extending from the apex of the femoral triangle to the opening in the Adductor magnus. It is bounded, in front and laterally, by the Vastus medialis; behind by the Adductores longus and magnus; and is covered in by a strong aponeurosis which extends from the Vastus medialis, across the femoral vessels to the Adductores longus and magnus; lying on the aponeurosis is the Sartorius muscle. The canal contains the femoral artery and vein, the saphenous nerve, and the nerve to the Vastus medialis.

Great saphenous vein

FIG. 624.—The left femoral triangle.

Relations of the Femoral Artery.—In the *femoral triangle* (Fig. 624) the artery is superficial. In front of it are the skin and superficial fascia, the superficial subinguinal lymph glands, the superficial iliac circumflex vein, the superficial layer of the fascia lata and the anterior part of the femoral sheath. The lumboinguinal nerve courses for a short distance within the lateral compartment of the femoral sheath, and lies at first in front and then lateral to the artery. Near the apex of the femoral triangle the medial branch of the anterior femoral cutaneous nerve crosses the artery from its lateral to its medial side.

Behind the artery are the posterior part of the femoral sheath, the pectineal fascia, the medial part of the tendon of the Psoas major, the Pectineus and the Adductor longus. The artery is separated from the capsule of the hip-joint by the tendon of the Psoas major, from the Pectineus by the femoral vein and profunda vessels, and from the Adductor longus by the femoral vein. The nerve to the Pectineus passes medialward behind the artery. On the lateral side of the artery, but separated from it by some fibres of the Psoas major, is the femoral nerve. The femora

ANGIOLOGY

medial side of the upper part of the artery, but is behind the vessel in the lower oral triangle.

For canal (Fig. 625) the femoral artery is more deeply situated, being covered by the superficial and deep fasciæ, the Sartorius and the fibrous roof of the canal; the nerve crosses from its lateral to its medial side. Behind the artery are the Adductor magnus; in front and lateral to it is the Vastus medialis. The femoral vein is the upper part, and lateral to the lower part of the artery

FIG. 625.—The femoral artery.

Several cases are recorded in which the femoral artery divided into two trunks, one of the profunda, and became reunited near the opening in the Adductor magnus, forming a single popliteal artery. One occurred in a patient who was operated upon for aneurysm. A few cases have been recorded in which the femoral artery was absent, and was supplied by the inferior gluteal artery which accompanied the sciatic nerve to the

popliteal fossa. The external iliac in these cases was small, and terminated in the profunda. The femoral vein is occasionally placed along the medial side of the artery throughout the entire extent of the femoral triangle; or it may be split so that a large vein is placed on either side of the artery for a greater or lesser distance.

Applied Anatomy.—Compression of the femoral artery, which is constantly requisite in amputations and other operations on the lower limb, is most effectually made immediately below the inguinal ligament. In this situation the artery is very superficial, and is merely separated from the superior ramus of the pubis by the Psoas major; here digital compression will effectually control the circulation through it. The vessel may also be controlled in the middle third of the thigh by a tourniquet, which presses the vessel against the medial side of the body of the femur.

The superficial position of the femoral artery in the femoral triangle renders it particularly liable to be injured in wounds, stabs, or gunshot injuries in the groin. On account of the close relationship between the artery and vein, the latter vessel is also liable to be wounded in these injuries. In such cases, the artery being compressed as it crosses the ramus of the pubis, the skin wound should be enlarged and the wound in the vessel sought for, and a ligature applied above and below the bleeding point.

The application of a ligature to the femoral artery may be required in cases of wound or aneurism of the popliteal, femoral, or arteries of the leg; and the vessel may be exposed and tied in any part of its course. The most favorable situation for the application of a ligature to the femoral is at the apex of the femoral triangle. In order to reach the artery in this situation, an incision 7 cm. long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outward. A large vein is frequently met with, passing in the course of the artery to join the great saphenous vein; this must be avoided, and the fascia lata having been cautiously divided, and the Sartorius displayed, that muscle must be drawn lateralward, in order to expose fully the sheath of the vessels. The finger having been introduced into the wound, and the pulsation of the artery felt, the sheath is opened on the lateral side of the vessel to a sufficient extent to allow of the introduction of the aneurism needle. In this part of the operation the saphenous nerve and the nerve to the Vastus medialis, which are in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course, and is very closely bound up with it.

To expose the artery in the adductor canal, an incision 7 cm. in length should be made through the integument, a finger's breadth medial to the line of the artery, the centre of the incision being in the middle of the thigh—i. e., midway between the groin and the knee. The fascia lata having been divided, and the lateral border of the Sartorius exposed, this muscle should be drawn medialward, when the strong fascia which is stretched across from the Adductors to the Vastus medialis will be observed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between it and the vein, from the lateral to the medial side of the artery. In this situation the femoral vein lies lateral to, and the saphenous nerve in front of the artery.

Collateral Circulation.—After ligature of the femoral artery, the main channels for carrying on the circulation are the anastomoses between—(1) the superior and inferior gluteal branches of the hypogastric with the medial and lateral femoral circumflex and first perforating branches of the profunda femoris; (2) the obturator branch of the hypogastric with the medial femoral circumflex of the profunda; (3) the internal pudendal of the hypogastric with the superficial and deep external pudendal of the femoral; (4) the deep iliac circumflex of the external iliac with the lateral femoral circumflex of the profunda and the superficial iliac circumflex of the femoral, and (5) the inferior gluteal of the hypogastric with the perforating branches of the profunda.

Branches.—The branches of the femoral artery are;

Superficial Epigastric.

Deep External Pudendal.

Superficial Iliac Circumflex.

Muscular.

Superficial External Pudendal.

Profunda Femoris.

Highest Genicular.

The **superficial epigastric artery** (*a. epigastrica superficialis*) arises from the front of the femoral artery about 1 cm. below the inguinal ligament, and, passing through the femoral sheath and the fascia cribrosa, turns upward in front of the inguinal ligament, and ascends between the two layers of the superficial fascia of the abdominal wall nearly as far as the umbilicus. It distributes branches to the superficial subinguinal lymph glands, the superficial fascia, and the integument; it anastomoses with branches of the inferior epigastric, and with its fellow of the opposite side.

The **superficial iliac circumflex artery** (*a. circumflexa ilium superficialis*), the smallest of the cutaneous branches, *arises* close to the preceding, and, piercing the fascia lata, runs lateralward, parallel with the inguinal ligament, as far as the crest of the ilium; it divides into branches which supply the integument of the groin, the superficial fascia, and the superficial subinguinal lymph glands, anastomosing with the deep iliac circumflex, the superior gluteal and lateral femoral circumflex arteries.

The **superficial external pudendal artery** (*a. pudenda externa superficialis; superficial external pudic artery*) *arises* from the medial side of the femoral artery, close to the preceding vessels, and, after piercing the femoral sheath and fascia cribrosa, courses medialward, across the spermatic cord (or round ligament in the female), to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium majus in the female, anastomosing with branches of the internal pudendal.

The **deep external pudendal artery** (*a. pudenda externa profunda; deep external pudic artery*), more deeply seated than the preceding, passes medialward across the Pectineus and the Adductor longus muscles; it is covered by the fascia lata, which it pierces at the medial side of the thigh, and is distributed, in the male, to the integument of the scrotum and perineum, in the female to the labium majus; its branches anastomose with the scrotal (or labial) branches of the perineal artery.

Muscular branches (*rami musculares*) are supplied by the femoral artery to the Sartorius, Vastus medialis, and Adductores.

The **profunda femoris artery** (*a. profunda femoris; deep femoral artery*) (Fig. 625) is a large vessel *arising* from the lateral and back part of the femoral artery, from 2 to 5 cm. below the inguinal ligament. At first it lies lateral to the femoral artery; it then runs behind it and the femoral vein to the medial side of the femur, and, passing downward behind the Adductor longus, ends at the lower third of the thigh in a small branch, which pierces the Adductor magnus, and is distributed on the back of the thigh to the hamstring muscles. The terminal part of the profunda is sometimes named the **fourth perforating artery**.

Relations.—*Behind it*, from above downward, are the Iliacus, Pectineus, Adductor brevis, and Adductor magnus. *In front* it is separated from the femoral artery by the femoral and profunda veins above and by the Adductor longus below. *Laterally*, the origin of the Vastus medialis intervenes between it and the femur.

Peculiarities.—This vessel sometimes arises from the medial side, and, more rarely, from the back of the femoral artery; but a more important peculiarity, from a surgical point of view, is that relating to the height at which the vessel arises. In three-fourths of a large number of cases it arose from 2.25 to 5 cm. below the inguinal ligament; in a few cases the distance was less than 2.25 cm.; more rarely, opposite the ligament; and in one case above the inguinal ligament, from the external iliac. Occasionally the distance between the origin of the vessel and the inguinal ligament exceeds 5 cm.

Branches.—The profunda gives off the following branches:

Lateral Femoral Circumflex.
Medial Femoral Circumflex.

Perforating.
Muscular.

The **Lateral Femoral Circumflex Artery** (*a. circumflexa femoris lateralis; external circumflex artery*) *arises* from the lateral side of the profunda, passes horizontally between the divisions of the femoral nerve, and behind the Sartorius and Rectus femoris, and divides into ascending, transverse, and descending branches.

The **ascending branch** passes upward, beneath the Tensor fasciae latae, to the lateral aspect of the hip, and anastomoses with the terminal branches of the superior gluteal and deep iliac circumflex arteries.

The **descending branch** runs downward, behind the Rectus femoris, upon the Vastus lateralis, to which it gives offsets; one long branch descends in the muscle as far as the knee, and anastomoses with the superior lateral genicular branch of

the popliteal artery. It is accompanied by the branch of the femoral nerve to the Vastus lateralis.

The **transverse branch**, the smallest, passes lateralward over the Vastus intermedius, pierces the Vastus lateralis, and winds around the femur, just below the greater trochanter, anastomosing on the back of the thigh with the medial femoral circumflex, inferior gluteal, and first perforating arteries.

The **Medial Femoral Circumflex Artery** (*a. circumflexa femoris medialis*; *internal circumflex artery*) arises from the medial and posterior aspect of the profunda, and winds around the medial side of the femur, passing first between the Pectineus and Psoas major, and then between the Obturator externus and the Adductor brevis. At the upper border of the Adductor brevis it gives off two branches: one is distributed to the Adductores, the Gracilis, and Obturator externus, and anastomoses with the obturator artery; the other descends beneath the Adductor brevis, to supply it and the Adductor magnus; the continuation of the vessel passes backward and divides into superficial, deep, and acetabular branches. The **superficial branch** appears between the Quadratus femoris and upper border of the Adductor magnus, and anastomoses with the inferior gluteal, lateral femoral circumflex, and first perforating arteries (*crucial anastomosis*). The **deep branch** runs obliquely upward upon the tendon of the Obturator externus and in front of the Quadratus femoris toward the trochanteric fossa, where it anastomoses with twigs from the gluteal arteries. The **acetabular branch** arises opposite the acetabular notch and enters the hip-joint beneath the transverse ligament in company with an articular branch from the obturator artery; it supplies the fat in the bottom of the acetabulum, and is continued along the round ligament to the head of the femur.

The **Perforating Arteries** (Fig. 620), usually three in number, are so named because they perforate the tendon of the Adductor magnus to reach the back of the thigh. They pass backward close to the linea aspera of the femur under cover of small tendinous arches in the muscle. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The **first perforating artery** (*a. perforans prima*) passes backward between the Pectineus and Adductor brevis (sometimes it perforates the latter); it then pierces the Adductor magnus close to the linea aspera. It gives branches to the Adductores brevis and magnus, Biceps femoris, and Glutaeus maximus, and anastomoses with the inferior gluteal, medial and lateral femoral circumflex and second perforating arteries.

The **second perforating artery** (*a. perforans secunda*), larger than the first, pierces the tendons of the Adductores brevis and magnus, and divides into ascending and descending branches, which supply the posterior femoral muscles, anastomosing with the first and third perforating. The second artery frequently arises in common with the first. The **nutrient artery** of the femur is usually given off from the second perforating artery; when two nutrient arteries exist, they usually spring from the first and third perforating vessels.

The **third perforating artery** (*a. perforans tertia*) is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the posterior femoral muscles; anastomosing above with the higher perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal. The nutrient artery of the femur may arise from this branch. The termination of the profunda artery, already described, is sometimes termed the **fourth perforating artery**.

Numerous **muscular branches** arise from the profunda; some of these end in the Adductores, others pierce the Adductor magnus, give branches to the hamstrings, and anastomose with the medial femoral circumflex artery and with the superior muscular branches of the popliteal.

The **highest genicular artery** (*a. genu suprema; anastomotica magna artery*) (Fig. 625) arises from the femoral just before it passes through the opening in the tendon of the Adductor magnus, and immediately divides into a saphenous and a musculo-articular branch.

The **saphenous branch** pierces the aponeurotic covering of the adductor canal, and accompanies the saphenous nerve to the medial side of the knee. It passes between the Sartorius and Gracilis, and, piercing the fascia lata, is distributed to the integument of the upper and medial part of the leg, anastomosing with the medial inferior genicular artery.

The **musculoarticular branch** descends in the substance of the Vastus medialis, and in front of the tendon of the Adductor magnus, to the medial side of the knee, where it anastomoses with the medial superior genicular artery and anterior recurrent tibial artery. A branch from this vessel crosses above the patellar surface of the femur, forming an anastomotic arch with the lateral superior genicular artery, and supplying branches to the knee-joint.

THE POPLITEAL FOSSA (Fig. 626).

Dissection.—A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in Fig. 570.

Boundaries.—The **popliteal fossa** or **space** is a lozenge-shaped space, at the back of the knee-joint. Laterally it is bounded by the Biceps femoris above, and by the Plantaris and the lateral head of the Gastrocnemius below; medially it is limited by the Semitendinosus and Semimembranosus above, and by the medial head of the Gastrocnemius below. The floor is formed by the popliteal surface of the femur, the oblique popliteal ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus; the fossa is covered in by the fascia lata.

Contents.—The popliteal fossa contains the popliteal vessels, the tibial and the common peroneal nerves, the termination of the small saphenous vein, the lower part of the posterior femoral cutaneous nerve, the articular branch from the obturator nerve, a few small lymph glands, and a considerable quantity of fat. The tibial nerve descends through the middle of the fossa, lying under the deep fascia and crossing the vessels posteriorly from the lateral to the medial side. The common peroneal nerve descends on the lateral side of the upper part of the fossa, close to the tendon of the Biceps femoris. On the floor of the fossa are the popliteal vessels, the vein being superficial to the artery and united to it by dense areolar tissue; the vein is a thick-walled vessel, and lies at first lateral to the artery, and then crosses it posteriorly to gain its medial side below; sometimes it is double, the artery lying between the two veins, which are usually connected by short transverse branches. The articular branch from the obturator nerve descends upon the artery to the knee-joint. The popliteal lymph glands, six or seven in number, are imbedded in the fat; one lies beneath the popliteal fascia near the termination of the external saphenous vein, another between the popliteal artery and the back of the knee-joint, while the others are placed at the sides of the popliteal vessel. Arising from the artery, and passing off from it at right angles, are its genicular branches.

The Popliteal Artery (**A. Poplitea**) (Fig. 626).

The **popliteal artery** is the continuation of the femoral, and courses through the popliteal fossa. It extends from the opening in the Adductor magnus, at the junction of the middle and lower thirds of the thigh, downward and lateralward to the intercondyloid fossa of the femur, and then vertically downward to the lower border of the Popliteus, where it divides into **anterior** and **posterior tibial arteries**.

Relations.—In front of the artery from above downward are the popliteal surfaces of the femur (which is separated from the vessel by some fat), the back of the knee-joint, and the fascia covering the Popliteus. Behind, it is overlapped by the Semimembranosus above, and is covered by the Gastrocnemius and Plantaris below. In the middle part of its course the artery is separated from the integument and fasciæ by a quantity of fat, and is crossed from the lateral to the medial side by the tibial nerve and the popliteal vein, the vein being between the nerve and the artery and closely adherent to the latter. On its lateral side, above, are the Biceps femoris, the tibial nerve, the popliteal vein, and the lateral condyle of the femur; below, the Plantaris and the lateral head of the Gastrocnemius. On its medial side, above, are the Semimembranosus and the medial condyle of the femur; below, the tibial nerve, the popliteal vein, and the medial head of the Gastrocnemius. The relations of the popliteal lymph glands to the artery are described above.

Peculiarities in Point of Division.—Occasionally the popliteal artery divides into its terminal branches opposite the knee-joint. The anterior tibial under these circumstances usually passes in front of the Popliteus.

Unusual Branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting, or very small. Occasionally it divides into three branches, the anterior and posterior tibial, and peroneal.

Applied Anatomy.—The popliteal artery is not unfrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart wheel over the knee, or by hyperextension of the knee. It may also be lacerated by fracture of the lower part of the body of the femur, or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing MacEwen's operation of osteotomy of the lower end of the femur for genu valgum. The popliteal artery is more frequently the seat of aneurism than any other artery in the body, with the exception of the thoracic aorta. No doubt this is due in a great measure to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles as is the case with most arteries. When the knee is acutely flexed the popliteal artery becomes bent on itself to such an extent as to entirely arrest the circulation through it.

Ligature of the popliteal artery is required in cases of wound of the vessel, but for aneurism it is preferable to tie the femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the fossa the operation is attended with considerable difficulty, from the great depth of the vessel, and from the extreme degree of tension of the lateral and medial boundaries of the fossa.

In order to expose the upper part of the vessel, the patient should be placed in the supine position, with the knee flexed and the thigh abducted and rotated outward, so that it rests on its lateral surface; an incision 7 or 8 cm. in length, beginning at the junction of the middle and lower thirds of the thigh, is to be made parallel

Medial calcaneal

FIG. 626.—The popliteal, posterior tibial, and peroneal arteries.

to and immediately behind the tendon of the adductor magnus, and the skin, superficial and deep fasciæ divided. The tendon of the muscle is thus exposed, and is to be drawn forward, and the hamstring tendons backward. A quantity of fatty tissue will now be opened up, in which the artery will be felt pulsating. This is to be separated with the point of a director until the artery is exposed. The vein and nerve will not be seen, as they lie to the lateral side of the artery. The sheath is to be opened and the aneurism needle passed from before backward, keeping its point close to the artery for fear of injuring the vein. The only structure to avoid in the superficial incision is the great saphenous vein.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the prone position with the limb extended. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the small saphenous vein and the medial sural cutaneous nerve. After dividing the deep fascia, and separating some dense cellular tissue, the artery, vein, and nerve will be exposed, between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn medialward and the vein lateralward, and the aneurism needle passed between the artery and vein from the lateral to the medial side.

Branches.—The branches of the popliteal artery are:

Muscular	{ Superior	Lateral Superior Genicular.
	{ Sural.	Middle Genicular.
Cutaneous.		Medial Inferior Genicular.
Medial Superior Genicular		Lateral Inferior Genicular.

The **superior muscular branches**, two or three in number, *arise* from the upper part of the artery, and are distributed to the lower parts of the Adductor magnus and hamstring muscles, anastomosing with the terminal part of the profunda femoris.

The **sural arteries** (*aa. surales; inferior muscular arteries*) are two large branches, which are distributed to the Gastrocnemius, Soleus, and Plantaris. They *arise* from the popliteal artery opposite the knee-joint.

The **cutaneous branches** *arise* either from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius, and, piercing the deep fascia, are distributed to the skin of the back of the leg. One branch usually accompanies the small saphenous vein.

The **superior genicular arteries** (*aa. genu superiores; superior articular arteries*) (Figs. 625, 626), two in number, *arise* one on either side of the popliteal, and wind around the femur immediately above its condyles to the front of the knee-joint. The **medial superior genicular** runs in front of the Semimembranosus and Semitendinosus, above the medial head of the Gastrocnemius, and passes beneath the tendon of the Adductor magnus. It divides into two branches, one of which supplies the Vastus medialis, anastomosing with the highest genicular and medial inferior genicular arteries; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the lateral superior genicular artery. The medial superior genicular artery is frequently of small size, a condition, which is associated with an increase in the size of the highest genicular. The **lateral superior genicular** passes above the lateral condyle of the femur, beneath the tendon of the Biceps femoris, and divides into a superficial and a deep branch; the superficial branch supplies the Vastus lateralis, and anastomoses with the descending branch of the lateral femoral circumflex and the lateral inferior genicular arteries; the deep branch supplies the lower part of the femur and knee-joint, and forms an anastomotic arch across the front of the bone with the highest genicular and the medial inferior genicular arteries.

The **middle genicular artery** (*a. genu media; azygos articular artery*) is a small branch, *arising* opposite the back of the knee-joint. It pierces the oblique popliteal ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The **inferior genicular arteries** (*aa. genu inferiores; inferior articular arteries*) (Figs. 625, 626), two in number, *arise* from the popliteal beneath the Gastrocnemius. The **medial inferior genicular** first descends along the upper margin of the Popliteus, to which it gives branches; it then passes below the medial condyle of the tibia, beneath the tibial collateral ligament, at the anterior border of which it ascends to the front and medial side of the joint, to supply the upper end of the tibia and the articulation of the knee, anastomosing with the lateral inferior and medial superior genicular arteries. The **lateral inferior genicular** runs lateralward above the head of the fibula to the front of the knee-joint, passing in its course beneath the lateral head of the Gastrocnemius, the fibular collateral ligament, and the tendon of the Biceps femoris. It ends by dividing into branches, which anastomose with the medial inferior and lateral superior genicular arteries, and with the anterior recurrent tibial artery.

FIG. 627.—Circumpatellar anastomosis.

The **Anastomosis Around the Knee-joint** (Fig. 627).—Around and above the patella, and on the contiguous ends of the femur and tibia, is an intricate net-work of vessels forming a superficial and a deep plexus. The **superficial plexus** is situated between the fascia and skin around about the patella, and forms three well-defined arches: one, above the upper border of the patella, in the loose connective tissue over the Quadriceps femoris; the other two, below the level of the patella, are situated in the fat behind the ligamentum patellae. The **deep plexus**, which forms a close net-work of vessels, lies on the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The arteries which form this plexus are the two medial and the two lateral genicular branches of the popliteal, the highest genicular, the descending branch of the lateral femoral circumflex, and the anterior recurrent tibial.

The Anterior Tibial Artery (A. Tibialis Anterior) (Fig. 628).

The **anterior tibial artery** commences at the bifurcation of the popliteal, at the lower border of the Popliteus, passes forward between the two heads of the Tibialis posterior, and through the aperture above the upper border of the interosseous membrane, to the deep part of the front of the leg: it here lies close to the medial side of the neck of the fibula. It then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; at the lower part of the leg it lies on this bone, and then on the front of the ankle-joint, where it is more superficial, and becomes the **dorsalis pedis**.

Relations.—In the upper two-thirds of its extent, the anterior tibial artery rests upon the interosseous membrane; in the lower third, upon the front of the tibia, and the anterior ligament of the ankle-joint. In the upper third of its course, it lies between the Tibialis anterior and Extensor digitorum longus; in the middle third between the Tibialis anterior and Extensor hallucis longus. At the ankle it is crossed from the lateral to the medial side by the tendon of the Extensor hallucis longus, and lies between it and the first tendon of the Extensor digitorum longus. It is covered in the upper two-thirds of its course, by the muscles which lie on either side of it, and by the deep fascia; in the lower third, by the integument and fascia, and the transverse and cruciate crural ligaments.

The anterior tibial artery is accompanied by a pair of venae comitantes which lie one on either side of the artery; the deep peroneal nerve, coursing around the lateral side of the neck of the fibula, comes into relation with the lateral side of the artery shortly after it has reached the front of the leg; about the middle of the leg the nerve is in front of the artery; at the lower part it is generally again on the lateral side.

Peculiarities in Size.—This vessel may be diminished in size, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial, or by the perforating branch of the peroneal artery.

Course.—The artery occasionally deviates toward the fibular side of the leg, regaining its usual position at the front of the ankle. In rare instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

Applied Anatomy.—The anterior tibial artery is liable to be injured in fractures of the lower third of the tibia, on account of its close proximity to the bone. The application of a ligature to the vessel is rarely required, except in cases of wound or for traumatic aneurism. The operation in the upper third of the leg is attended with great difficulty on account of the depth of the vessel from the surface. An incision about 10 cm. in length is made in the line of the artery to about a hand's breadth below the level of the knee-joint. The skin and superficial structures having been divided and the deep fascia exposed, the wound must be carefully dried, its edges retracted, and the white line separating the Tibialis anterior from the Extensor digitorum longus sought for. When this has been clearly defined, the deep fascia is to be divided in this line, and the Tibialis anterior separated from adjacent muscles until the interosseous membrane is reached. The foot is to be flexed in order to relax the muscles, and upon drawing them apart the artery will be found lying on the interosseous membrane with the nerve lateral or superficial to it. The nerve should be drawn lateralward, the venae comitantes separated from the artery and the needle passed around it.

To tie the vessel in the lower third of the leg above the ankle-joint, an incision about 7 cm. in length should be made through the integument between the tendons of the Tibialis anterior and Extensor hallucis longus, the deep fascia being divided to the same extent. The tendon on either side should be retracted, when the vessel, accompanied by the venae comitantes, will be seen lying upon the tibia, with the nerve on the lateral side.

Branches.—The branches of the anterior tibial artery are:

Posterior Tibial Recurrent.	Muscular.
Fibular.	Anterior Medial Malleolar.
Anterior Tibial Recurrent.	Anterior Lateral Malleolar.

The **posterior tibial recurrent artery** (*a. recurrens tibialis posterior*) an inconstant branch, is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends in front of the Popliteus, which it supplies, and anastomoses with the inferior genicular branches of the popliteal artery, giving an offset to the tibiofibular joint.

The **fibular artery** is sometimes derived from the anterior tibial, sometimes from the posterior tibial. It passes lateralward, around the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus.

The **anterior tibial recurrent artery** (*a. recurrens tibialis anterior*) arises from the anterior tibial, as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anterior, ramifies on the front and sides of the knee-joint, and assists in the formation of the patellar plexus by anastomosing with the genicular branches of the popliteal, and with the highest genicular artery.

The **muscular branches** (*rami musculares*) are numerous; they are distributed to the muscles which lie on either side of the vessel, some piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

The **anterior medial malleolar artery** (*a. malleolaris anterior medialis; internal malleolar artery*) arises about 5 cm. above the ankle-joint, and passes behind the tendons of the Extensor hallucis longus and Tibialis anterior, to the medial side of the ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and medial plantar arteries and with the medial calcaneal from the posterior tibial.

The **anterior lateral malleolar artery** (*a. malleolaris anterior lateralis; external malleolar artery*) passes beneath the tendons of the Extensor digitorum longus and Peroneus tertius and supplies the lateral side of the ankle, anastomosing with the perforating branch of the peroneal artery, and with ascending twigs from the lateral tarsal artery.

The arteries around the ankle-joint anastomose freely with one another and form net-works below the corresponding malleoli. The **medial malleolar net-work** is formed by the anterior medial malleolar branch of the anterior tibial, the medial tarsal branches of the dorsalis pedis, the posterior medial malleolar and medial calcaneal branches of the posterior tibial and branches

from the medial plantar artery. The **lateral malleolar net-work** is formed by the anterior lateral malleolar branch of the anterior tibial, the lateral tarsal branch of the dorsalis pedis, the perforating and the lateral calcaneal branches of the peroneal, and twigs from the lateral plantar artery.

The Arteria Dorsalis Pedis (Dorsalis Pedis Artery) (Fig. 628).

The **arteria dorsalis pedis**, the continuation of the anterior tibial, passes forward from the ankle-joint along the tibial side of the dorsum of the foot to the proximal part of the first intermetatarsal space, where it divides into two branches, the **first dorsal metatarsal** and the **deep plantar**.

Relations.—This vessel, in its course forward, rests upon the front of the articular capsule of the ankle-joint, the talus, navicular, and second cuneiform bones, and the ligaments connecting them, being covered by the integument, fascia and cruciate ligament, and crossed near its termination by the first tendon of the Extensor digitorum brevis. On its *tibial side* is the tendon of the Extensor hallucis longus; on its *fibular side*, the first tendon of the Extensor digitorum longus, and the termination of the deep peroneal nerve. It is accompanied by two veins.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or its terminal branches to the toes may be absent, the toes then being supplied by the medial plantar; or its place may be taken altogether by a large perforating branch of the peroneal artery.

Position.—This artery frequently curves lateralward, lying lateral to the line between the middle of the ankle and the back part of the first interosseous space.

Applied Anatomy.—This artery may be tied, by making an incision 5 cm. in length, through the integument, on the fibular side of the tendon of the Extensor hallucis longus, in the interval between it and the medial border of the Extensor digitorum brevis. The incision should not extend farther forward than the proximal part of the first intermetatarsal space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the deep peroneal nerve lying lateral to it.

Branches.—The branches of the arteria dorsalis pedis are:

Lateral Tarsal.

Arcuate.

Medial Tarsal.

First Dorsal Metatarsal.

Deep Plantar.

The **lateral tarsal artery** (*a. tarsea lateralis; tarsal artery*) arises from the dorsalis pedis, as that vessel crosses the navicular bone; it passes in an arched direction lateralward, lying upon the tarsal bones, and covered by the Extensor digitorum brevis; it supplies this muscle and the articulations of the tarsus, and anastomoses with branches of the arcuate, anterior lateral malleolar and lateral plantar arteries, and with the perforating branch of the peroneal artery.

The **medial tarsal arteries** (*aa. tarseae mediales*) are two or three small branches which ramify on the medial border of the foot and join the medial malleolar net-work.

The **arcuate artery** (*a. arcuata; metatarsal artery*) arises a little anterior to the lateral tarsal artery; it passes lateralward, over the bases of the metatarsal bones, beneath the tendons of the Extensor digitorum brevis, its direction being influenced by its point of origin; and it anastomoses with the lateral tarsal and lateral plantar arteries. This vessel gives off the **second, third, and fourth dorsal metatarsal arteries**, which run forward upon the corresponding Interossei dorsales; in the clefts between the toes, each divides into two dorsal digital branches for the adjoining toes. At the proximal parts of the interosseous spaces these vessels receive the posterior perforating branches from the plantar arch, and at the distal parts of the spaces they are joined by the anterior perforating branches, from the plantar metatarsal arteries. The fourth dorsal metatarsal artery gives off a branch which supplies the lateral side of the fifth toe.

The **first dorsal metatarsal artery** (*a. dorsalis hallucis*) runs forward on the first Interosseous dorsalis, and at the cleft between the first and second toes divides

into two branches, one of which passes beneath the tendon of the Extensor hallucis longus, and is distributed to the medial border of the great toe; the other bifurcates to supply the adjoining sides of the great and second toes.

The **deep plantar artery** (*ramus plantaris profundus; communicating artery*) descends into the sole of the foot, between the two heads of the first Interosseous dorsalis, and unites with the termination of the lateral plantar artery, to complete the plantar arch. It sends a branch along the medial side of the great toe, and is continued forward along the first interosseous space as the **first plantar metatarsal artery**, which bifurcates for the supply of the adjacent sides of the great and second toes.

The Posterior Tibial Artery (A. Tibialis Posterior) (Fig. 626).

The **posterior tibial artery** begins at the lower border of the Popliteus, opposite the interval between the tibia and fibula; it extends obliquely downward, and, as it descends, it approaches the tibial side of the leg, lying behind the tibia, and in the lower part of its course is situated midway between the medial malleolus and the medial process of the calcaneal tuberosity. Here it divides beneath the origin of the Adductor hallucis into the **medial** and **lateral plantar arteries**.

Relations.—The posterior tibial artery lies successively upon the Tibialis posterior, the Flexor digitorum longus, the tibia, and the back of the ankle-joint. It is covered by the deep transverse fascia of the leg, which separates it above from the Gastrocnemius and Soleus; at its termination it is covered by the Abductor hallucis. In the lower third of the leg, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the medial border of the tendo calcaneus. It is accompanied by two veins, and by the tibial nerve, which lies at first to the medial side of the artery, but soon crosses it posteriorly, and is in the greater part of its course on its lateral side.

Behind the medial malleolus, the tendons, bloodvessels, and nerve are arranged, under cover of the lacinate ligament, in the following order from the medial to the lateral side: (1) the tendons of the Tibialis posterior and Flexor digitorum longus, lying in the same groove, behind the malleolus, the former being the more medial. Next is the posterior tibial artery, with a vein on either side of it; and lateral to the vessels is the tibial nerve; about 1.25 cm. nearer the heel is the tendon of the Flexor hallucis longus.

Peculiarities in Size.—The posterior tibial is not infrequently smaller than usual, or absent, its place being supplied by a large peroneal artery, which either joins the small posterior tibial artery, or continues alone to the sole of the foot.

Applied Anatomy.—The application of a ligature to the posterior tibial may be required in cases of wound of the sole of the foot, attended with great hemorrhage, when the vessel should be tied at the ankle. In cases of wound of the posterior tibial, it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg.

To tie the posterior tibial artery at the ankle, a semilunar incision, about 6 cm. in length, convex backward, should be made through the integument, midway between the heel and the medial malleolus, or a little nearer the latter. The subcutaneous tissue having been divided, a strong and dense fascia, the lacinate (internal annular) ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the *venae comitantes* on either side. The aneurism needle should be passed around the vessel from the heel toward the ankle, in order to avoid the tibial nerve, care at the same time being taken not to include the *venae comitantes*.

The vessel may also be tied in the lower third of the leg by making an incision about 8 cm. in length, parallel with the medial border of the tendo calcaneus. The great saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the lateral margin of the Flexor digitorum longus, with one of its *venae comitantes* on either side, and the nerve lying lateral to it.

Ligature of the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its fibular side, the knee being partially bent, and the foot extended, so as to relax the muscles of the calf. An incision about 10 cm. in length should then be made through the integument, a finger's breadth behind the medial margin of the tibia, care being taken to avoid the great saphenous vein. The deep fascia having been divided, the

margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Soleus divided. The artery may now be felt pulsating beneath the deep transverse fascia, about 2.5 cm. from the margin of the tibia. This fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery and the aneurism needle passed around the vessel from the lateral to the medial side, so as to avoid wounding the tibial nerve.

Branches.—The branches of the posterior tibial artery are:

Peroneal.	Posterior Medial Malleolar.
Nutrient.	Communicating.
Muscular.	Medial Calcaneal.

The **peroneal artery** (*a. peronea*) is deeply seated on the back of the fibular border of the leg. It *arises* from the posterior tibial, about 2.5 cm. below the lower side of the Popliteus, passes obliquely toward the fibula, and then descends along the medial side of that bone, contained in a fibrous canal between the Tibialis posterior and the Flexor hallucis longus, or in the substance of the latter muscle. It then runs behind the tibiofibular syndesmosis and divides into lateral calcaneal branches which ramify on the lateral and posterior surfaces of the calcaneus.

It is covered, in the *upper* part of its course, by the Soleus and deep transverse fascia of the leg; *below*, by the Flexor hallucis longus.

Peculiarities in Origin.—The peroneal artery may arise 7 or 8 cm. below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual, a branch from the posterior tibial supplies its place; and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery was entirely wanting.

Branches.—The branches of the peroneal are:

Muscular.	Perforating.
Nutrient.	Communicating.
Lateral Calcaneal.	

Muscular Branches.—The peroneal artery, in its course, gives off branches to the Soleus, Tibialis posterior, Flexor hallucis longus, and Peronei.

The **Nutrient Artery** (*a. nutricia fibulae*) supplies the fibula, and is directed downward.

The **Perforating Branch** (*ramus perforans; anterior peroneal artery*) pierces the interosseous membrane, about 5 cm. above the lateral malleolus, to reach the front of the leg, where it anastomoses with the anterior lateral malleolar; it then passes down in front of the tibiofibular syndesmosis, gives branches to the tarsus, and anastomoses with the lateral tarsal. The perforating branch is sometimes enlarged, and takes the place of the dorsalis pedis artery.

The **Communicating Branch** (*ramus communicans*) is given off from the peroneal about 2.5 cm. from its lower end, and joins the communicating branch of the posterior tibial.

The **Lateral Calcaneal** (*ramus calcaneus lateralis; external calcaneal*) are the terminal branches of the peroneal artery; they pass to the lateral side of the heel, and communicate with the lateral malleolar and, on the back of the heel, with the medial calcaneal arteries.

The **nutrient artery** (*a. nutricia tibiae*) of the tibia *arises* from the posterior tibial, near its origin, and after supplying a few muscular branches enters the nutrient canal of the bone, which it traverses obliquely from above downward. This is the largest nutrient artery of bone in the body.

The **muscular branches** of the posterior tibial are distributed to the Soleus and deep muscles along the back of the leg.

The **posterior medial malleolar artery** (*a. malleolaris posterior medialis; internal malleolar artery*) is a small branch which winds around the tibial malleolus and ends in the medial malleolar net-work.

The **communicating branch** (*ramus communicans*) runs transversely across the back of the tibia, about 5 cm. above its lower end, beneath the Flexor hallucis longus, and joins the communicating branch of the peroneal.

The **medial calcaneal** (*rami calcanei mediales; internal calcaneal*) are several large arteries which arise from the posterior tibial just before its division; they pierce the lacinate ligament and are distributed to the fat and integument behind the tendo calcaneus and about the heel, and to the muscles on the tibial side of the sole, anastomosing with the peroneal and medial malleolar and, on the back of the heel, with the lateral calcaneal arteries.

Deep plantar

*1st plantar }
metatarsal }*

FIG. 629.—The plantar arteries. Superficial view.

FIG. 630.—The plantar arteries. Deep view.

The **medial plantar artery** (*a. plantaris medialis; internal plantar artery*) (Figs. 629 and 630), much smaller than the lateral, passes forward along the medial side of the foot. It is at first situated above the Abductor hallucis, and then between it and the Flexor digitorum brevis, both of which it supplies. At the base of the first metatarsal bone, where it is much diminished in size, it passes along the medial border of the first toe, anastomosing with the first dorsal metatarsal artery. Small superficial digital branches accompany the digital branches of the medial plantar nerve and join the plantar metatarsal arteries of the first three spaces.

The **lateral plantar artery** (*a. plantaris lateralis; external plantar artery*), much larger than the medial, passes obliquely lateralward and forward to the base of the fifth metatarsal bone. It then turns medialward to the interval between the bases of the first and second metatarsal bones, where it unites with the deep plantar branch of the dorsalis pedis artery, thus completing the **plantar arch**. As this artery passes lateralward, it is first placed between the calcaneus and Abductor hallucis,

and then between the *Flexor digitorum brevis* and *Quadratus plantae*; as it runs forward to the base of the little toe it lies more superficially between the *Flexor digitorum brevis* and *Abductor digiti quinti*, covered by the plantar aponeurosis and integument. The remaining portion of the vessel is deeply situated; it extends from the base of the fifth metatarsal bone to the proximal part of the first interosseous space, and forms the plantar arch; it is convex forward, lies below the bases of the second, third, and fourth metatarsal bones and the corresponding *Interossei*, and upon the oblique part of the *Adductor hallucis*.

Applied Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligature it. They must be treated on similar lines to those of wounds of the volar arches (see p. 682). Pressure locally, combined with elevation of the limb, may in some cases be sufficient to arrest the bleeding, but this failing, an attempt should be made to find the bleeding point and ligature it. Should this prove unsuccessful, it may be necessary to ligature the femoral below the origin of the *profunda femoris*, as ligature of the anterior and posterior tibial arteries may not be sufficient to control the hemorrhage, and it is safer and quicker to tie the femoral under the circumstances.

Branches.—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciæ in the sole, gives off the following branches:

Perforating.

Plantar Metatarsal.

The **Perforating Branches** (*rami perforantes*) are three in number; they ascend through the proximal parts of the second, third, and fourth interosseous spaces, between the heads of the *Interossei dorsales*, and anastomose with the dorsal metatarsal arteries.

The **Plantar Metatarsal Arteries** (*aa. metatarsae plantares; digital branches*) are four in number, and run forward between the metatarsal bones and in contact with the *Interossei*. Each divides into a pair of plantar digital arteries which supply the adjacent sides of the toes. Near their points of division each sends upward an **anterior perforating branch** to join the corresponding dorsal metatarsal artery. The **first plantar metatarsal artery** (*arteria princeps hallucis*) springs from the junction between the lateral plantar and deep plantar arteries and sends a digital branch to the medial side of the first toe. The digital branch for the lateral side of the fifth toe arise from the lateral plantar artery near the base of the fifth metatarsal bone.

THE VEINS.

THE Veins convey the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the **pulmonary** and **systemic**.

The **Pulmonary Veins**, unlike other veins, contain arterial blood, which they return from the lungs to the left atrium of the heart.

The **Systemic Veins** return the venous blood from the body generally, to the right atrium of the heart.

The **Portal Vein**, an appendage to the systemic venous system, is confined to the abdominal cavity, and returns the venous blood from the spleen and the viscera of digestion to the liver. This vessel ramifies in the substance of the liver and there breaks up into a minute network of capillary-like vessels, from which the blood is conveyed by the hepatic veins to the inferior vena cava.

The veins commence by minute plexuses which receive the blood from the capillaries. The branches arising from these plexuses unite together into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries, or join other veins. The veins are larger and altogether more numerous than the arteries; hence, the entire capacity of the venous system is much greater than that of the arterial; the capacity of the pulmonary veins, however, only slightly exceeds that of the pulmonary arteries. The veins are cylindrical like the arteries; their walls, however, are thin and they collapse when the vessels are empty, and the uniformity of their surfaces is interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior. They communicate very freely with one another, especially in certain regions of the body; and these communications exist between the larger trunks as well as between the smaller branches. Thus, between the venous sinuses of the cranium, and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, large and frequent anastomoses are found. The same free communication exists between the veins throughout the whole extent of the vertebral canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, *e. g.*, the spermatic, uterine, vesical, and pudendal.

The systemic venous channels are subdivided into three sets, *viz.*, **superficial** and **deep veins**, and **venous sinuses**.

The **Superficial Veins** (*cutaneous veins*) are found between the layers of the superficial fascia immediately beneath the skin; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

The **Deep Veins** accompany the arteries, and are usually enclosed in the same sheaths with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called **venae comitantes**. The larger arteries—such as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and vertebral canal, the hepatic veins in the liver, and the larger veins returning blood from the bones.

Venous Sinuses are found only in the interior of the skull, and consist of canals formed by a separation of the two layers of the dura mater; their outer coat consists of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

THE PULMONARY VEINS (VENAE PULMONALES).

The **pulmonary veins** return the arterialized blood from the lungs to the left atrium of the heart. They are four in number, two from each lung, and are destitute of valves. They commence in a capillary net-work upon the walls of the air sacs, where they are continuous with the capillary ramifications of the pulmonary artery, and, joining together, form one vessel for each lobule. These vessels uniting successively, form a single trunk for each lobe, three for the right, and two for the left lung. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, so that ultimately two trunks from each lung are formed; they perforate the fibrous layer of the pericardium and open separately into the upper and back part of the left atrium. Occasionally the three veins on the right side remain separate. Not infrequently the two left pulmonary veins end by a common opening.

At the root of the lung, the superior pulmonary vein lies in front of and a little below the pulmonary artery; the inferior is situated at the lowest part of the hilus of the lung and on a plane posterior to the upper vein. Behind the pulmonary artery is the bronchus.

Within the pericardium, their anterior surfaces are invested by the serous layer of this membrane.

The right pulmonary veins pass behind the right atrium and superior vena cava; the left in front of the descending thoracic aorta.

THE SYSTEMIC VEINS.

The **systemic veins** may be arranged into three groups: (1) The **veins of the heart**. (2) The veins of the **upper extremities, head, neck, and thorax**, which end in the superior vena cava. (3) The veins of the **lower extremities, abdomen, and pelvis**, which end in the inferior vena cava.

THE VEINS OF THE HEART (VV. Cordis) (Fig. 631).

Coronary Sinus (*sinus coronarius*).—Most of the veins of the heart open into the coronary sinus. This is a wide venous channel about 2.25 cm. in length situated in the posterior part of the coronary sulcus, and covered by muscular fibres from the left atrium. It ends in the right atrium between the opening of the inferior vena cava and the atrioventricular aperture, its orifice being guarded by a semilunar valve, the **valve of the coronary sinus** (*valve of Thebesius*).

Tributaries.—Its tributaries are the great, small, and middle cardiac veins, the posterior vein of the left ventricle, and the oblique vein of the left atrium, all of which, except the last, are provided with valves at their orifices.

1. The **Great Cardiac Vein** (*v. cordis magna; left coronary vein*) begins at the apex of the heart and ascends along the anterior longitudinal sulcus to the base of the ventricles. It then curves to the left in the coronary sulcus, and reaching the back of the heart, opens into the left extremity of the coronary sinus. It receives tributaries from the left atrium and from both ventricles: one, the **left marginal vein**, is of considerable size, and ascends along the left margin of the heart.

2. The **Small Cardiac Vein** (*v. cordis parva; right coronary vein*) runs in the coronary sulcus between the right atrium and ventricle, and opens into the right extremity of the coronary sinus. It receives blood from the back of the right atrium and ventricle; the **right marginal vein** ascends along the right margin of the heart and joins it in the coronary sulcus, or opens directly into the right atrium.

3. The **Middle Cardiac Vein** (*v. cordis media*) commences at the apex of the heart, ascends in the posterior longitudinal sulcus, and ends in the coronary sinus near its right extremity.

4. The **Posterior Vein of the Left Ventricle** (*v. posterior ventriculi sinistri*) runs on the diaphragmatic surface of the left ventricle to the coronary sinus, but may end in the great cardiac vein.

5. The **Oblique Vein of the Left Atrium** (*v. obliqua atrii sinistri* [*Marshalli*]; *oblique vein of Marshall*) is a small vessel which descends obliquely on the back of the left atrium and ends in the coronary sinus near its left extremity; it is continuous above with the **ligament of the left vena cava** (*lig. venae cavae sinistrae*; *vestigial fold of Marshall*), and the two structures form the remnant of the left Cuvierian duct.

Middle cardiac vein

FIG. 631.—Base and diaphragmatic surface of heart.

The following cardiac veins do not end in the coronary sinus: (1) the **anterior cardiac veins**, comprising three or four small vessels which collect blood from the front of the right ventricle and open into the right atrium; the right marginal vein frequently opens into the right atrium, and is therefore sometimes regarded as belonging to this group; (2) the **smallest cardiac veins** (*veins of Thebesius*), consisting of a number of minute veins which arise in the muscular wall of the heart; the majority open into the atria, but a few end in the ventricles.

THE VEINS OF THE HEAD AND NECK.

The veins of the head and neck may be subdivided into three groups: (1) The **veins of the exterior of the head and face**. (2) The **veins of the neck**. (3) The **diploic veins**, the veins of the brain, and the **venous sinuses of the dura mater**.

The Veins of the Exterior of the Head and Face (Fig. 632).

The veins of the exterior of the head and face are:

Frontal.	Superficial Temporal
Supraorbital.	Internal Maxillary.
Angular.	Posterior Facial.
Anterior Facial.	Posterior Auricular.
Occipital.	

floating branch
ophthalmic vein
ular

FIG. 632 — Veins of the head and neck.

The **frontal vein** (*v. frontalis*) begins on the forehead in a venous plexus which communicates with the frontal branches of the superficial temporal vein. The veins converge to form a single trunk, which runs downward near the middle line of the forehead parallel with the vein of the opposite side. The two veins are joined, at the root of the nose, by a transverse branch, called the **nasal arch**, which receives some small veins from the dorsum of the nose. At the root of the nose the veins diverge, and, each at the medial angle of the orbit, joins the **supraorbital vein**, to

form the **angular vein**. Occasionally the frontal veins join to form a single trunk, which bifurcates at the root of the nose into the two angular veins.

The **supraorbital vein** (*v. supraorbitalis*) begins on the forehead where it communicates with the frontal branch of the superficial temporal vein. It runs downward superficial to the Frontalis muscle, and joins the frontal vein at the medial angle of the orbit to form the **angular vein**. Previous to its junction with the frontal vein, it sends through the supraorbital notch into the orbit a branch which communicates with the ophthalmic vein; as this vessel passes through the notch, it receives the frontal diploic vein through a foramen at the bottom of the notch.

The **angular vein** (*v. angularis*) formed by the junction of the frontal and supraorbital veins, runs obliquely downward, on the side of the root of the nose, to the level of the lower margin of the orbit, where it becomes the anterior facial vein. It receives the veins of the ala nasi, and communicates with the superior ophthalmic vein through the nasofrontal vein, thus establishing an important anastomosis between the anterior facial vein and the cavernous sinus.

The **anterior facial vein** (*v. facialis anterior; facial vein*) commences at the side of the root of the nose, and is a direct continuation of the angular vein. It lies behind the external maxillary (facial) artery and follows a less tortuous course. It runs obliquely downward and backward, beneath the zygomaticus and zygomatic head of the Quadratus labii superioris, descends along the anterior border and then on the superficial surface of the Masseter, crosses over the body of the mandible, and passes obliquely backward, beneath the Platysma and cervical fascia, superficial to the submaxillary gland, the Digastricus and Stylohyoideus. It unites with the posterior facial vein to form the **common facial vein**, which crosses the external carotid artery and enters the internal jugular vein at a variable point below the hyoid bone. From near its termination a communicating branch often runs down the anterior border of the Sternocleidomastoideus to join the lower part of the anterior jugular vein.

Tributaries.—The anterior facial vein receives a branch of considerable size, the **deep facial vein**, from the pterygoid venous plexus. It is also joined by the superior and inferior palpebral, the superior and inferior labial, the buccinator and the masseteric veins. Below the mandible it receives the submental, palatine, and submaxillary veins, and, generally, the vena comitans of the hypoglossal nerve.

Applied Anatomy.—There are some points about the anterior facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by the angular and supraorbital veins which communicate with the ophthalmic vein, a tributary of the cavernous sinus, but also by the deep facial vein, which communicates through the pterygoid plexus with the cavernous sinus by branches which pass through the foramen ovale and foramen lacerum (see p. 746). These facts have an important bearing upon the surgery of some diseases; any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the anterior facial vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. On account of its communications with the cerebral sinuses, these thrombi are apt to extend upward into them, and so induce a fatal issue; this has been known to follow in cases of ordinary carbuncle of the face. The position of the vein should always be borne in mind when incisions are made for the relief of suppuration about the mandible.

The **superficial temporal vein** (*v. temporalis superficialis*) begins on the side and vertex of the skull in a plexus which communicates with the frontal and supraorbital veins, with the corresponding vein of the opposite side, and with the posterior auricular and occipital veins. From this net-work frontal and parietal branches arise, and unite above the zygomatic arch to form the trunk of the vein, which is joined in this situation by the **middle temporal vein**, from the substance of the Temporalis. It then crosses the posterior root of the zygomatic arch, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the **posterior facial vein**.

Tributaries.—The superficial temporal vein receives in its course some parotid veins, articular veins from the temporomandibular joint, anterior auricular veins from the auricula, and the **transverse facial** from the side of the face. The middle temporal vein receives the **orbital vein**, which is formed by some lateral palpebral branches, and passes backward between the layers of the temporal fascia to join the superficial temporal vein.

The **pterygoid plexus** (*plexus pterygoideus*) is of considerable size, and is situated between the Temporalis and Pterygoideus externus, and partly between the two Pterygoidei. It receives tributaries corresponding with the branches of the internal maxillary artery. Thus it receives the sphenopalatine, the middle meningeal, the deep temporal, the pterygoid, masseteric, buccinator, alveolar, and some palatine veins, and a branch which communicates with the ophthalmic vein through the inferior orbital fissure. This plexus communicates freely with the anterior facial vein; it also communicates with the cavernous sinus, by branches through the foramen Vesalii, foramen ovale, and foramen lacerum.

The **internal maxillary vein** (*v. maxillaris interna*) is a short trunk which accompanies the first part of the internal maxillary artery. It is *formed* by a confluence of the veins of the pterygoid plexus, and passes backward between the sphenomandibular ligament and the neck of the mandible, and unites with the temporal vein to form the posterior facial vein.

The **posterior facial vein** (*v. facialis posterior; temporomaxillary vein*), *formed* by the union of the superficial temporal and internal maxillary veins, descends in the substance of the parotid gland, superficial to the external carotid artery but beneath the facial nerve, between the ramus of the mandible and the Sternocleidomastoideus muscle. It divides into two branches, an **anterior**, which passes forward and unites with the anterior facial vein to form the common facial vein and a **posterior**, which is joined by the posterior auricular vein and becomes the external jugular vein.

The **posterior auricular vein** (*v. auricularis posterior*) *begins* upon the side of the head, in a plexus which communicates with the tributaries of the occipital, and superficial temporal veins. It descends behind the auricula, and joins the posterior division of the posterior facial vein to form the external jugular. It receives the stylomastoid vein, and some tributaries from the cranial surface of the auricula.

The **occipital vein** (*v. occipitalis*) *begins* in a plexus at the back part of the vertex of the skull. From the plexus emerges a single vessel, which pierces the cranial attachment of the Trapezius and, dipping into the suboccipital triangle, joins the deep cervical and vertebral veins. Occasionally it follows the course of the occipital artery and ends in the internal jugular; in other instances, it joins the posterior auricular and through it opens into the external jugular. The parietal emissary vein connects it with the superior sagittal sinus; and as it passes across the mastoid portion of the temporal bone, it receives the mastoid emissary vein which connects it with the transverse sinus. The occipital diploic vein sometimes joins it.

The Veins of the Neck (Fig. 633).

The veins of the neck, which return the blood from the head and face, are:

External Jugular.

Anterior Jugular.

Posterior External Jugular.

Internal Jugular.

Vertebral.

The **external jugular vein** (*v. jugularis externa*) receives the greater part of the blood from the exterior of the cranium and the deep parts of the face, being formed by the junction of the posterior division of the posterior facial with the posterior

auricular vein. It commences in the substance of the parotid gland, on a level with the angle of the mandible, and runs perpendicularly down the neck, in the direction of a line drawn from the angle of the mandible to the middle of the clavicle at the posterior border of the Sternocleidomastoideus. In its course it crosses the Sternocleidomastoideus obliquely, and in the subclavian triangle perforates the deep fascia, and ends in the subclavian vein, lateral to or in front of the Scalenus anterior. It is separated from the Sternocleidomastoideus by the investing layer of the deep cervical fascia, and is covered by the Platysma, the superficial fascia, and the integument; it crosses the cutaneous cervical nerve, and its upper half runs parallel with the great auricular nerve. The external jugular vein varies in

Subclavian vein

FIG. 633.—The veins of the neck, viewed from in front. (After Spalteholz.)

size, bearing an inverse proportion to the other veins of the neck, it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper in most cases about 4 cm. above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the *sinus*. These valves do not prevent the regurgitation of the blood, or the passage of injection from below upward.

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and, near its termination, the transverse cervical, transverse scapular, and anterior jugular veins; in the substance of the parotid, a large branch of communication from the internal jugular joins it.

Applied Anatomy.—Venesection used formerly to be performed on the external jugular vein, but is now probably never resorted to. The anatomical point to be remembered in performing this operation is to cut across the fibres of the Platysma in opening the vein, so that by their contraction they will expose the orifice in the vein and so allow the flow of blood.

The **posterior external jugular vein** (*v. jugularis posterior*) begins in the occipital region and returns the blood from the skin and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius. It runs down the back part of the neck; and opens into the external jugular vein just below the middle of its course.

The **anterior jugular vein** (*v. jugularis anterior*) begins near the hyoid bone by the confluence of several superficial veins from the submaxillary region. It descends between the median line and the anterior border of the Sternocleidomastoideus, and, at the lower part of the neck, passes beneath that muscle to open into the termination of the external jugular, or, in some instances, into the subclavian vein (Figs. 632, 633). It varies considerably in size, bearing usually an inverse proportion to the external jugular; most frequently there are two anterior jugulars, a right and left; but sometimes only one. Its tributaries are some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum the two anterior jugular veins communicate by a transverse trunk, the **venous jugular arch**, which receive tributaries from the inferior thyroid veins; each also communicates with the internal jugular. There are no valves in this vein.

The **internal jugular vein** (*v. jugularis interna*) collects the blood from the brain, from the superficial parts of the face, and from the neck. It is directly continuous with the transverse sinus, and begins in the posterior compartment of the jugular foramen, at the base of the skull. At its origin it is somewhat dilated, and this dilatation is called the **superior bulb**. It runs down the side of the neck in a vertical direction, lying at first lateral to the internal carotid artery, and then lateral to the common carotid, and at the root of the neck unites with the subclavian vein to form the innominate vein; a little above its termination is a second dilatation, the **inferior bulb**. Above, it lies upon the Rectus capitis lateralis, behind the internal carotid artery and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glossopharyngeal and hypoglossal nerves passing forward between them; the vagus descends between and behind the vein and the artery in the same sheath, and the accessory runs obliquely backward, superficial or deep to the vein. At the root of the neck the right internal jugular vein is placed at a little distance from the common carotid artery, and crosses the first part of the subclavian artery, while the left internal jugular vein usually overlaps the common carotid artery. The left vein is generally smaller than the right, and each contains a pair of valves, which are placed about 2.5 cm. above the termination of the vessel.

Tributaries.—This vein receives in its course the inferior petrosal sinus, the common facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital. The thoracic duct on the left side and the right lymphatic duct on the right side open into the angle of union of the internal jugular and subclavian veins.

The **Inferior Petrosal Sinus** (*sinus petrosus inferior*) leaves the skull through the anterior part of the jugular foramen, and joins the superior bulb of the internal jugular vein.

The **Lingual Veins** (*vv. linguales*) begin on the dorsum, sides, and under surface of the tongue, and, passing backward along the course of the lingual artery, end in the internal jugular vein. The vena comitans of the hypoglossal nerve (**ranine vein**), a branch of considerable size, begins below the tip of the tongue, and may join the lingual; generally, however, it passes backward on the Hyoglossus, and joins the common facial.

The **Pharyngeal Veins** (*vv. pharyngeae*) begin in the **pharyngeal plexus** on the outer surface of the pharynx, and, after receiving some posterior meningeal veins and the vein of the pterygoid canal, end in the internal jugular. They occasionally open into the facial, lingual, or superior thyroid vein.

The **Superior Thyroid Vein** (*v. thyroidea superioris*) (Fig. 634) begins in the substance and on the surface of the thyroid gland, by tributaries corresponding with the branches of the superior thyroid artery, and ends in the upper part of the internal jugular vein. It receives the superior laryngeal and cricothyroid veins.

The **Middle Thyroid Vein** (Fig. 634) collects the blood from the lower part of the thyroid gland, and after being joined by some veins from the larynx and trachea, ends in the lower part of the internal jugular vein.

The common facial and occipital veins have been described.

FIG. 634.—The veins of the thyroid gland.

Applied Anatomy.—The internal jugular vein requires ligature in cases of septic thrombosis of the transverse sinus, in order to prevent septic emboli being carried into the general circulation. This operation has been performed in many cases, with the most satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and setting up septic thrombosis of the transverse sinus and extending downward into the internal jugular vein. Such cases are always extremely grave, for there is danger of portions of the septic clot being detached and causing septic embolism in the lungs, the portions of clot having passed through the right side of the heart. If the condition be suspected, the diseased bone should be removed at once from the mastoid process. The sinus is then investigated, and if it be found thrombosed, the surgeon should proceed to ligature the internal jugular vein, by an incision along the anterior border of the Sternocleidomastoideus, the centre of which is on a level with the greater cornu of the hyoid bone. The vein should be ligatured in two places and divided between. After the vessel has been secured and divided, the transverse sinus is to be thoroughly cleared out, and, by removing the ligature from the upper end of the divided vein, all septic clots removed by syringing from the sinus through the vein. If hemorrhage occur from the distal end of the sinus, it can be arrested by careful plugging with antiseptic gauze.

The internal jugular vein is also surgically important, because it is surrounded by a large number of deep cervical lymph glands; and when these are enlarged in tuberculous or malignant disease, they are apt to become adherent to the vessel, rendering their removal difficult and often dangerous. The proper course to pursue in these cases is to ligature the vessel above and below the glandular mass, and resect the included portion together with the glands.

Cardiac pulsation is often demonstrable in the internal jugular vein at the root of the neck. There are no valves in the innominate veins or superior vena cava; in consequence, the systole of the right atrium causes a wave to pass up these vessels, and when the conditions are favorable this wave appears as a somewhat feeble flicker over the internal jugular vein at the root of the neck, quite distinct from, and just preceding, the more forcible impulse transmitted from the underlying common carotid artery and due to the ventricular systole. This atrial systolic venous impulse is much increased in conditions in which the right atrium is abnormally distended with blood or is hypertrophied, as is often the case in disease of the bicuspid valve. In Stokes-Adams disease (p. 614) it is this pulsation which gives evidence of the fact that the atria are beating faster—often two or three times faster—than the ventricles.

The **vertebral vein** (*a. vertebralis*) is formed in the suboccipital triangle, from numerous small tributaries which spring from the internal vertebral venous plexuses and issue from the vertebral canal above the posterior arch of the atlas. They unite with small veins from the deep muscles at the upper part of the back of the neck, and form a vessel which enters the foramen in the transverse process of the atlas, and descends, forming a dense plexus around the vertebral artery, in the canal formed by the foramina transversaria of the cervical vertebræ. This plexus ends in a single trunk, which emerges from the foramen transversarium of the sixth cervical vertebra, and opens at the root of the neck into the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side, it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein communicates with the transverse sinus by a vein which passes through the condyloid canal, when that canal exists. It receives branches from the occipital vein and from the prevertebral muscles, from the internal and external vertebral venous plexuses, from the anterior vertebral and the deep cervical veins; close to its termination it is sometimes joined by the first intercostal vein.

The **Anterior Vertebral Vein** *commences* in a plexus around the transverse processes of the upper cervical vertebræ, descends in company with the ascending cervical artery between the Scalenus anterior and Longus capitis muscles, and opens into the terminal part of the vertebral vein.

The **Deep Cervical Vein** (*v. cervicalis profunda*; *posterior vertebral or posterior deep cervical vein*) accompanies its artery between the Semispinales capitis and colli. It begins in the suboccipital region by communicating branches from the occipital vein and by small veins from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebræ, and terminates in the lower part of the vertebral vein.

The Diploic Veins (*Venae Diploicae*) (Fig. 635).

The **diploic veins** occupy channels in the diploë of the cranial bones. They are large and exhibit at irregular intervals pouch-like dilatations; their walls are thin, and formed of endothelium resting upon a layer of elastic tissue.

So long as the cranial bones are separable from one another, these veins are confined to the particular bones; but when the sutures are obliterated, they unite with each other, and increase in size. They communicate with the meningeal veins and the sinuses of the dura mater, and with the veins of the pericranium. They consist of (1) the **frontal**, which opens into the supraorbital vein and the superior sagittal sinus; (2) the **anterior temporal**, which is confined chiefly to the frontal bone, and opens into the sphenoparietal sinus and into one of the deep temporal veins, through an aperture in the great wing of the sphenoid; (3) the

posterior temporal, which is situated in the parietal bone, and ends in the transverse sinus, through an aperture at the mastoid angle of the parietal bone or through the mastoid foramen; and (4) the occipital, the largest of the four, which is confined to the occipital bone, and opens either externally into the occipital vein, or internally into the transverse sinus or into the confluence of the sinuses (*torcular Herophili*).

FIG. 635.—Veins of the diploë as displayed by the removal of the outer table of the skull.

The Veins of the Brain.

The veins of the brain possess no valves, and their walls, owing to the absence of muscular tissue, are extremely thin. They pierce the arachnoid membrane and the inner or meningeal layer of the dura mater, and open into the cranial venous sinuses. They may be divided into two sets, cerebral and cerebellar.

The cerebral veins (*vv. cerebri*) are divisible into external and internal groups according as they drain the outer surfaces or the inner parts of the hemispheres.

The external veins are the superior, inferior, and middle cerebral.

The Superior Cerebral Veins (*vv. cerebri superiores*), eight to twelve in number, drain the superior, lateral, and medial surfaces of the hemispheres, and are mainly lodged in the sulci between the gyri, but some run across the gyri. They open into the superior sagittal sinus; the anterior veins runs nearly at right angles to the sinus; the posterior and larger veins are directed obliquely forward and open into the sinus in a direction more or less opposed to the current of the blood contained within it.

The Middle Cerebral Vein (*v. cerebri media*; *superficial Sylvian vein*) begins on the lateral surface of the hemisphere, and, running along the lateral cerebral fissure, ends in the cavernous or the sphenoparietal sinus. It is connected (a) with the superior sagittal sinus by the great anastomotic vein of Trolard, which opens into one of the superior cerebral veins; (b) with the transverse sinus by the posterior anastomotic vein of Labbé, which courses over the temporal lobe.

The Inferior Cerebral Veins (*vv. cerebri inferiores*), of small size, drain the under surfaces of the hemispheres. Those on the orbital surface of the frontal lobe join the superior cerebral veins, and through these open into the superior sagittal sinus; those of the temporal lobe anastomose with the middle cerebral and basal veins, and join the cavernous, sphenoparietal, and superior petrosal sinuses.

The **basal vein** is formed at the anterior perforated substance by the union of (a) a small **anterior cerebral vein** which accompanies the anterior cerebral artery, (b) the **deep middle cerebral vein** (*deep Sylvian vein*), which receives tributaries from the insula and neighboring gyri, and runs in the lower part of the lateral cerebral fissure, and (c) the **inferior striate veins**, which leave the corpus striatum through the anterior perforated substance. The basal vein passes backward around the cerebral peduncle, and ends in the internal cerebral vein (*vein of Galen*); it receives tributaries from the interpeduncular fossa, the inferior horn of the lateral ventricle, the hippocampal gyrus, and the mid-brain.

The **Internal Cerebral Veins** (*vv. cerebri internae; veins of Galen; deep cerebral veins*) drain the deep parts of the hemisphere and are two in number; each is formed near the interventricular foramen by the union of the **terminal** and **choroid veins**. They run backward parallel with one another, between the layers of the tela chorioidea of the third ventricle, and beneath the splenium of the corpus callosum, where they unite to form a short trunk, the **great cerebral vein**; just before their union each receives the corresponding basal vein.

The **terminal vein** (*v. terminalis; vena corporis striati*) commences in the groove between the corpus striatum and thalamus, receives numerous veins from both of these parts, and unites behind the crus fornicis with the choroid vein, to form one of the internal cerebral veins. The **choroid vein** runs along the whole length of the choroid plexus, and receives veins from the hippocampus, the fornix, and the corpus callosum.

The **Great Cerebral Vein** (*v. cerebri magna [Galen]; great vein of Galen*), formed by the union of the two internal cerebral veins, is a short median trunk which curves backward and upward around the splenium of the corpus callosum and ends in the anterior extremity of the straight sinus.

The **cerebellar veins** are placed on the surface of the cerebellum, and are disposed in two sets, superior and inferior. The **superior cerebellar veins** (*vv. cerebelli superiores*) pass partly forward and medialward, across the superior vermis, to end in the straight sinus and the internal cerebral veins, partly lateralward to the transverse and superior petrosal sinuses. The **inferior cerebellar veins** (*vv. cerebelli inferiores*) of large size, end in the transverse, superior petrosal, and occipital sinuses.

The Sinuses of the Dura Mater (Sinus Durae Matris). Ophthalmic Veins and Emissary Veins.

The **sinuses of the dura mater** are venous channels which drain the blood from the brain; they are devoid of valves, and are situated between the two layers of the dura mater and lined by endothelium continuous with that which lines the veins. They may be divided into two groups: (1) a **postero-superior**, at the upper and back part of the skull, and (2) an **antero-inferior**, at the base of the skull.

The postero-superior group comprises the

Superior Sagittal.
Inferior Sagittal.

Straight.
Two Transverse.

Occipital.

The **superior sagittal sinus** (*sinus sagittalis superior; superior longitudinal sinus*) (Figs. 636, 637) occupies the attached or convex margin of the falx cerebri. Commencing at the foramen cecum, through which it receives a vein from the nasal cavity, it runs from before backward, grooving the inner surface of the frontal, the adjacent margins of the two parietals, and the superior division of the cruciate eminence of the occipital; near the internal occipital protuberance it deviates to one or other side (usually the right), and is continued as the corresponding transverse sinus. It is triangular in section, narrow in front, and gradually increases in

size as it passes backward. Its inner surface presents the openings of the superior cerebral veins, which run, for the most part, obliquely forward, and open chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands (*chordae Willisii*) extend transversely across the inferior angle of the sinus; and, lastly, small openings communicate with irregularly shaped venous spaces (*venous lacunæ*) in the dura mater near the sinus. There are usually three lacunæ on either side of the sinus: a small frontal, a large parietal, and an occipital, intermediate in size between the other two (Sargent¹). Most of the cerebral veins from the outer surface of the hemisphere open into these lacunæ, and numerous *arachnoid granulations* (*Pacchionian bodies*) project into them from below. The superior sagittal sinus receives the superior cerebral veins, veins from the diploë and dura mater, and, near the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramina.

Dural

r sagittal
sinus

Venous
lacuna

FIG. 636.—Superior sagittal sinus laid open after removal of the skull cap. The *chordae Willisii* are clearly seen. The venous lacunæ are also well shown; from two of them probes are passed into the superior sagittal sinus. (Poirier and Charpy.)

Applied Anatomy.—The numerous communications which take place between this sinus and the veins of the nose, scalp, and diploë, cause it to be at times the seat of infective thrombosis from suppurative processes in these parts.

The **inferior sagittal sinus** (*sinus sagittalis inferior; inferior longitudinal sinus*) (Fig. 637) is contained in the posterior half or two-thirds of the free margin of the falx cerebri. It is of a cylindrical form, increases in size as it passes backward, and ends in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the medial surfaces of the hemispheres.

The **straight sinus** (*sinus rectus; tentorial sinus*) (Figs. 637, 638) is situated at the line of junction of the falx cerebri with the tentorium cerebelli. It is triangular

¹ Journal of Anatomy and Physiology, vol. xlv.

in section, increases in size as it proceeds backward, and runs downward and backward from the end of the inferior sagittal sinus to the transverse sinus of the opposite side to that into which the superior sagittal sinus is prolonged. Its terminal part communicates by a cross branch with the confluence of the sinuses. Besides the inferior sagittal sinus, it receives the great cerebral vein (*great vein of Galen*) and the superior cerebellar veins. A few transverse bands cross its interior.

Abducent nerve Trigeminal nerve

FIG. 637.—Dura mater and its processes exposed by removing part of the right half of the skull, and the brain.

The **transverse sinuses** (*sinus transversus; lateral sinuses*) (Figs. 638, 639) are of large size and begin at the internal occipital protuberance; one, generally the right, being the direct continuation of the superior sagittal sinus, the other of the straight sinus. Each transverse sinus passes lateralward and forward, describing a slight curve with its convexity upward, to the base of the petrous portion of the temporal bone, and lies, in this part of its course, in the attached margin of the tentorium cerebelli; it then leaves the tentorium and curves downward and medialward to reach the jugular foramen, where it ends in the internal jugular vein. In its course it rests upon the squama of the occipital, the mastoid angle of the parietal, the mastoid part of the temporal, and, just before its termination, the jugular process of the occipital; the portion which occupies the groove on the mastoid part of the temporal is sometimes termed the **sigmoid sinus**. The transverse sinuses are frequently of unequal size, that formed by the superior sagittal sinus being the larger; they increase in size as they proceed from behind forward. On transverse section the horizontal portion exhibits a prismatic, the curved

portion a semicylindrical form. They receive the blood from the superior petrosal sinuses at the base of the petrous portion of the temporal bone; they communicate with the veins of the pericranium by means of the mastoid and condyloid emissary veins; and they receive some of the inferior cerebral and inferior cerebellar veins, and some veins from the diploë. The **petrosquamous sinus**, when present, runs backward along the junction of the squama and petrous portion of the temporal, and opens into the transverse sinus.

Optic nerves Internal carotid artery

220

Confluence of the sinuses

FIG. 638.—Tentorium cerebelli from above.

The **occipital sinus** (*sinus occipitalis*) (Fig. 639) is the smallest of the cranial sinuses. It is situated in the attached margin of the falx cerebelli, and is generally single, but occasionally there are two. It commences around the margin of the foramen magnum by several small venous channels, one of which joins the terminal part of the transverse sinus; it communicates with the posterior internal vertebral venous plexuses and ends in the confluence of the sinuses.

The **Confluence of the Sinuses** (*confluens sinuum*; *torcular Herophili*) is the term applied to the dilated extremity of the superior sagittal sinus. It is of irregular form, and is lodged on one side (generally the right) of the internal occipital protuberance. From it the transverse sinus of the same side is derived. It receives also the blood from the occipital sinus, and is connected across the middle line with the commencement of the transverse sinus of the opposite side.

The antero-inferior group of sinuses comprises the

Two Cavernous.

Two Superior Petrosal.

Two Intercavernous.

Two Inferior Petrosal.

Basilar Plexus.

The **cavernous sinuses** (*sinus cavernosus*) (Fig. 639) are so named because they present a reticulated structure, due to their being traversed by numerous interlacing filaments. They are of irregular form, larger behind than in front, and are placed one on either side of the body of the sphenoid bone, extending from the superior orbital fissure to the apex of the petrous portion of the temporal bone. Each opens behind into the petrosal sinuses. On the medial wall of each sinus is the internal carotid artery, accompanied by filaments of the carotid plexus; near the artery is the abducent nerve; on the lateral wall are the oculomotor and trochlear nerves, and the ophthalmic and maxillary divisions of the trigeminal nerve

oph-
tic vein
sphenoparietal
sinus

Superior sagittal sinus

FIG. 639.—The sinuses at the base of the skull.

(Fig. 640). These structures are separated from the blood flowing along the sinus by the lining membrane of the sinus. The cavernous sinus receives the superior ophthalmic vein through the superior orbital fissure, some of the cerebral veins, and also the small **sphenoparietal sinus**, which courses along the under surface of the small wing of the sphenoid. It communicates with the transverse sinus by means of the superior petrosal sinus; with the internal jugular vein through the inferior petrosal sinus and a plexus of veins on the internal carotid artery; with the pterygoid venous plexus through the foramen Vesalii, foramen ovale, and foramen lacerum, and with the angular vein through the ophthalmic vein. The two sinuses

also communicate with each other by means of the anterior and posterior intercavernous sinuses.

Applied Anatomy.—An arteriovenous communication may be established between the cavernous sinus and the internal carotid artery, giving rise to a pulsating tumor in the orbit. These communications may be the result of injury, such as a bullet wound, a stab, or a blow, or fall sufficiently severe to cause a fracture of the base of the skull in this situation. The symptoms are sudden noise and pain in the head, followed by exophthalmos, swelling and congestion of the lids and conjunctivæ, and development of a pulsating tumor at the margin of the orbit, with thrill and the characteristic bruit; accompanying these symptoms there may be impairment of sight, paralysis of the iris and orbital muscles, and pain of varying intensity. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the intercavernous sinuses; or the arterial blood may find its way through the emissary veins (see p. 747) into the pterygoid plexus, and thence into the veins of the face. Pulsating tumors of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumor may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery. Ligature of the internal or common carotid artery has been performed in these cases with considerable success.

Of recent years more attention has been paid to thrombosis of the cavernous sinus than formerly, and it is now well established that caries in the upper parts of the nasal cavities and suppuration in certain of the accessory sinuses of the nose are frequently responsible for septic thrombosis of the cavernous sinuses, in exactly the same way as transverse sinus thrombosis is due to septic disease in the mastoid process. Many deaths from meningitis, hitherto unaccounted for, are in reality due to the spread of an infection from an ethmoidal or sphenoidal air cell to the cavernous sinus, and thence to the meninges. It is obvious, therefore, that no case of chronic nasal suppuration should be left untreated.

Inferior
ophthalmic

FIG. 641.—Veins of orbit. (Poirier and Charpy.)

The **ophthalmic veins** (Fig. 641), two in number, superior and inferior, are devoid of valves.

The **Superior Ophthalmic Vein** (*v. ophthalmica superior*) begins at the inner angle of the orbit in a vein named the **nasofrontal** which communicates anteriorly with the angular vein; it pursues the same course as the ophthalmic artery, and receives

tributaries corresponding to the branches of that vessel. Forming a short single trunk, it passes between the two heads of the Rectus lateralis and through the medial part of the superior orbital fissure, and ends in the cavernous sinus.

The **Inferior Ophthalmic Vein** (*v. ophthalmica inferior*) begins in a venous net-work at the forepart of the floor and medial wall of the orbit; it receives some veins from the Rectus inferior, Obliquus inferior, lacrimal sac and eyelids, runs backward in the lower part of the orbit and divides into two branches. One of these passes through the inferior orbital fissure and joins the pterygoid venous plexus, while the other enters the cranium through the superior orbital fissure and ends in the cavernous sinus, either by a separate opening, or more frequently in common with the superior ophthalmic vein.

The **intercavernous sinuses** (*sini intercavernosi*) (Fig. 639) are two in number, an anterior and a posterior, and connect the two cavernous sinuses across the middle line. The **anterior** passes in front of the hypophysis cerebri, the **posterior** behind it, and they form with the cavernous sinuses a venous circle (**circular sinus**) around the hypophysis. The anterior one is usually the larger of the two, and one or other is occasionally absent.

The **superior petrosal sinus** (*sinus petrosus superior*) (Fig. 639) small and narrow, connects the cavernous with the transverse sinus. It runs lateralward and backward, from the posterior end of the cavernous sinus, over the trigeminal nerve, and lies in the attached margin of the tentorium cerebelli and in the superior petrosal sulcus of the temporal bone; it joins the transverse sinus where the latter curves downward on the inner surface of the mastoid part of the temporal. It receives some cerebellar and inferior cerebral veins, and veins from the tympanic cavity.

The **inferior petrosal sinus** (*sinus petrosus inferior*) (Fig. 639) is situated in the inferior petrosal sulcus formed by the junction of the petrous part of the temporal with the basilar part of the occipital. It begins in the postero-inferior part of the cavernous sinus, and, passing through the anterior part of the jugular foramen, ends in the superior bulb of the internal jugular vein. The inferior petrosal sinus receives the internal auditory veins and also veins from the medulla oblongata, pons, and under surface of the cerebellum.

The exact relation of the parts to one another in the jugular foramen is as follows: the inferior petrosal sinus lies medially and anteriorly with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the transverse sinus is situated at the lateral and back part of the foramen with a meningeal branch of the occipital artery, and between the two sinuses are the glossopharyngeal, vagus, and accessory nerves. These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the inferior petrosal sinus with the internal jugular vein takes place on the lateral aspect of the nerves.

The **basilar plexus** (*plexus basilaris; transverse or basilar sinus*) (Fig. 640) consists of several interlacing venous channels between the layers of the dura mater over the basilar part of the occipital bone, and serves to connect the two inferior petrosal sinuses. It communicates with the anterior vertebral venous plexus.

Emissary Veins (*emissaria*).—The emissary veins pass through apertures in the cranial wall and establish communication between the sinuses inside the skull and the veins external to it. Some are always present, others only occasionally so. The principal emissary veins are the following: (1) A mastoid emissary vein, usually present, runs through the mastoid foramen and unites the transverse sinus with the posterior auricular or with the occipital vein. (2) A parietal emissary vein passes through the parietal foramen and connects the superior sagittal sinus with the veins of the scalp. (3) A net-work of minute veins (*rete canalis hypoglossi*) traverses the hypoglossal canal and joins the transverse sinus with the vertebral

vein and deep veins of the neck. (4) An inconstant condyloid emissary vein passes through the condyloid canal and connects the transverse sinus with the deep veins of the neck. (5) A net-work of veins (*rete foraminis ovalis*) unites the cavernous sinus with the pterygoid plexus through the foramen ovale. (6) Two or three small veins run through the foramen lacerum and connect the cavernous sinus with the pterygoid plexus. (7) The emissary vein of the foramen of Vesalius connects the same parts. (8) An internal carotid plexus of veins traverses the carotid canal and unites the cavernous sinus with the internal jugular vein. (9) A vein is transmitted through the foramen caecum and connects the superior sagittal sinus with the veins of the nasal cavity.

Applied Anatomy.—These emissary veins together with the other communications between the intra- and extracranial circulation are of great importance in surgery. Inflammatory processes commencing on the outside of the skull may travel inward through them, and lead to osteophlebitis of the diploë and inflammation of the membranes of the brain. To this in former days was to be attributed one of the principal dangers of wounds of the scalp.

By means of these emissary veins blood may be abstracted from the intracranial circulation—e. g., leeches applied behind the ear drain blood almost directly from the transverse sinus, through the mastoid vein. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being partly derived from the superior sagittal sinus by means of the vein passing through the foramen caecum.

THE VEINS OF THE UPPER EXTREMITY AND THORAX.

The veins of the upper extremity are divided into two sets, **superficial and deep**; the two sets anastomose frequently with each other. The superficial veins are placed immediately beneath the integument between the two layers of superficial fascia. The deep veins accompany the arteries, and constitute the *venae comitantes* of those vessels. Both sets are provided with valves, which are more numerous in the deep than in the superficial veins.

The Superficial Veins of the Upper Extremity.

The superficial veins of the upper extremity are the **digital, metacarpal, cephalic, basilic, median**.

Digital Veins.—The dorsal digital veins pass along the sides of the fingers and are joined to one another by oblique communicating branches. Those from the adjacent sides of the fingers unite to form three **dorsal metacarpal veins** (Fig. 642), which end in a dorsal venous net-work opposite the middle of the metacarpus. The radial part of the net-work is joined by the dorsal digital vein from the radial side of the index finger and by the dorsal digital veins of the thumb, and is prolonged upward as the cephalic vein. The ulnar part of the net-work receives the dorsal digital vein of the ulnar side of the little finger and is continued upward as the basilic vein. A communicating branch frequently connects the dorsal venous network with the cephalic vein about the middle of the forearm.

The **volar digital veins** on each finger are connected to the dorsal digital veins by oblique **intercapitular veins**. They drain into a venous plexus which is situated over the thenar and hypothenar eminences and across the front of the wrist.

The **cephalic vein** (Fig. 643) begins in the radial part of the dorsal venous network and winds upward around the radial border of the forearm, receiving tributaries from both surfaces. Below the front of the elbow it gives off the **vena mediana cubiti** (*median basilic vein*), which receives a communicating branch from the deep veins of the forearm and passes across to join the basilic vein. The cephalic vein then ascends in front of the elbow in the groove between the Brachioradialis and the Biceps brachii. It crosses superficial to the musculocutaneous nerve and ascends in the groove along the lateral border of the Biceps brachii. In the upper third

of the arm it passes between the Pectoralis major and Deltoideus, where it is accompanied by the deltoid branch of the thoracoacromial artery. It pierces the coracoclavicular fascia and, crossing the axillary artery, ends in the axillary vein just below the clavicle. Sometimes it communicates with the external jugular vein by a branch which ascends in front of the clavicle.

FIG. 612.—The veins on the dorsum of the hand. (Boutgery.)

The **accessory cephalic vein** (*v. cephalica accessoria*) arises either from a small tributary plexus on the back of the forearm or from the ulnar side of the dorsal venous net-work; it joins the cephalic below the elbow. In some cases the accessory cephalic springs from the cephalic above the wrist and joins it again higher up. A large oblique branch frequently connects the basilic and cephalic veins on the back of the forearm.

The **basilic vein** (*v. basilica*) (Fig. 643) begins in the ulnar part of the dorsal venous network. It runs up the posterior surface of the ulnar side of the forearm and inclines forward to the anterior surface below the elbow, where it is joined by the vena mediana cubiti. It ascends obliquely in the groove between the Biceps brachii and Pronator teres and crosses the brachial artery, from which it is separated

by the lacertus fibrosus; filaments of the medial antibrachial cutaneous nerve pass both in front of and behind this portion of the vein. It then runs upward along the medial border of the Biceps brachii, perforates the deep fascia a little below the middle of the arm, and, ascending on the medial side of the brachial artery to the lower border of the Teres major, is continued onward as the axillary vein.

The **median antibrachial vein** (*v. mediana antibrachii*) drains the venous plexus on the volar surface of the hand. It ascends on the ulnar side of the front of the forearm and ends in the basilic vein or in the vena mediana cubiti; in a small proportion of cases it divides into two branches, one of which joins the basilic, the other the cephalic, below the elbow.

Applied Anatomy.—*Venesection* is generally performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the vena mediana cubiti (*median basilic*), and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that in addition to its being the largest vessel, and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the lacertus fibrosus (*bicipital fascia*), on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the lacertus fibrosus; and formerly, when venesection was frequently practised, arteriovenous aneurism was no uncommon result of this practice.

Intravenous infusion of normal saline solution is very frequently required in modern surgery for all conditions of severe shock and after profuse hemorrhages, the older method of transfusion of blood having quite sunk into oblivion. The patient's arm is surrounded by a tight bandage so as to impede the venous return, and a small incision is made over the largest vein visible in front of the elbow; a double ligature is now passed around the vein, and the lower one is tied; the vein is then opened and a cannula connected with a funnel by tubing and filled with hot saline solution is inserted. The bandage is next removed from the arm, and two, three, or more pints of fluid are allowed to flow into the vein; when a sufficient quantity has gone in, the upper ligature around the vein is tied and a stitch put in the skin wound.

FIG. 643.—The superficial veins of the upper extremity.

The Deep Veins of the Upper Extremity.

The **deep veins** follow the course of the arteries, forming their *venae comitantes*. They are generally arranged in pairs, and are situated one on either side of the corresponding artery, and connected at intervals by short transverse branches.

Deep Veins of the Hand.—The superficial and deep volar arterial arches are each accompanied by a pair of *venae comitantes* which constitute respectively the **superficial and deep volar venous arches**, and receive the veins corresponding to the branches of the arterial arches; thus the **common volar digital veins**, formed by the union of the **proper volar digital veins**, open into the superficial, and the **volar metacarpal veins** into the deep volar venous arches. The **dorsal metacarpal veins** receive perforating branches from the volar metacarpal veins and end in the radial veins and in the superficial veins on the dorsum of the wrist.

The **deep veins of the forearm** are the *venae comitantes* of the radial and ulnar veins and constitute respectively the upward continuations of the deep and superficial volar venous arches; they unite in front of the elbow to form the brachial veins. The radial veins are smaller than the ulnar and receive the dorsal metacarpal veins. The ulnar veins receive tributaries from the deep volar venous arches and communicate with the superficial veins at the wrist; near the elbow they receive the volar and dorsal interosseous veins and send a large communicating branch (*profunda vein*) to the *vena mediana cubiti*.

The **brachial veins** (*vv. brachiales*) are placed one on either side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel; near the lower margin of the Subscapularis, they join the axillary vein; the medial one frequently joins the basilic vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The **axillary vein** (*v. axillaris*) begins at the lower border of the *Teres major*, as the continuation of the basilic vein, increases in size as it ascends, and ends at the outer border of the first rib as the subclavian vein. Near the lower border of the Subscapularis it receives the brachial veins and, close to its termination, the cephalic vein; its other tributaries correspond with the branches of the axillary artery. It lies on the medial side of the artery, which it partly overlaps; between the two vessels are the medial cord of the brachial plexus, the median, the ulnar, and the medial anterior thoracic nerves. It is provided with a pair of valves opposite the lower border of the Subscapularis; valves are also found at the ends of the cephalic and subscapular veins.

Applied Anatomy.—Since the axillary vein is superficial to and larger than the axillary artery, which it overlaps, it is more liable to be wounded than the artery in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to it. When it is wounded, there is always a danger of air being drawn into it, and death resulting. To avoid wounding the axillary vein in the extirpation of glands from the axilla, it is advisable to expose the vein as soon as possible; no sharp cutting instruments should be used after the axillary cavity has been freely exposed; and care should be taken to use no undue force in isolating the glands (see p. 781). Should the vein be so imbedded in a malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done after the vessel has been ligatured above and below.

The **subclavian vein** (*v. subclavia*), the continuation of the axillary, extends from the outer border of the first rib to the sternal end of the clavicle, where it unites with the internal jugular to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius; behind and above, with the subclavian artery, from which it is separated medially by the *Scalenus anterior* and the phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. It is usually provided with a pair of valves, which are situated about 2.5 cm. from its termination.

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and occasionally passes with this vessel behind the Scalenus anterior.

Tributaries.—This vein receives the external jugular vein, sometimes the anterior jugular vein, and occasionally a small branch, which ascends in front of the clavicle, from the cephalic. At its angle of junction with the internal jugular, the left subclavian vein receives the thoracic duct, and the right subclavian vein the right lymphatic duct.

The Veins of the Thorax (Fig. 644)

The **innominate veins** (*vv. anonymae; brachiocephalic veins*) are two large trunks, placed one on either side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side; they are devoid of valves.

The **Right Innominate Vein** (*v. anonyma dextra*) is a short vessel, about 2.5 cm. in length, which begins behind the sternal end of the clavicle, and, passing almost vertically downward, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies in front and to the right of the innominate artery; on its right side are the phrenic nerve and the pleura, which are interposed between it and the apex of the lung. This vein, at its commencement, receives the right vertebral vein; and, lower down, the right internal mammary and right inferior thyroid veins, and sometimes the vein from the first intercostal space.

The **Left Innominate Vein** (*v. anonyma sinistra*), about 6 cm. in length, begins behind the sternal end of the clavicle and runs obliquely downward and to the right behind the upper half of the manubrium sterni to the sternal end of the first right costal cartilage, where it unites with the right innominate vein to form the **superior vena cava**. It is separated from the manubrium sterni by the Sternohyoideus and Sternothyroideus, the thymus or its remains, and some loose areolar tissue. Behind it are the three large arteries, innominate, left common carotid, and left subclavian, arising from the aortic arch, together with the vagus and phrenic nerves. The left innominate vein may occupy a higher level, crossing the jugular notch and lying directly in front of the trachea.

Tributaries.—Its tributaries are the left vertebral, left internal mammary, left inferior thyroid, and the left highest intercostal veins, and occasionally some thymic and pericardiac veins.

Peculiarities.—Sometimes the innominate veins open separately into the right atrium; in such cases the right vein takes the ordinary course of the superior vena cava; the left vein—*left superior vena cava*, as it is then termed—which may communicate by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, ends in the right atrium. This occasional condition in the adult is due to the persistence of the early fetal condition, and is the normal state of things in birds and some mammalia.

The **internal mammary veins** (*vv. mammae internae*) are *venae comitantes* to the lower half of the internal mammary artery, and receive tributaries corresponding to the branches of the artery. They then unite to form a single trunk, which runs up on the medial side of the artery and ends in the corresponding innominate vein. The **superior phrenic vein**, *i. e.*, the vein accompanying the pericardiophrenic artery, usually opens into the internal mammary vein.

The **inferior thyroid veins** (*vv. thyroideae inferiores*) two, frequently three or four, in number, arise in the venous plexus on the thyroid gland, communicating with the middle and superior thyroid veins. They form a plexus in front of the trachea, behind the Sternothyroidei. From this plexus, a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downward and to the right across the innominate artery to open into the right innominate vein,

just at its junction with the superior vena cava; sometimes the right and left veins open by a common trunk in the latter situation. These veins receive œsophageal,

S₁

1

S₁

FIG. 644.—The venae cavae and axygos veins, with their tributaries.

tracheal, and inferior laryngeal veins, and are provided with valves at their terminations in the innominate veins.

The **highest intercostal vein** (*v. intercostalis suprema; superior intercostal veins*) (right and left) drain the blood from the upper three or four intercostal spaces. The **right vein** (*v. intercostalis suprema dextra*) passes downward and opens into the vena azygos; the **left vein** (*v. intercostalis suprema sinistra*) runs across the arch of the aorta and the origins of the left subclavian and left common carotid arteries and opens into the left innominate vein. It usually receives the left bronchial vein, and sometimes the left superior phrenic vein, and communicates below with the accessory hemiazygos vein.

The **superior vena cava** (*v. cava superior*) drains the blood from the upper half of the body. It measures about 7 cm. in length, and is formed by the junction of the two innominate veins. It *begins* immediately below the cartilage of the right first rib close to the sternum, and, descending vertically behind the first and second intercostal spaces, ends in the upper part of the right atrium opposite the upper border of the third right costal cartilage: the lower half of the vessel is within the pericardium. In its course it describes a slight curve, the convexity of which is to the right side.

Relations.—*In front* are the anterior margins of the right lung and pleura with the pericardium intervening below; these separate it from the first and second intercostal spaces and from the second and third right costal cartilages; *behind* it are the root of the right lung and the right vagus nerve. On its *right side* are the phrenic nerve and right pleura; on its *left side*, the commencement of the innominate artery and the ascending aorta, the latter overlapping it. Just before it pierces the pericardium, it receives the azygos vein and several small veins from the pericardium and other contents of the mediastinal cavity. The portion contained within the pericardium is covered, in front and laterally, by the serous layer of the membrane. The superior vena cava has no valves.

The **azygos vein** (*v. azygos; vena azygos major*) *begins* opposite the first or second lumbar vertebra, by a branch, the **ascending lumbar vein** (page 763); sometimes by a branch from the right renal vein, or from the inferior vena cava. It enters the thorax through the aortic hiatus in the Diaphragma, and passes along the right side of the vertebral column to the fourth thoracic vertebra, where it arches forward over the root of the right lung, and ends in the superior vena cava, just before that vessel pierces the pericardium. In the aortic hiatus, it lies with the thoracic duct on the right side of the aorta; in the thorax it lies upon the intercostal arteries, on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives the right subcostal and intercostal veins, the upper three or four of these latter opening by a common stem, the highest superior intercostal vein. It receives the hemiazygos veins, several œsophageal, mediastinal, and pericardial veins, and, near its termination, the right bronchial vein. A few imperfect valves are found in the azygos vein; but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the upper three intercostal spaces, usually form two trunks, named the **hemiazygos** and **accessory hemiazygos veins**.

The **Hemiazygos Veins** (*v. hemiazygos; vena azygos minor inferior*) *begins* in the left ascending lumbar or renal vein. It enters the thorax, through the left crus of the Diaphragma, and, ascending on the left side of the vertebral column, as high as the ninth thoracic vertebra, passes across the column, behind the aorta, œsophagus, and thoracic duct, to end in the azygos vein. It receives the lower four or five intercostal veins and the subcostal vein of the left side, and some œsophageal and mediastinal veins.

The **Accessory Hemiazygos Vein** (*v. hemiazygos accessoria; vena azygos minor superior*) descends on the left side of the vertebral column, and varies inversely in size with the highest left intercostal vein. It receives veins from the three or four intercostal spaces between the highest left intercostal vein and highest tributary of the hemiazygos; the left bronchial vein sometimes opens into it. It either crosses

the body of the eighth thoracic vertebra to join the azygos vein or ends in the hemiazygos. When this vein is small, or altogether wanting, the left highest intercostal vein may extend as low as the fifth or sixth intercostal space.

Applied Anatomy.—In obstruction of the superior vena cava, the azygos and hemiazygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior venæ cavæ, and communicating with the common iliac veins by the ascending lumbar veins and with many of the tributaries of the inferior vena cava.

Thrombosis of the superior vena cava is oftenest due to pressure exerted on the vessel by an aneurism or a tumor; it may also occur by propagation of clotting from a tributary peripheral vein. If occlusion of the vessel take place slowly, a collateral venous circulation may be established; the patient will have some œdema with dilatation and congestion of the veins about the head and neck, and may also suffer from attacks of dyspnoea and recurrent pleural effusion. In most cases, however, the blockage of the superior cava takes place rapidly, and is rapidly fatal.

The **Bronchial Veins** (*vv. bronchiales*) return the blood from the larger bronchi, and from the structures at the roots of the lungs; that of the right side opens into the azygos vein, near its termination; that of the left side, into the highest left intercostal or the accessory hemiazygos vein. A considerable quantity of the blood which is carried to the lungs through the bronchial arteries is returned to the left side of the heart through the pulmonary veins.

Posterior external plexuses

Posterior external plexus

Anterior external plexus

FIG. 645.—Transverse section of a thoracic vertebra, showing the vertebral venous plexuses.

FIG. 646.—Median sagittal section of two thoracic vertebrae, showing the vertebral venous plexuses.

The Veins of the Vertebral Column (Figs. 645, 646).

The veins which drain the blood from the vertebral column, the neighboring muscles, and the meninges of the medulla spinalis form intricate plexuses extending along the entire length of the column; these plexuses may be divided into two groups, external and internal, according to their positions inside or outside the vertebral canal. The plexuses of the two groups anastomose freely with each other and end in the intervertebral veins.

The **external vertebral venous plexuses** (*plexus venosi vertebrales externi; extra-spinal veins*) best marked in the cervical region, consist of anterior and posterior plexuses which anastomose freely with each other. The **anterior external plexuses** lie in front of the bodies of the vertebræ, communicate with the basivertebral and intervertebral veins, and receive tributaries from the vertebral bodies. The **posterior external plexuses** are placed partly on the posterior surfaces of the vertebral

arches and their processes, and partly between the deep dorsal muscles. They are best developed in the cervical region, and there anastomose with the vertebral, occipital, and deep cervical veins.

The **internal vertebral venous plexuses** (*plexus venosi vertebrales interni; intra-spinal veins*) lie within the vertebral canal between the dura mater and the vertebræ, and receive tributaries from the bones and from the medulla spinalis. They form a closer net-work than the external plexuses, and, running mainly in a vertical direction, form four longitudinal veins, two in front and two behind; they therefore may be divided into anterior and posterior groups. The **anterior internal plexuses** consist of large veins which lie on the posterior surfaces of the vertebral bodies and intervertebral fibrocartilages on either side of the posterior longitudinal ligament; under cover of this ligament they are connected by transverse branches into which the basivertebral veins open. The **posterior internal plexuses** are placed, one on either side of the middle line in front of the vertebral arches and ligamenta flava, and anastomose by veins passing through those ligaments with the posterior external plexuses. The anterior and posterior plexuses communicate freely with one another by a series of **venous rings** (*retia venosa vertebrarum*), one opposite each vertebra. Around the foramen magnum they form an intricate net-work which opens into the vertebral veins and is connected above with the occipital sinus, the basilar plexus, the condyloid emissary vein, and the rete canalis hypoglossi.

The **basivertebral veins** (*vv. basivertebrales*) emerge from the foramina on the posterior surfaces of the vertebral bodies. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. They communicate through small openings on the front and sides of the bodies of the vertebræ with the anterior external vertebral plexuses, and converge behind to the principal canal, which is sometimes double toward its posterior part, and open by valved orifices into the transverse branches which unite the anterior internal vertebral plexuses. They become greatly enlarged in advanced age.

The **intervertebral veins** (*vv. intervertebrales*) accompany the spinal nerves through the intervertebral foramina; they receive the veins from the medulla spinalis, drain the internal and external vertebral plexuses and end in the vertebral, intercostal, lumbar, and lateral sacral veins, their orifices being provided with valves.

The **veins of the medulla spinalis** (*vv. spinales; veins of the spinal cord*) are situated in the pia mater and form a minute, tortuous, venous plexus. They emerge chiefly from the median fissures of the medulla spinalis and are largest in the lumbar region. In this plexus there are (1) two median longitudinal veins, one in front of the anterior fissure, and the other behind the posterior sulcus of the cord, and (2) four lateral longitudinal veins which run behind the nerve roots. They end in the intervertebral veins. Near the base of the skull they unite, and form two or three small trunks, which communicate with the vertebral veins, and then end in the inferior cerebellar veins, or in the inferior petrosal sinuses.

THE VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS.

The veins of the lower extremity are subdivided, like those of the upper, into two sets, **superficial** and **deep**; the superficial veins are placed beneath the integument between the two layers of superficial fascia; the deep veins accompany the arteries. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. Valves are also more numerous in the veins of the lower than in those of the upper limb.

The Superficial Veins of the Lower Extremity.

The superficial veins of the lower extremity are the **great and small saphenous veins** and their tributaries.

On the **dorsum of the foot** the **dorsal digital veins** receive, in the clefts between the toes, the **intercapitular veins** from the plantar cutaneous venous arch and join to form short **common digital veins** which unite across the distal ends of the metatarsal bones in a **dorsal venous arch**. Proximal to this arch is an irregular venous net-work which receives tributaries from the deep veins and is joined at the sides of the foot by a **medial** and a **lateral marginal vein**, formed mainly by the union of branches from the superficial parts of the sole of the foot.

On the **sole of the foot** the superficial veins form a **plantar cutaneous venous arch** which extends across the roots of the toes and opens at the sides of the foot into the medial and lateral marginal veins. Proximal to this arch is a **plantar cutaneous venous net-work** which is especially dense in the fat beneath the heel; this net-work communicates with the cutaneous venous arch and with the deep veins, but is chiefly drained into the medial and lateral marginal veins.

The **great saphenous vein** (*v. saphena magna*; *internal or long saphenous vein*) (Fig. 647), the longest vein in the body, *begins* in the medial marginal vein of the dorsum of the foot and ends in the femoral vein about 3 cm. below the inguinal ligament. It ascends in front of the tibial malleolus and along the medial side of the leg in relation with the saphenous nerve. It runs upward behind the medial condyles of the tibia and femur and along the medial side of the thigh and, passing through the fossa ovalis, ends in the femoral vein.

Tributaries.—At the ankle it receives branches from the sole of the foot through the medial marginal vein; in the leg it anastomoses freely with the small saphenous vein, communicates with the anterior and posterior tibial veins and receives many cutaneous veins; in the thigh it communicates with the femoral vein and receives numerous tributaries; those from the medial and posterior parts of the thigh frequently unite to form a large **accessory saphenous vein** which joins the main vein at a variable level. Near the fossa ovalis (Fig. 648) it is joined by the superficial epigastric, superficial iliac circumflex, and superficial external pudendal veins. A vein, named the **thoracoepigastric**, runs along the lateral aspect of the trunk between the superficial epigastric vein below and the lateral thoracic vein above and establishes an important communication between the femoral and axillary veins.

FIG. 647.—The great saphenous vein and its tributaries.

The valves in the great saphenous vein vary from ten to twenty in number; they are more numerous in the leg than in the thigh.

The **small saphenous vein** (*v. saphena parva; external or short saphenous vein*) (Fig. 649) begins behind the lateral malleolus as a continuation of the lateral marginal vein; it first ascends along the lateral margin of the tendocalcaneus, and then crosses it to reach the middle of the back of the leg. Running directly upward, it perforates the deep fascia in the lower part of the popliteal fossa, and ends in the popliteal vein, between the heads of the Gastrocnemius. It communicates with the deep veins on the dorsum of the foot, and receives numerous large tributaries from the back of the leg. Before it pierces the deep fascia, it gives off a branch which runs upward and forward to join the great saphenous vein. The small saphenous vein possesses from nine to twelve valves, one of which is always found near its termination in the popliteal vein. In the lower third of the leg the small saphenous vein is in close relation with the sural nerve, in the upper two-thirds with the medial sural cutaneous nerve.

• FIG. 648.—The great saphenous vein and its tributaries at the fossa ovalis.

Applied Anatomy.—A varicose condition of the saphenous veins is more frequently met with than in the other veins of the body, except perhaps the spermatic and hemorrhoidal veins. The main cause of this is the high blood pressure, determined chiefly by the erect position, and the length of the column of blood, which has to be propelled in an uphill direction. In normal vessels there is only just sufficient force to perform this task; and in those cases where there is diminished resistance of the walls of the veins, these vessels are liable to dilate and a varicose condition is set up. This diminished resistance may be due to heredity, the vein walls being congenitally weak, or it may follow inflammatory conditions of the vessels. Increased blood pressure in the veins, caused by any obstacle to the return of the venous blood, such as the pressure of a tumor,

or the gravid uterus, or tight gartering, may also produce varix. In the normal condition of the veins, the valves in their interior break up the column of blood into a number of smaller columns, and so to a considerable extent mitigate the ill effects of the erect position; but when the dilatation of the veins has reached a certain limit, the valves become incapable of supporting the overlying column of blood, and the pressure is increased, tending to emphasize also the varicose condition. Both the saphenous veins in the leg are accompanied by nerves, the great saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact.

Operations for the relief of varicose veins are frequently required, portions of the veins being removed after having been ligatured above and below. It is important to note whether the main varicose area drains into the great or the small saphenous vein—the former condition being much the more common—and to control the venous return by removing a small portion of the main trunk just before it opens into the deep vein by passing through the deep fascia; thus in most cases a piece should be removed from the great saphenous just before it passes through the fossa ovalis (*saphenous opening*), and in addition the affected veins should be excised just above and just below the level of the knee-joint. In other cases the small saphenous will have to be dealt with immediately below the point where it pierces the fascial roof of the popliteal fossa.

The Deep Veins of the Lower Extremity.

The **deep veins** of the lower extremity accompany the arteries and their branches; they possess numerous valves.

The **plantar digital veins** (*vv. digitales plantares*) arise from plexuses on the plantar surfaces of the digits, and, after sending **intercapitular veins** to join the dorsal digital veins, unite to form four **metatarsal veins**; these run backward in the metatarsal spaces, communicate, by means of perforating veins, with the veins on the dorsum of the foot, and unite to form the **deep plantar venous arch** which lies alongside the plantar arterial arch. From the deep plantar venous arch the **medial** and **lateral plantar veins** run backward close to the corresponding arteries and, after communicating with the great and small saphenous veins, unite behind the medial malleolus to form the posterior tibial veins.

FIG. 649.—The small saphenous vein.

The **posterior tibial veins** (*vv. tibiales posteriores*) accompany the posterior tibial artery, and are joined by the **peroneal veins**.

The **anterior tibial veins** (*vv. tibiales anteriores*) are the upward continuation of the *venae comitantes* of the *dorsalis pedis* artery. They leave the front of the leg by passing between the tibia and fibula, over the interosseous membrane, and unite with the posterior tibial, to form the **popliteal vein**.

The **Popliteal Vein** (*v. poplitea*) is formed by the junction of the anterior and posterior tibial veins at the lower border of the Popliteus; it ascends through the popliteal fossa to the aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is placed medial to the artery; between the heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint, it is close to its lateral side. It receives tributaries corresponding to the branches of the popliteal artery, and it also receives the small saphenous vein. The valves in the popliteal vein are usually four in number.

The **femoral vein** (*v. femoralis*) accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies lateral to the

artery; higher up, it is behind it; and at the inguinal ligament, it lies on its medial side, and on the same plane. It receives numerous muscular tributaries, and about 4 cm. below the inguinal ligament is joined by the *v. profunda femoris*; near its termination it is joined by the great saphenous vein. The valves in the femoral vein are three in number.

The **Deep Femoral Vein** (*v. profunda femoris*) receives tributaries corresponding to the perforating branches of the profunda artery, and through these establishes communications with the popliteal vein below and the inferior gluteal vein above. It also receives the medial and lateral femoral circumflex veins.

FIG. 650.—The veins of the right half of the male pelvis. (Spalteholz.)

The Veins of the Abdomen and Pelvis (Fig. 650).

The **external iliac vein** (*v. iliaca externa*), the upward continuation of the femoral vein, begins behind the inguinal ligament, and, passing upward along the brim of the lesser pelvis, ends opposite the sacroiliac articulation, by uniting with the hypogastric vein to form the common iliac vein. On the right side, it lies at first medial to the artery: but, as it passes upward, gradually inclines behind it. On

the left side, it lies altogether on the medial side of the artery. It frequently contains one, sometimes two, valves.

Tributaries.—The external iliac vein receives the inferior epigastric, deep iliac circumflex, and pubic veins.

The **Inferior Epigastric Vein** (*v. epigastrica inferior; deep epigastric vein*) is formed by the union of the venae comitantes of the inferior epigastric artery, which communicate above with the superior epigastric vein; it joins the external iliac about 1.25 cm. above the inguinal ligament.

The **Deep Iliac Circumflex Vein** (*v. circumflexa ilium profunda*) is formed by the union of the venae comitantes of the deep iliac circumflex artery, and joins the external iliac vein about 2 cm. above the inguinal ligament.

The **Pubic Vein** communicates with the obturator vein in the obturator foramen, and ascends on the back of the pubis to the external iliac vein.

The **hypogastric vein** (*v. hypogastrica; internal iliac vein*) begins near the upper part of the greater sciatic foramen, passes upward behind and slightly medial to the hypogastric artery and, at the brim of the pelvis, joins with the external iliac to form the common iliac vein.

Tributaries.—With the exception of the fetal umbilical vein which passes upward and backward from the umbilicus to the liver, and the iliolumbar vein which usually joins the common iliac vein, the tributaries of the hypogastric vein correspond with the branches of the hypogastric artery. It receives (a) the **gluteal, internal pudendal, and obturator veins**, which have their origins outside the pelvis; (b) the **lateral sacral veins**, which lie in front of the sacrum; and (c) the **middle hemorrhoidal, vesical, uterine, and vaginal veins**, which originate in venous plexuses connected with the pelvic viscera.

1. The **Superior Gluteal Veins** (*vv. glutaeae superiores; gluteal veins*) are venae comitantes of the superior gluteal artery; they receive tributaries from the buttock corresponding with the branches of the artery, and enter the pelvis through the greater sciatic foramen, above the Piriformis, and frequently unite before ending in the hypogastric vein.

2. The **Inferior Gluteal Veins** (*vv. glutaeae inferiores; sciatic veins*), or venae comitantes of the inferior gluteal artery, begin on the upper part of the back of the thigh, where they anastomose with the medial femoral circumflex and first perforating veins. They enter the pelvis through the lower part of the greater sciatic foramen and join to form a single stem which opens into the lower part of the hypogastric vein.

3. The **Internal Pudendal Veins** (*internal pudic veins*) are the venae comitantes of the internal pudendal artery. They begin in the deep veins of the penis which issue from the corpus cavernosum penis, accompany the internal pudendal artery, and unite to form a single vessel, which ends in the hypogastric vein. They receive the veins from the urethral bulb, and the perineal and inferior hemorrhoidal veins. The deep dorsal vein of the penis communicates with the internal pudendal veins, but ends mainly in the pudendal plexus.

4. The **Obturator Vein** (*v. obturatoria*) begins in the upper portion of the adductor region of the thigh and enters the pelvis through the upper part of the obturator foramen. It runs backward and upward on the lateral wall of the pelvis below the obturator artery, and then passes between the ureter and the hypogastric artery, to end in the hypogastric vein.

5. The **Lateral Sacral Veins** (*vv. sacrales laterales*) accompany the lateral sacral arteries on the anterior surface of the sacrum and end in the hypogastric vein.

6. The **Middle Hemorrhoidal Vein** (*v. haemorrhoidalis media*) takes origin in the hemorrhoidal plexus and receives tributaries from the bladder, prostate, and seminal vesicle; it runs lateralward on the pelvic surface of the Levator ani to end in the hypogastric vein.

The **hemorrhoidal plexus** (*plexus haemorrhoidalis*) surrounds the rectum, and communicates in front with the vesical plexus in the male, and the uterovaginal plexus in the female. It consists of two parts, an **internal** in the submucosa, and an **external** outside the muscular coat. The internal plexus presents a series of dilated pouches which are arranged in a circle around the tube, immediately above the anal orifice, and are connected by transverse branches.

The lower part of the external plexus is drained by the inferior hemorrhoidal veins into the internal pudendal vein; the middle part by the middle hemorrhoidal vein which joins the hypogastric vein; and the upper part by the superior hemorrhoidal vein which forms the commencement of the inferior mesenteric vein, a tributary of the portal vein. A free communication between the portal and systemic venous systems is established through the hemorrhoidal plexus.

The **pudendal plexus** (*plexus pudendalis; vesicoprostatic plexus*) lies behind the arcuate pubic ligament and the lower part of the symphysis pubis, and in front of the bladder and prostate. Its chief tributary is the deep dorsal vein of the penis, but it also receives branches from the front of the bladder and prostate. It communicates with the vesical plexus and with the internal pudendal vein and drains into the vesical and hypogastric veins. The **prostatic veins** form a well-marked **prostatic plexus** which lies partly in the fascial sheath of the prostate and partly between the sheath and the prostatic capsule. It communicates with the pudendal and vesical plexuses.

The **vesical plexus** (*plexus vesicalis*) envelops the lower part of the bladder and the base of the prostate and communicates with the pudendal and prostatic plexuses. It is drained, by means of several vesical veins, into the hypogastric veins.

Applied Anatomy.—The veins of the hemorrhoidal plexus are apt to become dilated and varicose, and form piles. This is due to several anatomical reasons: the vessels are contained in very loose, connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure; the condition is favored by gravitation, being influenced by the erect posture, either sitting or standing, and by the fact that the superior hemorrhoidal and portal veins have no valves; the veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defecation; they are affected by every form of portal obstruction.

The prostatic plexus of veins is apt to become congested in many inflammatory conditions in the neighborhood, such as acute gonorrheal prostatitis. It is owing to the free communication which exists between this and the middle hemorrhoidal plexus that great relief can be given by free saline purgation.

Hemorrhage may be very free from the prostatic plexus after operations on that gland, but can usually be checked by hot fluid irrigation. Septic thrombosis sometimes occurs after operations, and infected emboli may find their way into the general circulation.

The **Dorsal Veins of the Penis** (*vv. dorsales penis*) are two in number, a superficial and a deep. The **superficial vein** drains the prepuce and skin of the penis, and, running backward in the subcutaneous tissue, inclines to the right or left, and opens into the corresponding superficial external pudendal vein, a tributary of the great saphenous vein. The **deep vein** lies beneath the deep fascia of the penis; it receives the blood from the glans penis and corpora cavernosa penis and courses backward in the middle line between the dorsal arteries; near the root of the penis it passes between the two parts of the suspensory ligament and then through an aperture between the arcuate pubic ligament and the transverse ligament of the pelvis, and divides into two branches, which enter the pudendal plexus. The deep vein also communicates below the symphysis pubis with the internal pudendal vein.

The **uterine plexuses** lie along the sides and superior angles of the uterus between the two layers of the broad ligament, and communicate with the ovarian and vaginal plexuses. They are drained by a pair of uterine veins on either side: these arise from the lower part of the plexuses, opposite the external orifice of the uterus, and open into the corresponding hypogastric vein.

The **vaginal plexuses** are placed at the sides of the vagina; they communicate with the uterine, vesical, and hemorrhoidal plexuses, and are drained by the vaginal veins, one on either side, into the hypogastric veins.

The **common iliac veins** (*vv. iliacae communes*) are formed by the union of the external iliac and hypogastric veins, in front of the sacroiliac articulation; passing obliquely upward toward the right side, they end upon the fifth lumbar vertebra, by uniting with each other at an acute angle to form the inferior vena cava. The **right common iliac** is shorter than the left, nearly vertical in its direction, and ascends behind and then lateral to its corresponding artery. The **left common iliac**, longer than the right and more oblique in its course, is at first situated on the medial side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the iliolumbar, and sometimes the lateral sacral veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The **Middle Sacral Veins** (*vv. sacrales mediales*) accompany the corresponding artery along the front of the sacrum, and join to form a single vein, which ends in the left common iliac vein; sometimes in the angle of junction of the two iliac veins.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the vena cava. In these cases, the two common iliacs are connected by a small communicating branch at the spot where they are usually united.

The **inferior vena cava** (*v. cava inferior*) (Fig. 644), returns to the heart the blood from the parts below the Diaphragma. It is formed by the junction of the two common iliac veins, on the right side of the fifth lumbar vertebra. It ascends along the front of the vertebral column, on the right side of the aorta, and, having reached the liver, is continued in a groove on its posterior surface. It then perforates the Diaphragma between the median and right portions of its central tendon; it subsequently inclines forward and medialward for about 2.5 cm., and, piercing the fibrous pericardium, passes behind the serous pericardium to open into the lower and back part of the right atrium. In front of its atrial orifice is a semilunar valve, termed the **valve of the inferior vena cava**: this is rudimentary in the adult, but is of large size and exercises an important function in the fetus (see page 618).

Relations.—The *abdominal portion* of the inferior vena cava is in relation *in front*, from below upward, with the right common iliac artery, the mesentery, the right internal spermatic artery, the inferior part of the duodenum, the pancreas, the common bile duct, the portal vein, and the posterior surface of the liver; the last partly overlaps and occasionally completely surrounds it; *behind*, with the vertebral column, the right Psoas major, the right crus of the Diaphragma, the right inferior phrenic, suprarenal, renal and lumbar arteries, right sympathetic trunk and right coeliac ganglion, and the medial part of the right suprarenal gland; on the *right side*, with the right kidney and ureter; on the *left side*, with the aorta, right crus of the Diaphragma, and the caudate lobe of the liver.

The *thoracic portion* is only about 2.5 cm. in length, and is situated partly inside and partly outside the pericardial sac. The *extrapericardial part* is separated from the right pleura and lung by a fibrous band, named the **right phrenicopericardiac ligament**. This ligament, often feebly marked, is attached below to the margin of the vena-caval opening in the Diaphragma, and above to the pericardium in front of and behind the root of the right lung. The *intrapericardiac part* is very short, and is covered antero-laterally by the serous layer of the pericardium.

Peculiarities.—*In Position.*—This vessel is sometimes placed on the left side of the aorta, as high as the left renal vein, and, after receiving this vein, crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, and in such a case the abdominal and thoracic viscera, together with the great vessels, are all transposed.

Point of Termination.—Occasionally the inferior vena cava joins the azygos vein, which is then of large size. In such cases, the superior vena cava receives the whole of the blood from the body before transmitting it to the right atrium, except the blood from the hepatic veins, which passes directly into the right atrium.

Applied Anatomy.—Thrombosis of the inferior vena cava is due to much the same causes as that of the superior (see p. 754). It usually causes œdema of the legs and back, without ascites;

if the renal veins are involved, blood and albumin will often appear in the urine. An extensive collateral venous circulation is soon established by enlargement either of the superficial or of the deep veins, or of both. In the first case the epigastric, the iliac circumflex, the lateral thoracic, the internal mammary, the intercostals, the external pudendal, and the lumbovertebral anastomatic veins of Braune effect the communication with the superior cava; in the second, the deep anastomosis is made by the azygos and hemiazygos and the lumbar veins.¹

Tributaries.—The inferior vena cava receives the following veins:

Lumbar.	Renal.	Inferior Phrenic.
Right Spermatic or Ovarian.	Suprarenal.	Hepatic.

The **Lumbar Veins** (*vv. lumbales*) four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins, and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the vertebral column, they receive veins from the vertebral plexuses, and then pass forward, around the sides of the bodies of the vertebræ, beneath the Psoas major, and end in the back part of the inferior cava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebræ, and is called the **ascending lumbar**; it forms the most frequent origin of the corresponding azygos or hemiazygos vein, and serves to connect the common iliac, ilio-lumbar, and azygos or hemiazygos veins of its own side of the body.

The **Spermatic Veins** (*vv. spermaticæ*) emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus, called the **pampiniform plexus**, which constitutes the greater mass of the spermatic cord; the vessels composing this plexus are very numerous, and ascend along the cord, in front of the ductus deferens. Below the subcutaneous inguinal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the abdominal inguinal ring, coalesce to form two veins, which ascend on the Psoas major, behind the peritoneum, lying one on either side of the internal spermatic artery. These unite to form a single vein, which opens on the right side into the inferior vena cava, at an acute angle; on the left side into the left renal vein, at a right angle. The spermatic veins are provided with valves.² The left spermatic vein passes behind the iliac colon, and is thus exposed to pressure from the contents of that part of the bowel.

Applied Anatomy.—The spermatic veins are very frequently varicose, constituting the condition known as *varicocele*. Though it is quite possible that the originating cause of this affection may be a congenital weakness of the walls of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose, viz.: the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall. Varicocele almost invariably occurs on the left side, and this has been accounted for by the facts that the left spermatic vein joins the left renal at a right angle; that it is overlaid by the iliac colon, and that when this portion of the gut is full of fecal matter, in cases of constipation, its weight impedes the return of the venous blood; and that the left spermatic veins are somewhat longer than the right.

The operation for the removal of a varicocele consists in making a small incision just over the subcutaneous inguinal ring and passing an aneurism needle around the mass of veins, taking care that the ductus deferens is not included. The veins are isolated from the ductus and ligatured above and below, as high and as low as possible, and the intermediate portion cut away; the divided ends are fixed together with a suture, and the skin wound closed.

¹ G. Blumer, in Osler and McCrae's *Modern Medicine*, Philadelphia, 1908, vol. iv.

² Rivington has pointed out that valves are usually found at the orifices of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within 6 mm. from the orifice of the spermatic vein.—*Journal of Anatomy and Physiology*, vii, 163.

The **Ovarian Veins** (*vv. ovaricae*) correspond with the spermatic in the male; they form a plexus in the broad ligament near the ovary and uterine tube, and communicate with the uterine plexus. They end in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. Like the uterine veins, they become much enlarged during pregnancy.

The **Renal Veins** (*vv. renales*) are of large size, and placed in front of the renal arteries. The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic and left inferior phrenic veins, and, generally, the left suprarenal vein. It opens into the inferior vena cava at a slightly higher level than the right.

The **Suprarenal Veins** (*vv. suprarenales*) are two in number: the right ends in the inferior vena cava; the left, in the left renal or left inferior phrenic vein.

The **Inferior Phrenic Veins** (*vv. phrenicae inferiores*) follow the course of the inferior phrenic arteries; the right ends in the inferior vena cava; the left is often represented by two branches, one of which ends in the left renal or suprarenal vein, while the other passes in front of the oesophageal hiatus in the Diaphragma and opens into the inferior vena cava.

The **Hepatic Veins** (*vv. hepaticae*) commence in the substance of the liver, in the terminations of the portal vein and hepatic artery, and are arranged in two groups, upper and lower. The **upper group** usually consists of three large veins, which converge toward the posterior surface of the liver, and open into the inferior vena cava, while that vessel is situated in the groove on the back part of the liver. The veins of the **lower group** vary in number, and are of small size; they come from the right and caudate lobes. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

THE PORTAL SYSTEM OF VEINS (Fig. 651).

The **portal system** includes all the veins which drain the blood from the abdominal part of the digestive tube (with the exception of the lower part of the rectum) and from the spleen, pancreas, and gall-bladder. From these viscera the blood is conveyed to the liver by the **portal vein**. In the liver this vein ramifies like an artery and ends in capillary-like vessels termed **sinusoids**, from which the blood is conveyed to the inferior vena cava by the hepatic veins. From this it will be seen that the blood of the portal system passes through two sets of minute vessels, viz., (a) the capillaries of the digestive tube, spleen, pancreas, and gall-bladder; and (b) the sinusoids of the liver. In the adult the portal vein and its tributaries are destitute of valves; in the fetus and for a short time after birth valves can be demonstrated in the tributaries of the portal vein; as a rule they soon atrophy and disappear, but in some subjects they persist in a degenerate form.

The **portal vein** (*vena portae*) is about 8 cm. in length, and is formed at the level of the second lumbar vertebra by the junction of the superior mesenteric and lienal veins, the union of these veins taking place in front of the inferior vena cava and behind the neck of the pancreas. It passes upward behind the superior part of the duodenum and then ascends in the right border of the lesser omentum to the right extremity of the porta hepatis, where it divides into a right and a left branch, which accompany the corresponding branches of the hepatic artery into the substance of the liver. In the lesser omentum it is placed behind and between the common bile duct and the hepatic artery, the former lying to the right of the latter. It is surrounded by the hepatic plexus of nerves, and is accompanied by numerous lymphatic vessels and some lymph glands. The **right branch** of the portal vein enters the right lobe of the liver, but before doing so generally receives the cystic vein. The **left branch**, longer but of smaller calibre than the right, crosses the left

sagittal fossa, gives branches to the caudate lobe, and then enters the left lobe of the liver. As it crosses the left sagittal fossa it is joined in front by a fibrous cord, the **ligamentum teres** (*obliterated umbilical vein*), and is united to the inferior vena cava by a second fibrous cord, the **ligamentum venosum** (*obliterated ductus venosus*).

FIG. 651.—The portal vein and its tributaries.

Tributaries.—The tributaries of the portal vein are:

Lienal.	Pyloric.
Superior Mesenteric.	Cystic.
Coronary.	Parumbilical.

The **Lienal Vein** (*v. lienalis; splenic vein*) commences by five or six large branches which return the blood from the spleen. These unite to form a single vessel, which passes from left to right, grooving the upper and back part of the pancreas, below the lineal artery, and ends behind the neck of the pancreas by uniting at a right angle with the superior mesenteric to form the portal vein. The lienal vein is of large size, but is not tortuous like the artery.

Tributaries.—The lineal vein receives the short gastric veins, the left gastroepiploic vein, the pancreatic veins, and the inferior mesenteric veins.

The **short gastric veins** (*vv. gastricae breves*), four or five in number, drain the fundus and left part of the greater curvature of the stomach, and pass between the two layers of the gastrolial ligament to end in the lienal vein or in one of its large tributaries.

The **left gastroepiploic vein** (*v. gastroepiploica sinistra*) receives branches from the antero-superior and postero-inferior surfaces of the stomach and from the greater omentum; it runs from right to left along the greater curvature of the stomach and ends in the commencement of the lienal vein.

The **pancreatic veins** (*vv. pancreaticae*) consist of several small vessels which drain the body and tail of the pancreas, and open into the trunk of the lienal vein.

The **inferior mesenteric vein** (*v. mesenterica inferior*) returns blood from the rectum and the sigmoid, and descending parts of the colon. It begins in the rectum as the **superior hemorrhoidal vein**, which has its origin in the hemorrhoidal plexus, and through this plexus communicates with the middle and inferior hemorrhoidal veins. The superior hemorrhoidal vein leaves the lesser pelvis and crosses the left common iliac vessels with the superior hemorrhoidal artery, and is continued upward as the inferior mesenteric vein. This vein lies to the left of its artery, and ascends behind the peritoneum and in front of the left Psoas major; it then passes behind the body of the pancreas and opens into the lienal vein; sometimes it ends in the angle of union of the lienal and superior mesenteric veins.

Tributaries.—The inferior mesenteric vein receives the **sigmoid veins** from the sigmoid colon and iliac colon, and the **left colic vein** from the descending colon and left colic flexure.

The **Superior Mesenteric Vein** (*v. mesenterica superior*) returns the blood from the small intestine, from the cecum, and from the ascending and transverse portions of the colon. It begins in the right iliac fossa by the union of the veins which drain the terminal part of the ileum, the cecum, and vermiform process, and ascends between the two layers of the mesentery on the right side of the superior mesenteric artery. In its upward course it passes in front of the right ureter, the inferior vena cava, the inferior part of the duodenum, and the lower portion of the head of the pancreas. Behind the neck of the pancreas it unites with the lienal vein to form the portal vein.

Tributaries.—Besides the tributaries which correspond with the branches of the superior mesenteric artery, viz., the **intestinal, ileocolic, right colic, and middle colic veins**, the superior mesenteric vein is joined by the right gastroepiploic and pancreaticoduodenal veins.

The **right gastroepiploic vein** (*v. gastroepiploica dextra*) receives branches from the greater omentum and from the lower parts of the antero-superior and postero-inferior surfaces of the stomach; it runs from left to right along the greater curvature of the stomach between the two layers of the greater omentum.

The **pancreaticoduodenal veins** (*vv. pancreaticoduodenales*) accompany their corresponding arteries; the lower of the two frequently joins the right gastroepiploic vein.

The **Coronary Vein** (*v. coronaria ventriculi; gastric vein*) derives tributaries from both surfaces of the stomach; it runs from right to left along the lesser curvature of the stomach, between the two layers of the lesser omentum, to the œsophageal opening of the stomach, where it receives some œsophageal veins. It then turns backward and passes from left to right behind the omental bursa and ends in the portal vein.

The **Pyloric Vein** is of small size, and runs from left to right along the pyloric portion of the lesser curvature of the stomach, between the two layers of the lesser omentum, to end in the portal vein.

The **Cystic Vein** (*v. cystica*) drains the blood from the gall-bladder, and, accompanying the cystic duct, usually ends in the right branch of the portal vein.

Parumbilical Veins (*vv. parumbilicales*).—In the course of the ligamentum teres of the liver and of the middle umbilical ligament, small veins (*parumbilical*) are found which establish an anastomosis between the veins of the anterior abdominal wall and the portal, hypogastric, and iliac veins. The best marked of these small veins is one which commences at the umbilicus and runs backward and upward in, or on the surface of, the ligamentum teres between the layers of the falciform ligament to end in the left portal vein.

Applied Anatomy.—Obstruction to the portal vein may produce ascites, and this may arise from many causes: as (1) the pressure of a tumor on the portal vein, such as cancer or hydatid cyst in the liver, enlarged lymph glands in the lesser omentum, or cancer of the head of the pancreas; (2) from cirrhosis of the liver, when the radicles of the portal vein are pressed upon by the contracting fibrous tissue in the portal canals; (3) from valvular disease of the heart, and back pressure on the hepatic veins, and so on the whole of the circulation through the liver. In this condition the prognosis as regards life and freedom from ascites may be much improved by the establishment of a good collateral venous circulation to relieve the portal obstruction in the liver. This is effected by communications between (a) the gastric veins and the œsophageal veins which often project as a varicose bunch into the stomach, emptying themselves into the hemiazygos vein; (b) the veins of the colon and duodenum and the left renal vein; (c) the accessory portal system of Sappey, branches of which pass in the round and falciform ligaments (particularly the latter) to unite with the epigastric and internal mammary veins, and through the diaphragmatic veins with the azygos; a single large vein, shown to be a parumbilical vein, may pass from the hilus of the liver by the round ligament to the umbilicus, producing there a bunch of prominent varicose veins known as the *caput medusae*; (d) the veins of Retzius, which connect the intestinal veins with the inferior vena cava and its retroperitoneal branches; (e) the inferior mesenteric veins, and the hemorrhoidal veins that open into the hypogastriacs; (f) very rarely the ductus venosus remains patent, affording a direct connection between the portal vein and the inferior vena cava.

An operation for the relief of portal obstruction on these lines has been advocated by Rutherford Morison and by Talma. It consists in curetting the opposed surfaces of the liver and Diaphragma and stitching them together, so as to secure vascular inflammatory adhesions between the two. The greater omentum may with advantage be interposed between them, so as to increase the amount of the adhesions, and the spleen has been similarly scraped and sutured to or into the abdominal wall. The operation should not be deferred until the patient is moribund.

Thrombosis of the portal vein, or pylethrombosis, is a very serious event, and is oftenest due to pathological processes causing compression of the vessel or injury to its wall, such as tumors or inflammation about the pylorus, head of the pancreas, or vermiform process, or to gall-stones, or cirrhosis of the liver. If the thrombus is infected with bacteria, as is often the case when it is due to appendicitis, septic or suppurative pylephlebitis results; this condition is known also as *portal pyemia*. Fragments of the infected clot break off and are carried away to lodge in the smaller veins in the liver, with the development of multiple abscesses in its substance and a rapidly fatal result. When the thrombus is sterile, the chief signs produced are enlargement of the spleen, recurrent ascites, and the establishment of a collateral venous circulation, the case clinically resembling one of atrophic cirrhosis of the liver.

The symptoms of thrombosis of the mesenteric veins are very much the same as those of embolism of the mesenteric arteries (see p. 696).

THE LYMPHATIC SYSTEM.

THE lymphatic system includes the **lymphatic vessels** and **lymph glands**. The lymphatic vessels of the small intestine receive the special designation of **lacteals** or **chyliferous vessels**; they differ in no respect from the lymphatic vessels generally excepting that during the process of digestion they contain a milk-white fluid, the **chyle**.

The **lymphatic vessels** are exceedingly delicate, and their coats are so transparent that the fluid they contain is readily seen through them. They are interrupted at intervals by constrictions, which give them a knotted or beaded appearance; these constrictions correspond to the situations of valves in their interior. Lymphatic vessels have been found in nearly every texture and organ of the body which contains bloodvessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but these with exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

Structure of Lymphatic Vessels.—The larger lymphatic vessels are each composed of three coats. The *internal* coat is thin, transparent, slightly elastic, and consists of a layer of elongated endothelial cells with wavy margins by which the contiguous cells are dovetailed into one another; the cells are supported on an elastic membrane. The *middle* coat is composed of smooth muscular and fine elastic fibres, disposed in a transverse direction. The *external* coat consists of connective tissue, intermixed with smooth muscular fibres longitudinally or obliquely disposed; it forms a protective covering to the other coats, and serves to connect the vessel with the neighboring structures. In the smaller vessels there are no muscular or elastic fibres, and the wall consists only of a connective-tissue coat, lined by endothelium. The thoracic duct has a more complex structure than the other lymphatic vessels; it presents a distinct subendothelial layer of branched corpuscles, similar to that found in the arteries; in the middle coat there is, in addition to the muscular and elastic fibres, a layer of connective tissue with its fibres arranged longitudinally. The lymphatic vessels are supplied by nutrient vessels, which are distributed to their outer and middle coats; and here also have been traced many non-medullated nerves in the form of a fine plexus of fibrils.

The valves of the lymphatic vessels are formed of thin layers of fibrous tissue covered on both surfaces by endothelium which presents the same arrangement as on the valves of veins (p. 599). In form the valves are semilunar; they are attached by their convex edges to the wall of the vessel, the concave edges being free and directed along the course of the contained current. Usually two such valves, of equal size, are found opposite one another; but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels. Thus, one valve may be of small size and the other increased in proportion.

In the lymphatic vessels the valves are placed at much shorter intervals than in the veins. They are most numerous near the lymph glands, and are found more frequently in the lymphatic vessels of the neck and upper extremity than in those of the lower extremity. The wall of the lymphatic vessel immediately above the point of attachment of each segment of a valve is expanded into a pouch or sinus which gives to these vessels, when distended, the knotted or beaded appearance already referred to. Valves are wanting in the vessels composing the plexiform net-work in which the lymphatic vessels usually originate on the surface of the body.

The **lymph glands** (*lymphoglandulae*) are small oval or bean-shaped bodies, situated in the course of lymphatic and lacteal vessels so that the lymph and chyle pass through them on their way to the blood. Each generally presents on one side a slight depression—the **hilus**—through which the bloodvessels enter and leave the interior. The efferent lymphatic vessel also emerges from the gland at this spot, while the afferent vessels enter the organ at different parts of the periphery. On section (Fig. 652) a lymph gland displays two different structures: an external,

of lighter color—the **cortical**; and an internal, darker—the **medullary**. The cortical structure does not form a complete investment, but is deficient at the hilum, where the medullary portion reaches the surface of the gland; so that the efferent vessel is derived directly from the medullary structures, while the afferent vessels empty themselves into the cortical substance.

*Lymphoid

*Lymph-path
in medulla*

FIG. 652.—Section of small lymph gland of rabbit $\times 100$.

Structure of Lymph Glands.—A lymph gland consists of (1) a fibrous envelope, or **capsule**, from which a frame-work of processes (*trabeculae*) proceeds inward, imperfectly dividing the gland into open spaces freely communicating with each other; (2) a quantity of lymphoid tissue occupying these spaces without completely filling them; (3) a free supply of bloodvessels, which

a.

c.

d.

FIG. 653.—Lymph gland tissue. Highly magnified. *a*, Trabecula. *b*, Small artery in substance of same. *c*, Lymph paths. *d*, Lymph corpuscles. *e*, Capillary plexus.

are supported in the trabeculae; and (4) the **afferent** and **efferent vessels** communicating through the lymph paths in the substance of the gland. The nerves passing into the hilus are few in number and are chiefly distributed to the bloodvessels supplying the gland.

The **capsule** is composed of connective tissue with some plain muscle fibres, and from its internal surface are given off a number of membranous processes or trabeculae, consisting, in man, of connective tissue, with a small admixture of plain muscle fibres; but in many of the lower animals composed almost entirely of involuntary muscle. They pass inward, radiating toward the centre

of the gland, for a certain distance—that is to say, for about one-third or one-fourth of the space between the circumference and the centre of the gland. In some animals they are sufficiently well-marked to divide the peripheral or cortical portion of the gland into a number of compartments (so-called follicles), but in man this arrangement is not obvious. The larger trabeculae springing from the capsule break up into finer bands, and these interlace to form a mesh-work in the central or medullary portion of the gland. In these spaces formed by the interlacing trabeculae is contained the proper gland substance or lymphoid tissue. The gland pulp does not, however, completely fill the spaces, but leaves, between its outer margin and the enclosing trabeculae, a channel or space of uniform width throughout. This is termed the **lymph path** or **lymph sinus** (Fig. 652). Running across it are a number of finer trabeculae of retiform connective tissue, the fibres of which are, for the most part, covered by ramifying cells.

On account of the peculiar arrangement of the frame-work of the organ, the gland pulp in the cortical portion is disposed in the form of nodules, and in the medullary part in the form of rounded cords. It consists of ordinary lymphoid tissue (Fig. 653), being made up of a delicate net-work of retiform tissue, which is continuous with that in the lymph paths, but marked off from it by a closer reticulation; it is probable, moreover, that the reticular tissue of the gland pulp and the lymph paths is continuous with that of the trabeculae, and ultimately with that of the capsule of the gland. In its meshes, in the nodules and cords of lymphoid tissue, are closely packed lymph corpuscles. The gland pulp is traversed by a dense plexus of capillary bloodvessels. The nodules or follicles in the cortical portion of the gland frequently show, in their centres, areas where karyokinetic figures indicate a division of the lymph corpuscles. These areas are termed **germ centres**. The cells composing them have more abundant protoplasm than the peripheral cells.

The **afferent vessels**, as stated above, enter at all parts of the periphery of the gland, and after branching and forming a dense plexus in the substance of the capsule, open into the lymph sinuses of the cortical part. In doing this they lose all their coats except their endothelial lining, which is continuous with a layer of similar cells lining the lymph paths. In like manner the **efferent vessel** commences from the lymph sinuses of the medullary portion. The stream of lymph carried to the gland by the afferent vessels thus passes through the plexus in the capsule to the lymph paths of the cortical portion, where it is exposed to the action of the gland pulp; flowing through these it enters the paths or sinuses of the medullary portion, and finally emerges from the hilus by means of the efferent vessel. The stream of lymph in its passage through the lymph sinuses is much retarded by the presence of the reticulum, hence morphological elements, either normal or morbid, are easily arrested and deposited in the sinuses. Many lymph corpuscles pass with the efferent lymph stream to join the general blood stream. The arteries of the gland enter at the hilus, and either go at once to the gland pulp, to break up into a capillary plexus, or else run along the trabeculae, partly to supply them and partly running across the lymph paths, to assist in forming the capillary plexus of the gland pulp. This plexus traverses the lymphoid tissue, but does not enter into the lymph sinuses. From it the veins commence and emerge from the organ at the same place as that at which the arteries enter.

The lymphatic vessels are arranged into a **superficial** and a **deep set**. On the surface of the body the **superficial** lymphatic vessels are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatic vessels in certain situations by perforating the deep fascia. In the interior of the body they lie in the submucous areolar tissue, throughout the whole length of the digestive, respiratory, and genito-urinary tracts; and in the subserous tissue of the thoracic and abdominal walls. Plexiform networks of minute lymphatic vessels are found interspersed among the proper elements and bloodvessels of the several tissues; the vessels composing the net-work, as well as the meshes between them, are much larger than those of the capillary plexus. From these net-works small vessels emerge, which pass, either to a neighboring gland, or to join some larger lymphatic trunk. The **deep** lymphatic vessels, fewer in number, but larger than the superficial, accompany the deep bloodvessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatic vessels of any part or organ exceed the veins in number, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect, the continuous trunks retaining the same diameter.

Applied Anatomy.—The lymphatic channels and lymph glands draining any infected area of the body are very liable to become infected, resulting in acute or chronic lymphangitis and lymphadenitis. In acute cases the paths of the superficial lymphatic vessels are often marked

out on the skin by pain, redness, heat, and swelling, while the glands swell and may suppurate. Chronic inflammation leads to growth and fibrosis of the lymphatic vessels and the connective tissue around them; obstruction to the passage of the lymph results, as the fibrous tissue contracts and causes stenosis or obliteration of the lymphatic channels, and hard cedema of the involved skin and subcutaneous tissues follows (*pachydermia lymphangiectatica*). Chronic lymphangitis, together with the blocking of numerous lymphatic vessels by the escaped ova of the minute parasitic worm *Microfilaria nocturna*, is the cause of elephantiasis, a condition common in the tropics and subtropics, and characterized by enormous enlargement and thickening of the integuments of some part of the body, most frequently of the leg. Tubercular and syphilitic enlargements of the lymphatic vessels and glands are both very commonly met with. Primary tumors of the lymphatic vessels are lymphangioma and endothelioma; the so-called "congenital cystic hygroma" of the neck, arm, trunk, or thigh, is a cystic lymphangioma. Primary tumors of the lymph glands may be innocent (lymphadenoma, myxoma, chondroma) or malignant (lymphosarcoma); cancer is never met with as a primary affection, but is extremely common secondarily to cancer of some other part of the body.

The appearance of secondary malignant deposits or of secondary infection in parts of the body that seem not to be directly associated by any lymphatic connection with the seat of the primary growth or infection has often been observed, and explained as due to "retrograde transport" of cancer cells or bacteria by a reversed flow of lymph. Weleminsky,¹ however, believes that the explanation is to be found in the fact that when the infected glands have grown to a certain size they no longer permit the normal flow of lymph through them, and that under these circumstances very delicate lymphatic connections, whose existence normally remains unsuspected, develop to a surprising extent between groups of lymph glands that at first sight appear to be unconnected with one another.

THE THORACIC DUCT.

The **thoracic duct** (*ductus thoracicus*) (Fig. 654) conveys the greater part of the lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body, excepting those on the right side of the head, neck, and thorax, and right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. In the adult it varies in length from 38 to 45 cm. and extends from the second lumbar vertebra to the root of the neck. It begins in the abdomen by a triangular dilatation, the **cisterna chyli**, which is situated on the front of the body of the second lumbar vertebra, to the right side of and behind the aorta, by the side of the right crus of the Diaphragma. It enters the thorax through the aortic hiatus of the Diaphragma, and ascends through the posterior mediastinal cavity between the aorta and azygos vein. Behind it in this region are the vertebral column, the right intercostal arteries, and the hemiazygos veins as they cross to open into the azygos vein; in front of it are the Diaphragma, œsophagus, and pericardium, the last being separated from it by a recess of the right pleural cavity. Opposite the fifth thoracic vertebra, it inclines toward the left side, enters the superior mediastinal cavity, and ascends behind the aortic arch and the thoracic part of the left subclavian artery and between the left side of the œsophagus and the left pleura, to the upper orifice of the thorax. Passing into the neck it forms an arch which rises about 3 or 4 cm. above the clavicle and crosses anterior to the subclavian artery, the vertebral artery and vein, and the thyrocervical trunk or its branches. It also passes in front of the phrenic nerve and the medial border of the Scalenus anterior, but is separated from these two structures by the pre-vertebral fascia. In front of it are the left common carotid artery, vagus nerve, and internal jugular vein; it ends by opening into the angle of junction of the left subclavian vein with the left internal jugular vein. The thoracic duct, at its commencement, is about equal in diameter to a goose-quill, but it diminishes considerably in calibre in the middle of the thorax, and is again dilated just before its termination. It is generally flexuous, and constricted at intervals so as to present a varicose appearance. Not infrequently it divides in the middle of its course into two vessels of unequal size which soon reunite, or into several branches which form

¹ Berliner klin. Woch., 1905, No. 24, p. 743.

a plexiform interlacement. It occasionally divides at its upper part into two branches, right and left; the left ending in the usual manner, while the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has several valves; at its termination it is provided with a pair, the free borders of which are turned toward the vein, so as to prevent the passage of venous blood into the duct.

R
lym
d

The *cisterna chyli* (*receptaculum chyli*) (Fig. 655) receives the two lumbar lymphatic trunks, right and left, and the intestinal lymphatic trunk. The lumbar trunks are formed by the union of the efferent vessels from the lateral aortic lymph glands. They receive the lymph from the lower limbs, from the walls and viscera of the pelvis, from the kidneys and suprarenal glands and the deep lymphatics of the greater part of the abdominal wall. The *intestinal trunk* receives the lymph from the stomach and intestine, from the pancreas and spleen, and from the lower and front part of the liver.

6

Tributaries.—Opening into the commencement of the thoracic duct, on either side, is a descending trunk from the posterior intercostal lymph glands of the lower six or seven intercostal spaces. In the thorax the duct is joined, on either side, by a trunk which drains the upper lumbar lymph glands and pierces the crus of the Diaphragm. It also receives the efferents from the posterior mediastinal lymph glands and from the posterior intercostal lymph glands of the upper six left spaces. In the neck it is joined by the *left jugular and left subclavian trunks*, and sometimes by the *left broncho-mediastinal trunk*; the last-named, however, usually opens independently into the junction of the left subclavian and internal jugular veins.

Lm

FIG. 654.—The thoracic and right lymphatic ducts.

The *right lymphatic duct* (*ductus lymphaticus dexter*) (Fig. 656), about 1.25 cm. in length, courses along the medial border of the *Scalenus anterior* at the root of the neck and ends in the right subclavian vein, at its angle of junction with the right internal jugular vein. Its orifice is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—The right lymphatic duct receives the lymph from the right side of the head and neck through the **right jugular trunk**; from the right upper extremity through the **right subclavian trunk**; from the right side of the thorax, right lung, right side of the heart, and part of the convex surface of the liver, through the **right bronchomediastinal trunk**. These three collecting trunks frequently open separately in the angle of union of the two veins.

FIG. 655.—Modes of origin of thoracic duct. (Poirier and Charpy.) a. Thoracic duct. a'. Cisterna chyli. b. Effluent trunks from lateral aortic glands. c. An efferent vessel which pierces the left crus of the diaphragm. d. Lateral aortic glands. e. Retroaortic glands. f. Intestinal trunk. g. Descending branch from intercostal lymphatics.

Applied Anatomy.—Blockage of the thoracic duct by mature specimens of the minute parasite *Microfilaria nocturna* gives rise to stasis of the chyle, and to its passage in various abnormal directions on its course past the obstruction. The neighboring abdominal, renal, and pelvic lymphatics become enlarged, varicose, and tortuous, and chyle may make its way into the urine (*chyluria*), the tunica vaginalis (*chylocele*), the abdominal cavity (*chylous ascites*), or the pleural cavity (*chylous pleural effusion*), in consequence of rupture of some of these distended lymphatics.

THE LYMPHATICS OF THE HEAD, FACE, AND NECK.**The Lymph Glands of the Head (Fig. 657).**

The lymph glands of the head are arranged in the following groups:

Occipital.

Posterior Auricular.

Anterior Auricular.

Parotid.

Facial.

Deep Facial.

Lingual.

Retropharyngeal.

of the auricula or pinna, and the back of the external acoustic meatus; their efferents pass to the superior deep cervical glands.

The **anterior auricular glands** (*lymphoglandulae auriculares anteriores*; *superficial parotid or preauricular glands*), from one to three in number, lie immediately in front of the tragus. Their afferents drain the lateral surface of the auricula and the skin of the adjacent part of the temporal region; their efferents pass to the superior deep cervical glands.

The **parotid glands** (*lymphoglandulae parotidae*), form two groups in relation with the parotid salivary gland, viz., a group imbedded in the substance of the gland and a group of subparotid glands lying on the lateral wall of the pharynx. Occasionally small glands are found in the subcutaneous tissue over the parotid gland. Their afferent vessels drain the root of the nose, the eyelids, the frontotemporal region, the external acoustic meatus and the tympanic cavity, possibly also the posterior parts of the palate and the floor of the nasal cavity. The efferents of these glands pass to the superior deep cervical glands. The afferents of the subparotid glands drain the nasal part of the pharynx and the posterior parts of the nasal cavities; their efferents pass to the superior deep cervical glands.

FIG. 653.—Lymphatics of pharynx. (Poirier and Charpy.)

The **facial glands** comprise three groups: (a) **infraorbital or maxillary**, scattered over the infraorbital region from the groove between the nose and cheek to the zygomatic arch; (b) **buccinator**, one or more placed on the Buccinator opposite the angle of the mouth; (c) **supramandibular**, on the outer surface of the mandible, in front of the Masseter and in contact with the external maxillary artery and anterior facial vein. Their efferent vessels drain the eyelids, the conjunctiva, and the skin and mucous membrane of the nose and cheek; their efferents pass to the submaxillary glands.

The **deep facial glands** (*lymphoglandulae faciales profunda*; *internal maxillary glands*) are placed beneath the ramus of the mandible, on the outer surface of the Pterygoideus externus, in relation to the internal maxillary artery. Their afferent vessels drain the temporal and infratemporal fossae and the nasal part of the pharynx; their efferents pass to the superior deep cervical glands.

The **lingual glands** (*lymphoglandulae linguales*) are two or three small nodules lying on the Hyoglossus and under the Genioglossus. They form merely substationary points in the course of the lymphatic vessels of the tongue.

The **retropharyngeal glands** (Fig. 658), from one to three in number, lie in the buccopharyngeal fascia, behind the upper part of the pharynx and in front of the arch of the atlas, being separated, however, from the latter by the *Longus capitis*. Their afferents drain the nasal cavities, the nasal part of the pharynx, and the auditory tubes; their efferents pass to the superior deep cervical glands.

The lymphatic vessels of the scalp are divisible into (a) those of the frontal region, which terminate in the anterior auricular and parotid glands; (b) those of the temporoparietal region, which end in the parotid and posterior auricular glands; and (c) those of the occipital region, which terminate partly in the occipital glands and partly in a trunk which runs down along the posterior border of the *Sternocleidomastoideus* to end in the inferior deep cervical glands.

The lymphatic vessels of the auricle and external acoustic meatus are also divisible into three groups: (a) an anterior, from the lateral surface of the auricle and anterior wall of the meatus to the anterior auricular glands; (b) a posterior, from the margin of the auricle, the upper part of its cranial surface, the internal surface and posterior wall of the meatus to the posterior auricular and superior deep cervical glands; (c) an inferior, from the floor of the meatus and from the lobule of the auricle to the superficial and superior deep cervical glands.

Parotid glands

Facial glands

Submaxillary glands

Superficial cervical glands

Deep cervical glands

FIG. 659.—The lymphatics of the face. (After Kottner.)

The lymphatic vessels of the face (Fig. 659) are more numerous than those of the scalp. Those from the eyelids and conjunctiva terminate partly in the submaxillary but mainly in the parotid glands. The vessels from the posterior part of the cheek also pass to the parotid glands, while those from the anterior portion of the cheek, the side of the nose, the upper lip, and the lateral portions of the lower lip end in the submaxillary glands. The deeper vessels from the temporal and infratemporal fossæ pass to the deep facial and superior deep cervical glands. The deeper vessels of the cheek and lips end, like the superficial, in the submaxillary glands. Both superficial and deep vessels of the central part of the lower lip run to the submental glands.

The lymphatic vessels of the nasal cavities can be injected from the subdural the submaxillary cavities. Those from the anterior parts of the nasal cavities

communicate with the vessels of the integument of the nose and end in the submaxillary glands; those from the posterior two-thirds of the nasal cavities and from the accessory air sinuses pass partly to the retropharyngeal and partly to the superior deep cervical glands.

Lymphatic Vessels of the Mouth.—The vessels of the gums pass to the submaxillary glands; those of the hard plate are continuous in front with those of the upper gum, but pass backward to pierce the Constrictor pharyngis superior and end in the superior deep cervical and subparotid glands; those of the soft palate pass backward and lateralward and end partly in the retropharyngeal and subparotid, and partly in the superior deep cervical glands. The vessels of the anterior part of the floor of the mouth pass either directly to the inferior glands of the superior deep cervical group, or indirectly through the submental glands; from the rest of the floor of the mouth the vessels pass to the submaxillary and superior deep cervical glands.

Sup

FIG. 560.—Lymphatics of the tongue. (Poirier.)

The lymphatic vessels of the palatine tonsil, usually three to five in number, pierce the buccopharyngeal fascia and constrictor pharyngis superior and pass between the Stylohyoideus and internal jugular vein to the uppermost of the superior deep cervical glands. They end in a gland which lies at the side of the posterior belly of the Digastricus, on the internal jugular vein; occasionally one or two additional vessels run to small glands on the lateral side of the cover of the Sternocleidomastoideus.

The **lymphatic vessels of the tongue** (Fig. 660) are drained chiefly into the deep cervical glands lying between the posterior belly of the Digastricus and the superior belly of the Omohyoideus; one gland situated at the bifurcation of the common carotid artery is so intimately associated with these vessels that it is known as the **principal gland of the tongue**. The lymphatic vessels of the tongue may be divided into four groups: (1) apical, from the tip of the tongue to the suprahyoid glands and principal gland of the tongue; (2) lateral, from the margin of the tongue—some of these pierce the Mylohyoideus to end in the submaxillary glands, others pass down on the Hyoglossus to the superior deep cervical glands; (3) basal, from the region of the papillae vallatae to the superior deep cervical glands; and (4) median, a few of which perforate the Mylohyoideus to reach the submaxillary glands, while the majority turn around the posterior border of the muscle to enter the superior deep cervical glands.

The Lymph Glands of the Neck.

The lymph glands of the neck include the following groups:

Submaxillary.
Submental.

Superficial Cervical.
Anterior Cervical.

Deep Cervical.

The **submaxillary glands** (*lymphoglandulae submaxillares*) (Fig. 659), three to six in number, are placed beneath the body of the mandible in the submaxillary triangle, and rest on the superficial surface of the submaxillary salivary gland.

One gland, the **middle gland of Stahr**, which lies on the external maxillary artery as it turns over the mandible, is the most constant of the series; small lymph glands are sometimes found on the deep surface of the submaxillary salivary glands. The afferents of the submaxillary glands drain the medial palpebral commissure, the cheek, the side of the nose, the upper lip, the lateral part of the lower lip, the gums, and the anterior part of the margin of the tongue; efferent vessels from the facial and submental glands also enter the submaxillary glands. Their efferent vessels pass to the superior deep cervical glands.

The **submental or suprahyoid glands** are situated between the anterior bellies of the Digastrici. Their afferents drain the central portions of the lower lip and floor of the mouth and the apex of the tongue; their efferents pass partly to the submaxillary glands and partly to a gland of the deep cervical group situated on the internal jugular vein at the level of the cricoid cartilage.

The **superficial cervical glands** (*lymphoglandulae cervicales superficiales*) lie in close relationship with the external jugular vein as it emerges from the parotid gland, and, therefore, superficial to the Sternocleidomastoideus. Their afferents drain the lower parts of the auricula and parotid region, while their efferents pass around the anterior margin of the Sternocleidomastoideus to join the superior deep cervical glands.

The **anterior cervical glands** form an irregular and inconstant group on the front of the larynx and trachea. They may be divided into (a) a **superficial set**, placed on the anterior jugular vein; (b) a **deeper set**, which is further subdivided into prelaryngeal, on the middle cricothyroid ligament, and pretracheal, on the front of the trachea. This deeper set drains the lower part of the larynx, the thyroid gland, and the upper part of the trachea; its efferents pass to the lowest of the superior deep cervical glands.

The **deep cervical glands** (*lymphoglandulae cervicales profundae*) (Figs. 657, 658) are numerous and of large size: they form a chain along the carotid sheath, lying by the side of the internal jugular vein, oesophagus, and trachea, and extending from the base of the skull to the upper part of the neck. They are usually described in two groups: the **superior deep cervical glands** and the **inferior deep cervical glands**.

(1) the **superior deep cervical glands** lying under the Sternocleidomastoideus in close relation with the accessory nerve and the internal jugular vein, some of the glands lying in front of and others behind the vessel; (2) the **inferior deep cervical glands** extending beyond the posterior margin of the Sternocleidomastoideus into the supraclavicular triangle, where they are closely related to the brachial plexus and subclavian vein. A few minute **paratracheal glands** are situated alongside the recurrent nerves on the lateral aspects of the trachea and oesophagus. The superior deep cervical glands drain the occipital portion of the scalp, the auricula, the back of the neck, a considerable part of the tongue, the larynx, thyroid gland, trachea, nasal part of the pharynx, nasal cavities, palate, and oesophagus. They receive also the efferent vessels from all the other glands of the head and neck, except those from the inferior deep cervical glands. The inferior deep cervical glands drain the back of the scalp and neck, the superficial pectoral region, part of the arm (see page 782), and, occasionally, part of the superior surface of the liver. In addition, they receive vessels from the superior deep cervical glands. The efferents of the superior deep cervical glands pass partly to the inferior deep cervical glands and partly to a trunk which unites with the efferent vessel of the inferior deep cervical glands and forms the **jugular trunk**. On the right side, this trunk ends in the junction of the internal jugular and subclavian veins; on the left side it joins the thoracic duct.

The **lymphatic vessels of the skin and muscles of the neck** pass to the deep cervical glands. From the upper part of the *pharynx* the lymphatic vessels pass to the retropharyngeal, from the lower part to the deep cervical glands. From the *larynx* two sets of vessels arise, an upper and a lower. The vessels of the upper set pierce the hyothyroid membrane and join the superior deep cervical glands. Of the lower set, some pierce the conus elasticus and join the pretracheal and prelaryngeal glands; others run between the cricoid and first tracheal ring and enter the inferior deep cervical glands. The lymphatic vessels of the *thyroid gland* consist of two sets, an upper, which accompanies the superior thyroid artery and pierces the superior deep cervical glands, and a lower, which runs partly to the pretracheal glands and partly to the small paratracheal glands which accompany the recurrent nerves. These latter glands receive also the lymphatic vessels from the cervical portion of the trachea.

Applied Anatomy.—The cervical glands are very frequently the seat of tuberculous disease. This condition is most usually set up by some lesion in those parts from which they receive their lymph. It is very desirable therefore for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery, while in order to eradicate them by operation a long and difficult dissection may be required.

THE LYMPHATICS OF THE UPPER EXTREMITY.

The Lymph Glands of the Upper Extremity (Fig. 661).

The lymph glands of the upper extremity are divided into two sets, **superficial** and **deep**.

The **superficial lymph glands** are few and of small size. One or two **supratrochlear glands** are placed above the medial epicondyle of the humerus, medial to the basilic vein. Their afferents drain the middle, ring, and little fingers, the medial portion of the hand, and the superficial area over the ulnar side of the forearm; these vessels are, however, in free communication with the other lymphatic vessels of the forearm. Their efferents accompany the basilic vein to the deeper vessels. One or two **deltoideopectoral glands** are found between the pectoral and deltoid muscles, and between the axillary vein and the axillary artery. The superficial lymphatic plexus, which everywhere pervades the skin; the meshes of the plexus:

ANGIOLOGY

deep lymph glands are chiefly grouped in the axilla, although a few may be found in the forearm, in the course of the radial, ulnar, and interosseous vessels, in the arm along the medial side of the brachial artery.

FIG. 661.—The superficial lymph glands and lymphatic vessels of the upper extremity.

The **Axillary Glands** (*lymphoglandulae axillares*) (Fig. 662) are of large size, vary from twenty to thirty in number, and may be arranged in the following groups:

1. A **lateral group** of from four to six glands lies in relation to the medial and posterior aspects of the axillary vein; the afferents of these glands drain the whole arm with the exception of that portion whose vessels accompany the cephalic vein. The efferent vessels pass partly to the central and subclavicular groups of axillary glands and partly to the inferior deep cervical glands.

2. An **anterior or pectoral group** consists of four or five glands situated beneath the Pectoralis minor, in relation with the lateral axillary vein. Their afferents drain the skin and muscles of the anterior axillary region, and their efferents pass into the venous blood into the duct.

3. A **posterior or subscapular group** of six or seven glands is placed along the lower margin of the posterior wall of the axilla in the course of the subscapular artery. The afferents of this group drain the skin and muscles of the lower part of the back of the neck and of the posterior thoracic wall; their efferents pass to the central group of axillary glands.

4. A **central or intermediate group** of three or four large glands is imbedded in the adipose tissue near the base of the axilla. Its afferents are the efferent vessels of all the preceding groups of axillary glands; its efferents pass to the subclavicular group.

FIG. 662.—Lymphatics of the mamma, and the axillary glands (semidiagrammatic). (Poirier and Charpy.)

5. A **medial or subclavicular group** of six to twelve glands is situated partly posterior to the upper portion of the Pectoralis minor and partly above the upper border of this muscle. Its only direct territorial afferents are those which accompany the cephalic vein and one which drains the upper peripheral part of the mamma, but it receives the efferents of all the other axillary glands. The efferent vessels of the subclavicular group unite to form the **subclavian trunk**, which opens either directly into the junction of the internal jugular and subclavian veins or into the jugular lymphatic trunk; on the left side it may end in the thoracic duct. A few efferents from the subclavicular glands usually pass to the inferior deep cervical glands.

Applied Anatomy.—In malignant disease or infectious processes implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the front and side of the abdomen, or the hand, forearm, and arm, enlargement of the axillary glands is very often found.

The Lymphatic Vessels of the Upper Extremity.

The lymphatic vessels of the upper extremity are divided into two sets, superficial and deep.

The **superficial lymphatic vessels** commence (Fig. 663) in the lymphatic plexus which everywhere pervades the skin; the meshes of the plexus are much finer in the

palm and on the flexor aspect of the digits than elsewhere. The digital plexuses are drained by a pair of vessels which run on the sides of each digit, and incline backward to reach the dorsum of the hand. From the dense plexus of the palm, vessels pass in different directions, viz., upward toward the wrist, downward to join the digital vessels, medialward to join the vessels on the ulnar border of the hand, and lateralward to those on the thumb. Several vessels from the central part of the plexus unite to form a trunk, which passes around the metacarpal bone of the index finger to join the vessels on the back of that digit and on the back of the thumb. Running upward in front of and behind the wrist, the lymphatic vessels are collected into radial, median, and ulnar groups, which accompany respectively the cephalic, median, and basilic veins in the forearm. A few of the ulnar lymphatics end in the supratrochlear glands, but the majority pass directly to the lateral group of axillary glands. Some of the radial vessels are collected into a trunk which ascends with the cephalic vein to the deltoideopectoral glands; the efferents from this group pass either to the subclavicular axillary glands or to the inferior cervical glands.

FIG. 663.—Lymphatic vessels of the dorsal surface of the hand. (Sappey)

The deep lymphatic vessels accompany the deep bloodvessels. In the forearm, they consist of four sets, corresponding with the radial, ulnar, volar, and dorsal interosseous arteries; they communicate at intervals with the superficial lymphatics, and some of them end in the glands which are occasionally found beside the arteries. In their course upward, a few end in the glands which lie upon the brachial artery; but most of them pass to the lateral group of axillary glands.

THE LYMPHATICS OF THE LOWER EXTREMITY.

The Lymph Glands of the Lower Extremity.

The lymph glands of the lower extremity consist of the anterior tibial gland and the popliteal and inguinal glands.

The anterior tibial gland (*lymphoglandula tibialis anterior*) is small and inconstant. It lies on the interosseous membrane in relation to the upper part of the anterior tibial vessels, and constitutes a substation in the course of the anterior tibial lymphatic trunks.

The popliteal glands (*lymphoglandulae popliteae*) (Fig. 664), small in size and some six or seven in number, are imbedded in the fat contained in the popliteal fossa. One lies immediately beneath the popliteal fascia, near the terminal part of the small saphenous vein, and drains the region from which this vein derives

its tributaries. Another is placed between the popliteal artery and the posterior surface of the knee-joint; it receives the lymphatic vessels from the knee-joint together with those which accompany the genicular arteries. The others lie at the sides of the popliteal vessels, and receive as efferents the trunks which accompany the anterior and posterior tibial vessels. The efferents of the popliteal glands pass almost entirely alongside the femoral vessels to the deep inguinal glands, but a few may accompany the great saphenous vein, and end in the glands of the superficial subinguinal group.

The **inguinal glands** (*lymphoglandulae inguinales*) (Fig. 665), from twelve to twenty in number, are situated at the upper part of the femoral triangle. They may be divided into two groups by a horizontal line at the level of the termination of the great saphenous vein; those lying above this line are termed the **superficial inguinal glands**, and those below it the **subinguinal glands**, the latter group consisting of a *superficial* and a *deep* set.

FIG. 664.—Lymph glands of popliteal fossa. (Poirier and Charpy.)

The **Superficial Inguinal Glands** form a chain immediately below the inguinal ligament. They receive as afferents lymphatic vessels from the integument of the penis, scrotum, perineum, buttock, and abdominal wall below the level of the umbilicus.

The **Superficial Subinguinal Glands** (*lymphoglandulae subinguinales superficiales*) are placed on either side of the upper part of the great saphenous vein; their efferents consist chiefly of the superficial lymphatic vessels of the lower extremity; but they also receive some of the vessels which drain the integument of the penis, scrotum, perineum, and buttock.

The **Deep Subinguinal Glands** (*lymphoglandulae subinguinales profundae*) vary from one to three in number, and are placed under the fascia lata, on the medial side of the femoral vein. When three are present, the lowest is situated just below the junction of the great saphenous and femoral veins, the middle in the femoral canal, and the highest in the lateral part of the femoral ring. The middle one is the most inconstant of the three, but the highest, the **gland of Cloquet** or **Rosenmüller**,

is also frequently absent. They receive as afferents the deep lymphatic trunks which accompany the femoral vessels, the lymphatics from the glans penis vel clitoridis, and also some of the efferents from the superficial subinguinal glands.

Applied Anatomy.—Inflammation and supuration of the popliteal glands are most commonly due to a sore on the lateral side of the heel.

The inguinal and subinguinal glands frequently become enlarged in diseases implicating the parts from which their lymphatic vessels originate. Thus in malignant or syphilitic affections of the prepuce and penis, or labia majora, in cancer of the scrotum, in abscess in the perineum, or in similar diseases affecting the integument and superficial structures in those parts, or the subumbilical part of the abdominal wall, or the gluteal region, the upper group of glands is almost invariably enlarged, the lower groups being implicated in diseases affecting the lower limb.

The Lymphatic Vessels of the Lower Extremity.

The lymphatic vessels of the lower extremity consist of two sets, superficial and deep, and in their distribution correspond closely with the veins.

The **superficial lymphatic vessels** lie in the superficial fascia, and are divisible into two groups: a medial, which follows the course of the great saphenous vein, and a lateral, which accompanies the small saphenous vein. The vessels of the **medial group** (Fig. 665) are larger and more numerous than those of the lateral group, and commence on the tibial side and dorsum of the foot; they ascend both in front of and behind the medial malleolus, run up the leg with the great saphenous vein, pass with it behind the medial condyle of the femur, and accompany it to the groin, where they end in the subinguinal group of superficial glands. The vessels of the **lateral group** arise from the fibular side of the foot; some ascend in front of the leg, and, just below the knee, cross the tibia to join the lymphatics on the medial side of the thigh; others pass behind the lateral malleolus, and, accompanying the small saphenous vein, enter the popliteal glands.

FIG. 665.—The superficial lymph glands and lymphatic vessels of the lower extremity

The **deep lymphatic vessels** are few in number, and accompany the deep bloodvessels. In the leg, they consist of three sets, the anterior tibial, posterior tibial, and peroneal, which accompany the corresponding bloodvessels, two or three with each artery; they enter the popliteal lymph glands.

The deep lymphatic vessels of the gluteal and ischial regions follow the course of the corresponding bloodvessels. Those accompanying the superior gluteal vessels end in a gland which lies on the intrapelvic portion of the superior gluteal artery near the upper border of the greater sciatic foramen. Those following the inferior gluteal vessels traverse one or two small glands which lie below the Piriformis muscle, and end in the hypogastric glands.

Left lateral aortic

FIG. 566.—The parietal lymph glands of the pelvis. (Cunéo and Mareille.)

THE LYMPHATICS OF THE ABDOMEN AND PELVIS.

The Lymph Glands of the Abdomen and Pelvis.

The lymph glands of the abdomen and pelvis may be divided, from their situations, into (a) **parietal**, lying behind the peritoneum and in close association with the larger bloodvessels; and (b) **visceral**, which are found in relation to the visceral arteries.

The **parietal glands** (Figs. 666, 667) include the following groups:

External Iliac.	Iliac Circumflex.	Lumbar {	Lateral Aortic.
Common Iliac.	Hypogastric.		
Epigastric.	Sacral.		
			Preaortic.
			Retroaortic.

The **External Iliac Glands**, from eight to ten in number, lie along the external iliac vessels. They are arranged in three groups, one on the lateral, another on the medial, and a third on the anterior aspect of the vessels; the third group is, however, sometimes absent. Their principal afferents are derived from the inguinal and subinguinal glands, the deep lymphatics of the abdominal wall below the umbilicus and of the adductor region of the thigh, and the lymphatics from the glans penis vel clitoridis, the membranous urethra, the prostate, the fundus of the bladder, the cervix uteri, and upper part of the vagina.

FIG. 667.—Iliopelvic glands (lateral view). (Cunéo and Marcille.)

The **Common Iliac Glands**, four to six in number, are grouped behind and on the sides of the common iliac artery, one or two being placed below the bifurcation of the aorta, in front of the fifth lumbar vertebra. They drain chiefly the hypogastric and external iliac glands, and their efferents pass to the lateral aortic glands.

The **Epigastric Glands** (*lymphoglandulae epigastricae*), three or four in number, are placed alongside the lower portion of the inferior epigastric vessels.

The **Iliac Circumflex Glands**, two to four in number, are situated along the course of the deep iliac circumflex vessels; they are sometimes absent.

The **Hypogastric Glands** (*lymphoglandulae hypogastricae*; *internal iliac gland*) (Fig. 667) surround the hypogastric vessels, and receive the lymphatics corresponding to the distribution of the branches of the hypogastric artery, *i. e.*, they receive lymphatics from all the pelvic viscera, from the deeper parts of the perineum,

including the membranous and cavernous portions of the urethra, and from the buttock and back of the thigh. An **obturator gland** is sometimes seen in the upper part of the obturator foramen.

The **Sacral Glands** are placed in the concavity of the sacrum, in relation to the middle and lateral sacral arteries; they receive lymphatics from the rectum and posterior wall of the pelvis.

The efferents of the hypogastric group end in the common iliac glands.

The **Lumbar Glands** (*lymphoglandulae lumbales*) are very numerous, and consist of right and left lateral aortic, preaortic, and retroaortic groups.

The **right lateral aortic glands** are situated partly in front of the inferior vena cava, near the termination of the renal vein, and partly behind it on the origin of the Psoas major, and on the right crus of the Diaphragma. The **left lateral aortic glands** form a chain on the left side of the abdominal aorta in front of the origin of the Psoas major and left crus of the Diaphragma. The glands on either side receive (a) the efferents of the common iliac glands, (b) the lymphatics from the testis in the male and from the ovary, uterine tube, and body of the uterus in the female; (c) the lymphatics from the kidney and suprarenal gland; and (d) the lymphatics draining the lateral abdominal muscles and accompanying the lumbar veins. Most of the efferent vessels of the lateral aortic glands converge to form the **right and left lumbar trunks** which join the cisterna chyli, but some enter the pre- and retroaortic glands, and others pierce the crura of the Diaphragma to join the lower end of the thoracic duct. The **preaortic glands** lie in front of the aorta, and may be divided into **coeliac**, **superior mesenteric**, and **inferior mesenteric** groups, arranged around the origins of the corresponding arteries. They receive a few vessels from the lateral aortic glands, but their principal afferents are derived from the viscera supplied by the three arteries with which they are associated. Some of their efferents pass to the retroaortic glands, but the majority unite to form the **intestinal trunk**, which enters the cisterna chyli. The **retroaortic glands** are placed below the cisterna chyli, on the bodies of the third and fourth lumbar vertebræ. They receive lymphatic trunks from the lateral and preaortic glands, while their efferents end in the cisterna chyli.

The Lymphatic Vessels of the Abdomen and Pelvis.

The lymphatic vessels of the walls of the abdomen and pelvis may be divided into two sets, superficial and deep.

The **superficial vessels** follow the course of the superficial bloodvessels and converge to the superficial inguinal glands; those derived from the integument of the front of the abdomen below the umbilicus follow the course of the superficial epigastric vessels, and those from the sides of the lumbar part of the abdominal wall pass along the crest of the ilium, with the superficial iliac circumflex vessels. The superficial lymphatic vessels of the gluteal region turn horizontally around the buttock, and join the superficial inguinal and subinguinal glands.

The **deep vessels** run alongside the principal bloodvessels. Those of the parietes of the pelvis, which accompany the superior and inferior gluteal, and obturator vessels, follow the course of the hypogastric artery, and ultimately join the lateral aortic glands.

Lymphatic Vessels of the Perineum and External Genitals.—The lymphatic vessels of the perineum, of the integument of the penis, and of the scrotum (or vulva), follow the course of the external pudendal vessels, and end in the superficial inguinal and subinguinal glands. Those of the glans penis vel clitoridis terminate partly in the deep subinguinal glands and partly in the external iliac glands.

The **visceral glands** are associated with the branches of the coeliac, superior

and inferior mesenteric arteries. Those related to the branches of the cœliac artery form three sets, gastric, hepatic, and pancreaticolienal.

The **Gastric Glands** (Figs. 668, 669) consist of two sets, **superior** and **inferior**.

The **Superior Gastric Glands** (*lymphoglandulae gastricae superiores*) accompany the left gastric artery and are divisible into three groups, viz.: (a) **upper**, on the stem of the artery; (b) **lower**, accompanying the descending branches of the artery along the cardiac half of the lesser curvature of the stomach, between the two layers of the lesser omentum; and (c) **paracardial** outlying members of the gastric glands, disposed in a manner comparable to a chain of beads around the neck of the stomach (Jamieson and Dobson¹). They receive their afferents from the stomach; their efferents pass to the cœliac group of preaortic glands.

Paracardial glands

*Subp
gla*

Inferior gastric glands

FIG. 668.—Lymphatics of stomach, etc. (Jamieson and Dobson.)

The **Inferior Gastric Glands** (*lymphoglandulae gastricae inferiores*; *right gastroepiploic gland*), four to seven in number, lie between the two layers of the greater omentum along the pyloric half of the greater curvature of the stomach, and may be regarded as an outlying group of the hepatic glands.

The **Hepatic Glands** (*lymphoglandulae hepaticae*) (Fig. 668), consist of the following groups: (a) **hepatic**, on the stem of the hepatic artery, and extending upward along the common bile duct, between the two layers of the lesser omentum, as far as the porta hepatis; the **cystic gland**, a member of this group, is placed near the neck of the gall-bladder; (b) **subpyloric**, four or five in number, in close relation to the bifurcation of the gastroduodenal artery, in the angle between the superior and descending parts of the duodenum; an outlying member of this group is sometimes found above the duodenum on the right gastric (pyloric) artery. The glands of the hepatic chain receive afferents from the stomach, duodenum, liver, gall-bladder, and pancreas; their efferents join the cœliac group of preaortic glands.

The **Pancreaticolienal Glands** (*lymphoglandulae pancreaticolienales*; *splenic glands*) (Fig. 669) accompany the lienal (splenic) artery, and are situated in relation to the posterior surface and upper border of the pancreas; one or two members

¹ Lancet, April 20 and 27, 1907.

of this group are found in the gastrolial ligament (Jamieson and Dobson, *op. cit.*). Their afferents are derived from the stomach, spleen, and pancreas, their efferents join the coeliac group of preaortic glands.

The **superior mesenteric glands** may be divided into three principal groups: **mesenteric**, **ileocolic**, and **mesocolic**.

The **Mesenteric Glands** (*lymphoglandulae mesentericae*) lie between the layers of the mesentery. They vary from one hundred to one hundred and fifty in number, and may be grouped into three sets, viz.: one lying close to the wall of the small intestine, among the terminal twigs of the superior mesenteric artery; a second, in relation to the loops and primary branches of the vessels; and a third along the trunk of the artery.

Sub
9

FIG. 660.—Lymphatics of stomach, etc. The stomach has been turned upward. (Jamieson and Dobson.)

Applied Anatomy.—Enlargement of the mesenteric lymphatic glands is seen in most diseased conditions of the intestinal tract, and is well-marked in enteric fever, tuberculous ulceration or malignant growths of the bowel. The enlarged glands can often be palpated through the wall of the abdomen.

The **Ileocolic glands** (Figs. 670, 671), from ten to twenty in number, form a chain around the ileocolic artery, but show a tendency to subdivision into two groups, one near the duodenum and another on the lower part of the trunk of the artery. Where the vessel divides into its terminal branches the chain is broken up into several groups, viz.: (a) **ileal**, in relation to the ileal branch of the artery; (b) **anterior ileocolic**, usually of three glands, in the ileocolic fold, near the wall of the cecum; (c) **posterior ileocolic**, mostly placed in the angle between the ileum and the colon, but partly lying behind the cecum at its junction with the ascending colon; (d)

a single gland, between the layers of the mesenteriole of the vermiform process;
(e) **right colic**, along the medial side of the ascending colon.

*Lower group of
ileocolic glands*

Vermiform process

Cecum

FIG. 671.—The lymphatics of cecum and vermiform process from behind. (Jamieson and Dobson.)

The **Mesocolic Glands** (*lymphoglandulae mesocolicae*) are numerous, and lie between the layers of the transverse mesocolon, in close relation to the transverse colon; they are best developed in the neighborhood of the right and left colic flexures. One or two small glands are occasionally seen along the trunk of the right colic artery and others are found in relation to the trunk and branches of the middle colic artery.

The superior mesenteric glands receive afferents from the jejunum, ileum, cecum, vermiform process, and the ascending and transverse parts of the colon; their efferents pass to the preaortic glands.

FIG. 672.—Lymphatics of colon. (Jamieson and Dobson.)

The **inferior mesenteric glands** (Fig. 672) consist of: (a) small glands on the branches of the left colic and sigmoid arteries; (b) a group in the sigmoid mesocolon, around the superior hemorrhoidal artery; and (c) a **pararectal** group in contact with the muscular coat of the rectum. They drain the descending iliac and sigmoid parts of the colon and the upper part of the rectum; their efferents pass to the preaortic glands.

The Lymphatic Vessels of the Abdominal and Pelvic Viscera.

The lymphatic vessels of the abdominal and pelvic viscera consist of (1) those of the subdiaphragmatic portion of the digestive tube and its associated glands, the liver and pancreas; (2) those of the spleen and suprarenal glands; (3) those of the urinary organs; (4) those of the reproductive organs.

1. The **lymphatic vessels of the subdiaphragmatic portion of the digestive tube** are situated partly in the mucous membrane and partly in the seromuscular coats, but as the former system drains into the latter, the two may be considered as one.

The **Lymphatic Vessels of the Stomach** (Figs. 668, 669) are continuous at the cardiac orifice with those of the œsophagus, and at the pylorus with those of the duodenum. They mainly follow the bloodvessels, and may be arranged in four sets. Those of the first set accompany the branches of the left gastric artery, receiving tributaries from a large area on either surface of the stomach, and terminate in the superior gastric glands. Those of the second set drain the fundus and body of the stomach on the left of a line drawn vertically from the œsophagus; they accompany, more or less closely, the short gastric and left gastroepiploic arteries, and end in the pancreaticocolic glands. The vessels of the third set drain the right portion of the greater curvature as far as the pyloric portion, and end in the inferior gastric glands, the efferents of which pass to the subpyloric group. Those of the fourth set drain the pyloric portion and pass to the hepatic and subpyloric glands, and to the superior gastric glands.

The **Lymphatic Vessels of the Duodenum** consist of an anterior and a posterior set, which open into a series of small **pancreaticoduodenal glands** on the anterior and posterior aspects of the groove between the head of the pancreas and the duodenum. The efferents of these glands run in two directions, upward to the hepatic glands and downward to the preaortic glands around the origin of the superior mesenteric artery.

The **Lymphatic Vessels of the Jejunum and Ileum** are termed **lacteals**, from the milk-white fluid they contain during intestinal digestion. They run between the layers of the mesentery and enter the mesenteric glands, the efferents of which end in the preaortic glands.

The **Lymphatic Vessels of the Vermiform Process and Cecum** (Figs. 670, 671) are numerous, since in the wall of this process there is a large amount of adenoid tissue. From the body and tail of the vermiform process eight to fifteen vessels ascend between the layers of the mesenteriole, one or two being interrupted in the gland which lies between the layers of this peritoneal fold. They unite to form three or four vessels, which end partly in the lower and partly in the upper glands of the ileocolic chain. The vessels from the root of the vermiform process and from the cecum consist of an anterior and a posterior group. The anterior vessels pass in front of the cecum, and end in the anterior ileocolic glands and in the upper and lower glands of the ileocolic chain; the posterior vessels ascend over the back of the cecum and terminate in the posterior ileocolic glands and in the lower glands of the ileocolic chain.

Lymphatic Vessels of the Colon (Fig. 672).—The lymphatic vessels of the ascending and transverse parts of the colon finally end in the mesenteric glands, after traversing the right colic and mesocolic glands. Those of the descending and iliac sigmoid parts of the colon are interrupted by the small glands on the branches of the left colic and sigmoid arteries, and ultimately end in the preaortic glands around the origin of the inferior mesenteric artery.

Lymphatic Vessels of the Anus, Anal Canal, and Rectum.—The lymphatics from the **anus** pass forward and end with those of the integument of the perineum and scrotum in the superficial inguinal glands; those from the **anal canal** accompany the middle and inferior hemorrhoidal arteries, and end in the hypogastric glands; while the vessels from the **rectum** traverse the pararectal glands and pass to those in the sigmoid mesocolon; the efferents of the latter terminate in the preaortic glands around the origin of the inferior mesenteric artery.

The **Lymphatic Vessels of the Liver** are divisible into two sets, superficial and deep. The former arise in the subperitoneal areolar tissue over the entire surface of the organ, and may be grouped into (a) those on the convex surface, (b) those on the inferior surface.

(a) On the **convex surface**: The vessels from the back part of this surface reach

their terminal glands by three different routes; the vessels of the middle set, five or six in number, pass through the vena-caval foramen in the Diaphragma and end in one or two glands which are situated around the terminal part of the inferior vena cava; a few vessels from the left side pass backward toward the cesophageal hiatus, and terminate in the paracardial group of superior gastric glands; the vessels from the right side, one or two in number, run on the abdominal surface of the Diaphragma, and, after crossing its right crus, end in the preaortic glands which surround the origin of the coeliac artery. From the portions of the right and left lobes adjacent to the falciform ligament, the lymphatic vessels converge to form two trunks, one of which accompanies the inferior vena cava through the Diaphragma, and ends in the glands around the terminal part of this vessel; the other runs downward and forward, and, turning around the anterior sharp margin of the liver, accompanies the upper part of the ligamentum teres, and ends in the upper hepatic glands. From the anterior surface a few additional vessels turn around the anterior sharp margin to reach the upper hepatic glands.

(b) On the **inferior surface**: The vessels from this surface mostly converge to the porta hepatis, and accompany the deep lymphatics, emerging from the porta to the hepatic glands; one or two from the posterior parts of the right and caudate lobes accompany the inferior vena cava through the Diaphragma, and end in the glands around the terminal part of this vein.

The deep lymphatics converge to ascending and descending trunks. The ascending trunks accompany the hepatic veins and pass through the Diaphragma to end in the glands around the terminal part of the inferior vena cava. The descending trunks emerge from the porta hepatis, and end in the hepatic glands.

The **Lymphatic Vessels of the Gall-bladder** pass to the hepatic glands in the porta hepatis; those of the **common bile duct** to the hepatic glands alongside the duct and to the upper pancreaticoduodenal glands.

The **Lymphatic Vessels of the Pancreas** follow the course of its bloodvessels. Most of them enter the pancreaticolienal glands, but some end in the pancreaticoduodenal glands, and others in the preaortic glands near the origin of the superior mesenteric artery.

2. The lymphatic vessels of the spleen and suprarenal glands.

The **Lymphatic Vessels of the Spleen**, both superficial and deep, pass to the pancreaticolienal glands.

The **Lymphatic Vessels of the Suprarenal Glands** usually accompany the suprarenal veins, and end in the lateral aortic glands; occasionally some of them pierce the crura of the Diaphragma and end in the glands of the posterior mediastinal cavity.

3. The lymphatic vessels of the urinary organs.

The **Lymphatic Vessels of the Kidney** form three plexuses: one in the substance of the kidney, a second beneath its fibrous capsule, and a third in the perinephric fat; the second and third communicate freely with each other. The vessels from the plexus in the kidney substance converge to form four or five trunks which issue at the hilus. Here they are joined by vessels from the plexus under the capsule, and, following the course of the renal vein, end in the lateral aortic glands. The perinephric plexus is drained directly into the upper lateral aortic glands.

The **Lymphatic Vessels of the Ureter** run in different directions. Those from its upper portion end partly in the efferent vessels of the kidney and partly in the lateral aortic glands; those from the portion immediately above the brim of the lesser pelvis are drained into the common iliac glands; while the vessels from the intrapelvic portion of the tube either join the efferents from the bladder, or end in the hypogastric glands.

The **Lymphatic Vessels of the Bladder** (Fig. 673) originate in two plexuses, an intra- and an extramuscular, it being generally admitted that the mucous mem-

brane is devoid of lymphatic.¹ The efferent vessels are arranged in two groups, one from the anterior and another from the posterior surface of the bladder. The vessels from the *anterior* surface pass to the external iliac glands, but in their course minute glands are situated. These minute glands are arranged in two groups, an *anterior vesical*, in front of the bladder, and a *lateral vesical*, in relation to the lateral umbilical ligament. The vessels from the *posterior* surface pass to the hypogastric, external, and common iliac glands; those draining the upper part of this surface traverse the lateral vesical glands.

The **Lymphatic Vessels of the Prostate** (Fig. 674) terminate chiefly in the hypogastric and sacral glands, but one trunk from the posterior surface ends in the external iliac glands, and another from the anterior surface joins the vessels which drain the membranous part of the urethra.

FIG. 673.—Lymphatics of the bladder. (Cunéo and Marcille.)

Lymphatic Vessels of the Urethra.—The lymphatics of the cavernous portion of the urethra accompany those of the glans penis, and terminate with them in the deep subinguinal and external iliac glands. Those of the *membranous and prostatic* portions, and those of the whole urethra in the female, pass to the hypogastric glands.

(4) The **lymphatic vessels of the reproductive organs.**

The **Lymphatic Vessels of the Testes** consist of two sets, superficial and deep, the former commencing on the surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form from four to eight collecting trunks which ascend with the spermatic veins in the spermatic cord and along the front of the Psoas major to the level where the spermatic vessels cross the ureter and end in the lateral and preaortic groups of lumbar glands.²

The **Lymphatic Vessels of the Ductus Deferens** pass to the external iliac glands; those of the *vesiculæ seminales* partly to the hypogastric and partly to the external glands.

¹ Some authorities maintain that a plexus of lymphatic vessels does exist in the mucous membrane of the bladder (consult *Médecine opératoire des Voies urinaires*, par J. Albarran, Paris, 1909).

² "The Lymphatics of the Testicle," by Jameson and Dobson, *Lancet*, February 19, 1900.

The **Lymphatic Vessels of the Ovary** are similar to those of the testis, and ascend with the ovarian artery to the lateral and preaortic glands.

The **Lymphatic Vessels of the Uterine Tube** pass partly with those of the ovary and partly with those of the uterus.

FIG. 674.—Lymphatics of the prostate. (Cunéo and Marcille.) *a, b.* External iliac glands. *c* Vessel draining into external iliac glands. *d.* Retroprostatic lymph nodes. *e.* Vessels draining into gland on sacral promontory. *f.* Gland in front of sacral promontory. *g.* Lateral sacral glands. *h.* Middle hemorrhoidal gland. *i.* Middle hemorrhoidal lymphatic vessels.

The **Lymphatic Vessels of the Uterus** (Fig. 675) consist of two sets, superficial and deep, the former being placed beneath the peritoneum, the latter in the substance of the organ. The lymphatics of the cervix uteri run in three directions: transversely to the external iliac glands, postero-laterally to the hypogastric glands, and posteriorly to the common iliac glands. The majority of the vessels of the body and fundus of the uterus pass lateralward in the broad ligaments, and are continued up with the ovarian vessels to the lateral and preaortic glands; a few, however, run to the external iliac glands, and one or two to the superficial inguinal glands. In the unimpregnated uterus the lymphatic vessels are very small, but during gestation they are greatly enlarged.

The **Lymphatic Vessels of the Vagina** are carried in three directions: those of the upper part of the vagina to the external iliac glands, those of the middle part to the hypogastric glands, and those of the lower part to the common iliac glands.

On the course of the vessels from the middle and lower parts small glands are situated. Some lymphatic vessels from the lower part of the vagina join those of the vulva and pass to the superficial inguinal glands. The lymphatics of the vagina anastomose with those of the cervix uteri, vulva, and rectum, but not with those of the bladder.

THE LYMPHATICS OF THE THORAX

The lymph glands of the thorax may be divided into parietal and visceral—the former being situated in the thoracic wall, the latter in relation to the viscera.

The parietal lymph glands include the sternal, intercostal, and diaphragmatic glands.

1. The Sternal Glands (*lymphoglandulae sternales*; *internal mammary glands*) are placed at the anterior ends of the intercostal spaces, by the side of the internal mammary artery. They derive afferents from the mamma, from the deeper structures of the anterior abdominal wall above the level of the umbilicus, from the upper surface of the liver through a small group of glands which lie behind the xiphoid process, and from the deeper parts of the anterior portion of the thoracic wall. Their efferents usually unite to form a single trunk on either side; this may open directly into the junction of the internal jugular and subclavian veins, or

that of the right side may join the right subclavian trunk, and that of the left the thoracic duct.

2. The **Intercostal Glands** (*lymphoglandulae intercostales*) occupy the posterior parts of the intercostal spaces, in relation to the intercostal vessels. They receive the deep lymphatics from the postero-lateral aspect of the chest; some of these vessels are interrupted by small lateral intercostal glands. The efferents of the glands in the lower four or five spaces unite to form a trunk, which descends and opens either into the cisterna chyli or into the commencement of the thoracic duct. The efferents of the glands in the upper spaces of the left side end in the thoracic duct; those of the corresponding right spaces, in the right lymphatic duct.

3. The **Diaphragmatic Glands** lie on the thoracic aspect of the Diaphragma, and consist of three sets, anterior, middle, and posterior.

The **anterior set** comprises (a) two or three small glands behind the base of the xiphoid process, which receive afferents from the convex surface of the liver, and (b) one or two glands on either side near the junction of the seventh rib with its cartilage, which receive lymphatic vessels from the front part of the Diaphragma. The efferent vessels of the anterior set pass to the sternal glands.

The **middle set** consists of two or three glands on either side close to where the phrenic nerves enter the Diaphragma. On the right side some of the glands of this group lie within the fibrous sac of the pericardium, on the front of the termination of the inferior vena cava. The afferents of this set are derived from the middle part of the Diaphragma, those on the right side also receiving afferents from the convex surface of the liver. Their efferents pass to the posterior mediastinal glands.

The **posterior set** consists of a few glands situated on the back of the crura of the Diaphragma, and connected on the one hand with the lumbar glands and on the other with the posterior mediastinal glands.

The **superficial lymphatic vessels of the thoracic wall** ramify beneath the skin and converge to the axillary glands. Those over the Trapezius and Latissimus dorsi run forward and unite to form about ten or twelve trunks which end in the subscapular group. Those over the pectoral region, including the vessels from the skin covering the peripheral part of the mamma, run backward, and those over the Serratus anterior upward, to the pectoral group. Others near the lateral margin of the sternum pass inward between the rib cartilages and end in the sternal glands, while the vessels of opposite sides anastomose across the front of the sternum. A few vessels from the upper part of the pectoral region ascend over the clavicle to the supraclavicular group of cervical glands.

The **Lymphatic Vessels of the Mamma** originate in a plexus in the interlobular spaces and on the walls of the galactophorous ducts. Those from the central part of the gland pass to an intricate plexus situated beneath the areola, a plexus which receives also the lymphatics from the skin over the central part of the gland and those from the areola and nipple. Its efferents are collected into two trunks which pass to the pectoral group of axillary glands. The vessels which drain the medial part of the mamma pierce the thoracic wall and end in the sternal glands, while a vessel has occasionally been seen to emerge from the upper part of the mamma and, piercing the Pectoralis major, terminate in the subclavicular glands (Fig. 662).

The **deep lymphatic vessels of the thoracic wall** consist of:

1. The lymphatics of the muscles which lie on the ribs: most of these end in the axillary glands, but some from the Pectoralis major pass to the sternal glands.
2. The intercostal vessels which drain the Intercostales and parietal pleura. Those draining the Intercostales externi run backward and, after receiving the vessels which accompany the posterior branches of the intercostal arteries, end in the intercostal glands. Those of the Intercostales interni and parietal pleura consist of a single trunk in each space. These trunks run forward in the subpleural tissue and the upper six open separately into the sternal glands or into the vessels which

unite them; those of the lower spaces unite to form a single trunk which terminates in the lowest of the sternal glands. 3. The **lymphatic vessels of the Diaphragma**, which form two plexuses, one on its thoracic and another on its abdominal surface. These plexuses anastomose freely with each other, and are best marked on the parts covered respectively by the pleuræ and peritoneum. That on the thoracic surface communicates with the lymphatics of the costal and mediastinal parts of the pleura, and its efferents consist of three groups: (a) anterior, passing to the gland which lie near the junction of the seventh rib with its cartilage; (b) middle, to the glands on the œsophagus and to those around the termination of the inferior vena cava; and (c) posterior, to the glands which surround the aorta at the point where this vessel leaves the thoracic cavity.

The plexus on the abdominal surface is composed of fine vessels, and anastomoses with the lymphatics of the liver and, at the periphery of the Diaphragma, with those of the subperitoneal tissue. The efferents from the right half of this plexus terminate partly in a group of glands on the trunk of the corresponding inferior phrenic artery, while others end in the right lateral aortic glands. Those from the left half of the plexus pass to the pre- and lateral aortic glands and to the glands on the terminal portion of the œsophagus.

The **visceral lymph glands** consist of three groups, viz.: **anterior mediastinal**, **posterior mediastinal**, and **tracheobronchial**.

The **Anterior Mediastinal Glands** (*lymphoglandulae mediastinales anteriores*) are placed in the anterior part of the superior mediastinal cavity, in front of the aortic arch and in relation to the innominate veins and the large arterial trunks which arise from the aortic arch. They receive afferents from the thymus and pericardium, and from the sternal glands; their efferents unite with those of the tracheobronchial glands, to form the right and left bronchomediastinal trunks.

The **Posterior Mediastinal Glands** (*lymphoglandulae mediastinales posteriores*) lie behind the pericardium in relation to the œsophagus and descending thoracic aorta. Their afferents are derived from the œsophagus, the posterior part of the pericardium, the Diaphragma, and the convex surface of the liver. Their efferents mostly end in the thoracic duct, but some join the tracheobronchial glands.

The **Tracheobronchial Glands** (Fig. 676) form four main groups: (a) **tracheal**, on either side of the trachea; (b) **bronchial**, in the angles between the lower part of the trachea and bronchi and in the angle between the two bronchi; (c) **broncho-pulmonary**, in the hilus of each lung; and (d) **pulmonary**, in the lung substance, on the larger branches of the bronchi. The afferents of the tracheobronchial glands drain the lungs and bronchi, the thoracic part of the trachea and the heart; some of the efferents of the posterior mediastinal glands also end in this group. Their efferent vessels ascend upon the trachea and unite with efferents of the internal mammary and anterior mediastinal glands to form the **right and left bronchomediastinal trunks**. The right bronchomediastinal trunk may join the right lymphatic duct, and the left the thoracic duct, but more frequently they open independently of these ducts into the junction of the internal jugular and subclavian veins of their own side.

Applied Anatomy.—In all town dwellers there are continually being swept into these glands from the bronchi and alveoli large quantities of the dust and black carbonaceous pigment that are so freely inhaled in cities. At first the glands are moderately enlarged, firm, inky black, and gritty on section; later they enlarge still further, often becoming fibrous from the irritation set up by the minute foreign bodies with which they are crammed, and may break down into a soft slimy mass or may calcify. In tuberculosis of the lungs these glands are practically always infected; they enlarge, being filled with tuberculous deposits that may soften, or become fibrous, or calcify. Not infrequently an enlarged tuberculous gland perforates into a bronchus, discharging its contents into the tube. When this happens there is great danger of acute pulmonary tuberculosis, the infecting gland substance being rapidly spread throughout the bronchial system by the coughing its presence in the air passages excites.

The lymphatic vessels of the thoracic viscera comprise those of the heart and pericardium, lungs and pleura, thymus, and œsophagus.

The Lymphatic Vessels of the Heart consist of two plexuses: (*a*) deep, immediately under the endocardium; and (*b*) superficial, subjacent to the visceral pericardium. The deep plexus opens into the superficial, the efferents of which form right and left collecting trunks. The left trunks, two or three in number, ascend in the anterior longitudinal sulcus, receiving, in their course, vessels from both ventricles. On reaching the coronary sulcus they are joined by a large trunk from the diaphragmatic surface of the heart, and then unite to form a single vessel which ascends between the pulmonary artery and the left atrium and ends in one of the tracheobronchial

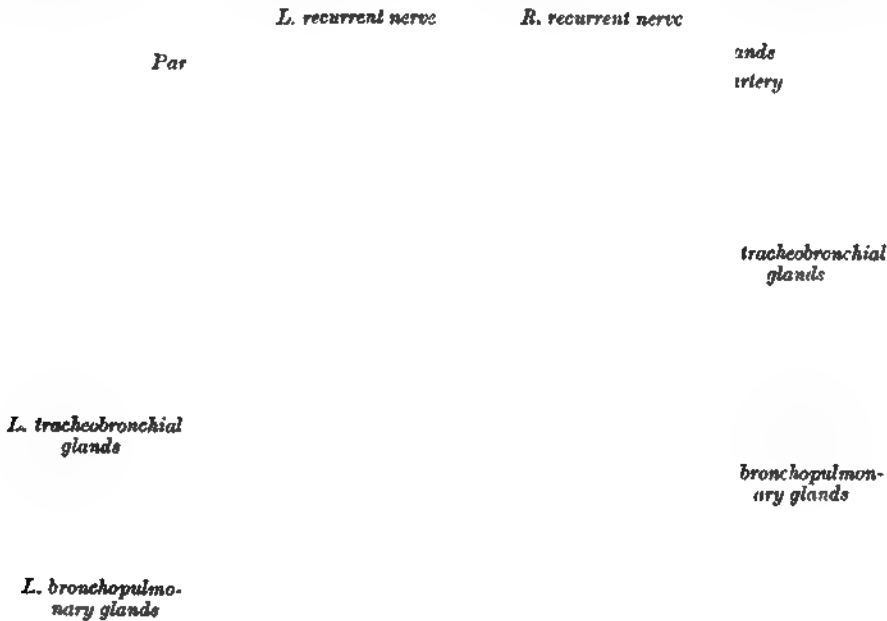

FIG. 676.—The tracheobronchial lymph glands. (From a figure designed by M. Hallé.)

glands. The right trunk receives its afferents from the right atrium and from the right border and diaphragmatic surface of the right ventricle. It ascends in the posterior longitudinal sulcus and then runs forward in the coronary sulcus, and passes up behind the pulmonary artery, to end in one of the tracheobronchial glands.

The Lymphatic Vessels of the Lungs originate in two plexuses, a superficial and a deep. The superficial plexus is placed beneath the pulmonary pleura. The deep accompanies the branches of the pulmonary vessels and the ramifications of the bronchi. In the case of the larger bronchi the deep plexus consists of two net-works—one, submucous, beneath the mucous membrane, and another, peribronchial, outside the walls of the bronchi. In the smaller bronchi there is but a single plexus, which extends as far as the bronchioles, but fails to reach the alveoli, in the walls

of which there are no traces of lymphatic vessels. The superficial efferents turn around the borders of the lungs and the margins of their fissures, and converge to end in some glands situated at the hilus; the deep efferents are conducted to the hilus along the pulmonary vessels and bronchi, and end in the tracheobronchial glands. Little or no anastomosis occurs between the superficial and deep lymphatics of the lungs, except in the region of the hilus.

The **Lymphatic Vessels of the Pleura** consist of two sets—one in the visceral and another in the parietal part of the membrane. Those of the visceral pleura drain into the superficial efferents of the lung, while the lymphatics of the parietal pleura have three modes of ending, viz.: (*a*) those of the costal portion join the lymphatics of the *Intercostales interni* and so reach the sternal glands; (*b*) those of the diaphragmatic part are drained by the efferents of the *Diaphragma*; while (*c*) those of the mediastinal portion terminate in the posterior mediastinal glands.

The **Lymphatic Vessels of the Thymus** end in the anterior mediastinal, tracheobronchial, and sternal glands.

The **Lymphatic Vessels of the Œsophagus** form a plexus around that tube, and the collecting vessels from the plexus drain into the posterior mediastinal glands.

NEUROLOGY.

THE Nervous System is the most complicated and highly organized of the various systems which make up the human body. It may be divided into two parts, **central** and **peripheral**.

The **central nervous system** consists of (a) an upper expanded portion, the **encephalon** or **brain**, contained within the cranium, and (b) a lower, elongated, nearly cylindrical portion, the **medulla spinalis** or **spinal cord**, lodged in the vertebral canal; the two portions are continuous with one another at the level of the upper border of the atlas vertebra.

The **peripheral nervous system** consists of a series of nerves by which the central nervous system is connected with the various tissues of the body. For descriptive purposes these nerves may be arranged in two groups, **cerebrospinal** and **sympathetic**, the arrangement, however, being an arbitrary one, since the two groups are intimately connected and closely intermingled. The cerebrospinal nerves are forty-three in number on either side—twelve **cerebral**, attached to the brain, and thirty-one **spinal**, to the medulla spinalis. They are associated with the functions of the special and general senses and with the voluntary movements of the body. The sympathetic nerves transmit the impulses which regulate the movements of the viscera, determine the calibre of the bloodvessels, and control the phenomena of secretion. In relation with them are two rows of **central ganglia**, situated one on either side of the middle line in front of the vertebral column; these ganglia are intimately connected with the medulla spinalis and the spinal nerves, and are also joined to each other by vertical strands of nerve fibres so as to constitute a pair of knotted cords, the **sympathetic trunks**, which reach from the base of the skull to the coccyx. The sympathetic nerves issuing from the ganglia form three great prevertebral plexuses which supply the thoracic, abdominal, and pelvic viscera; in relation to the walls of these viscera intricate nerve plexuses and numerous **peripheral ganglia** are found.

The nervous system is built up of nervous and non-nervous tissues—the former consisting of nerve cells and nerve fibres; the latter, of neuroglia and bloodvessels, together with certain enveloping membranes.

The minute structure of the nervous elements, and of the neuroglia, has been described in the chapter on Histology (pp. 69 to 76); and an outline of the development of the nervous system furnished in that on Embryology (pp. 117 to 133). The structure of the individual parts of the brain is given under their specific descriptions.

Structure of the Peripheral Nerves and Ganglia.—The **cerebrospinal nerves** consist of numerous nerve fibres collected together and enclosed in membranous sheaths (Fig. 677). A small bundle of fibres, enclosed in a tubular sheath, is called a **funiculus**; if the nerve is of small size, it may consist only of a single funiculus; but if large, the funiculi are collected together into larger bundles or **fasciculi**, which are bound together in a common membranous investment. In structure, the common membranous investment, or sheath of the whole nerve (**epineurium**), as well as the septa given off from it to separate the fasciculi, consist of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the funiculi (**perineurium**) is a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it is made up of connective tissue, which has a distinctly lamellar arrangement. The nerve fibres are held together and supported within

the funiculus by delicate connective tissue, called the **endoneurium**. It is continuous with septa which pass inward from the innermost layer of the perineurium, and shows a ground substance in which are imbedded fine bundles of fibrous connective tissue running for the most part longitudinally. It serves to support capillary vessels, arranged so as to form a net-work with elongated meshes. The cerebrospinal nerves consist almost exclusively of medullated nerve fibres, only a very small proportion of non-medullated being present.

The bloodvessels supplying a nerve end in a minute capillary plexus, the vessels composing which pierce the perineurium, and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve fibres, **vasomotor fibres**, accompany these capillary vessels, and break up into elementary fibrils, which form a network around the vessels. Horsley has demonstrated certain medullated fibres running in the epineurium and terminating in small **spheroidal tactile corpuscles** or **end bulbs of Krause**. These nerve fibres, which Marshall believes to be sensory, and which he has termed **nervi nervorum**, are considered by him to have an important bearing upon certain neuralgic pains.

FIG. 677

FIG. 677.—Transverse section of human tibial nerve.

The nerve fibres, so far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component funiculi, it may be seen that these do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other funiculi proceeding in the same direction; from this, branches are given off, to join again in like manner with other funiculi. It must be distinctly understood, however, that in these communications the individual nerve fibres do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its nerve fibres, and again pass on to intermingle with the nerve fibres in some adjoining funiculus.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighboring nerve. The communications which thus take place form what is called a **plexus**. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus, the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from all the primary nervous trunks which form the plexus. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the funiculi and primitive fibres. In each case, however, the individual fibres remain separate and distinct.

It is probable that through this interchange of fibres, every branch passing off from a plexus has a more extensive connection with the spinal cord than if it had proceeded to its distribution without forming connections with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The **sympathetic nerves** are constructed in the same manner as the cerebrospinal nerves, but consist mainly of non-medullated fibres, collected in funiculi and enclosed in sheaths of connective tissue. There is, however, in these nerves a certain admixture of medullated fibres. The number of the latter varies in different nerves, and may be estimated by the color of the nerve. Those branches of the sympathetic which present a well-marked gray color are composed chiefly of non-medullated nerve fibres, intermixed with a few medullated fibres; while those of a white color contain many of the latter fibres, and few of the former.

The cerebrospinal and sympathetic nerve fibres convey various impressions. The **sensory nerves**, called also **centripetal** or **afferent nerves**, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The **centrifugal** or **efferent nerves** transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either exciting muscular contraction, or influencing the processes of nutrition, growth, and secretion.

Origins and Terminations of Nerves.—By the expression “the terminations of nerve fibres” is signified their connections with the nerve centres and with the parts they supply. The former are sometimes called their **origins** or **central terminations**; the latter their **peripheral terminations**.

Origins of Nerves.—The origin in some cases is single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots which come off from different parts of the nerve centre, sometimes widely apart from each other, and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different; as, for example, in the spinal nerves, each of which arises by two roots, the anterior of which is motor, and the posterior sensory. The point where the nerve root or roots emerge from the surface of the nervous centre is named the **superficial** or **apparent origin**, but the fibres of the nerve can be traced for a certain distance into the substance of the nervous centre to some portion of the gray matter, which constitutes the **deep** or **real origin** of the nerve. The centrifugal or efferent nerve fibres originate in the nerve cells of the gray substance, the axis-cylinder processes of these cells being prolonged to form the fibres. In the case of the centripetal or afferent nerves the fibres grow inward either from nerve cells in the organs of special sense, *e. g.*, the retina, or from nerve cells in the ganglia. Having entered the nerve centre they branch and send their ultimate twigs among the cells, without, however, uniting with them.

Peripheral Terminations of Nerves.—Nerve fibres terminate peripherally in various ways, and these may be conveniently studied in the sensory and motor nerves respectively. The terminations of the sensory nerves are dealt with in the section on Sense Organs.

Motor nerves can be traced into either unstriped or striped muscular fibres. In the *unstriped* or *involuntary muscles* the nerves are derived from the sympathetic, and are composed mainly of non-medullated fibres. Near their terminations they divide into numerous branches, which communicate and form intimate plexuses. At the junctions of the branches small triangular nuclear bodies (ganglion cells) are situated. From these plexuses minute branches are given off which divide and break up into the ultimate fibrillæ of which the nerves are composed. These fibrillæ course between the involuntary muscle cells, and, according to Elischer, terminate on the surfaces of the cells, opposite the nuclei, in minute swellings.

In the *striped* or *voluntary muscle*, the nerves supplying the muscular fibres are derived from the cerebrospinal nerves, and are composed mainly of medullated fibres. The nerve, after entering the sheath of the muscle, breaks up into fibres or bundles of fibres, which form plexuses, and gradually divide until, as a rule, a single nerve fibre enters a single muscular fibre. Sometimes, however, if the muscular fibre be long, more than one nerve fibre enters it. Within the muscular fibre the nerve terminates in a special expansion, called by Kühne, who first accurately described it, a **motor end plate** (Fig. 678). The nerve fibre, on approaching the muscular fibre, suddenly loses its medullary sheath, the neurolemma becomes continuous with the sarcolemma of the muscle, and only the axis-cylinder enters the muscular fibre. There it at once spreads out, ramifying like the roots of a tree, immediately beneath the sarcolemma, and becomes imbedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting an end-plate from which the contractile wave of the muscular fibre is said to start.

Ganglia are small aggregations of nerve cells. They are found on the posterior roots of the spinal nerves; on the sensory roots of the trigeminal, facial, glossopharyngeal, and vagus nerves, and on the acoustic nerves. They are also found in connection with the sympathetic nerves. On section they are seen to consist of a reddish-gray substance, traversed by numerous white nerve fibres; they vary considerably in form and size; the largest are found in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera. Each ganglion is invested by a smooth and firm, closely adhering, membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior to support the bloodvessels supplying the substance of the ganglion.

In structure all ganglia are essentially similar, consisting of the same structural elements—viz., nerve cells and nerve fibres. Each nerve cell has a nucleated sheath which is continuous

with the neurolemma of the nerve fibre with which the cell is connected. The nerve cells in the ganglia of the spinal nerves (Fig. 679) are pyriform in shape, and have each a single process. A short distance from the cell and while still within the ganglion this process divides in a T-shaped manner, one limb of the cross-bar turning into the medulla spinalis, the other limb passing outward to the periphery. In the sympathetic ganglia (Fig. 680) the nerve cells are multipolar and each has one axis-cylinder process and several dendrons; the axon emerges from the ganglion

as a non-medullated nerve fibre. Similar cells are found in the ganglia connected with the trigeminal nerve, and these ganglia are therefore regarded as the cerebral portions of the "autonomic" system. The autonomic nervous system includes those portions of the nervous mechanism in which a medullated nerve fibre from the central system passes to a ganglion, sympathetic or peripheral, from which fibres, usually non-medullated, are distributed to such structures, *e. g.*, bloodvessels, as are not under voluntary control. The spinal and sympathetic ganglia differ somewhat in the size and disposition of the cells and in the number of nerve fibres entering and

leaving them. In the spinal ganglia (Fig. 679) the nerve cells are much larger and for the most part collected in groups near the periphery, while the fibres, which are mostly medullated, traverse the central portion of the ganglion; whereas in the sympathetic ganglia (Fig. 680) the cells are smaller and distributed in irregular groups throughout the whole ganglion; the fibres also are irregularly scattered; some of the entering ones are medullated, while many of those leaving the ganglion are non-medullated.

Neuron Theory.—The nerve cell and its processes collectively constitute what is termed a **neuron**, and Waldeyer formulated the theory that the nervous system is built up of numerous neurons, "anatomically and genetically independent of one another." According to this theory (*neuron theory*) the processes of one neuron only come into contact, and are never in direct continuity, with those of other neurons; while impulses are transmitted from one nerve cell to another through these points of contact. This theory is based on the following facts, viz.: (1) embryonic nerve cells or neuroblasts are entirely distinct from one another; (2) when nervous tissues are stained by the Golgi method no continuity is seen even between neighboring neurons; and (3) when degenerative changes occur in nervous tissue, either as the result of disease or experiment, they never spread from one neuron to another, but are limited to the individual neurons, or groups of neurons, primarily affected. It must, however, be

added that within the past few years the validity of the neuron theory has been called in question by certain eminent histologists, who maintain that by the employment of more delicate histological methods, minute fibrils can be followed from one nerve cell into another.

THE MEDULLA SPINALIS OR SPINAL CORD.

Dissection.—To dissect the medulla spinalis and its membranes it will be necessary to lay open the whole length of the vertebral canal. For this purpose the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and laminae of the vertebrae; and the latter must be sawn through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above to the sacrum below. The vertebral arches having been displaced by means of a chisel and the separate fragments removed, the dura will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebrae are best divided by means of a strong pair of cutting bone forceps or by a rachitome.

The **medulla spinalis** or **spinal cord** forms the elongated, nearly cylindrical, part of the central nervous system which occupies the upper two-thirds of the vertebral canal. Its average length in the male is about 45 cm., in the female from 42 to 43 cm., while its weight amounts to about 30 gms. It extends from the level of the upper border of the atlas to that of the lower border of the first, or upper border

of the second, lumbar vertebra. Above, it is continuous with the brain; below, it ends in a conical extremity, the **conus medullaris**, from the apex of which a delicate filament, the **filum terminale**, descends as far as the first segment of the coccyx (Fig. 681).

The position of the medulla spinalis varies with the movements of the vertebral column, its lower extremity being drawn slightly upward when the column is flexed. It also varies at different periods of life; up to the third month of fetal life the medulla spinalis is as long as the vertebral canal, but from this stage onward the vertebral column elongates more rapidly than the medulla spinalis, so that by the end of the fifth month the medulla spinalis terminates at the base of the sacrum, and at birth about the third lumbar vertebra.

The medulla spinalis does not fill the part of the vertebral canal in which it lies; it is ensheathed by three protective membranes, separated from each other by two concentric spaces. The three membranes are named from without inward, the **dura mater**, the **arachnoid**, and the **pia mater**. The **dura mater** is a strong, fibrous membrane which forms a wide, tubular sheath; this sheath extends below the termination of the medulla spinalis and ends in a pointed cul-de-sac at the level of the lower border of the second sacral vertebra. The **dura mater** is separated from the wall of the vertebral canal by the **epidural cavity**, which contains a quantity of loose areolar tissue and a plexus of veins; between the **dura mater** and the subjacent **arachnoid** is a capillary interval, the **subdural cavity**, which contains a small quantity of fluid, probably of the nature of lymph. The **arachnoid** is a thin, transparent sheath, separated from the **pia mater** by a comparatively wide interval, the **sub-arachnoid cavity**, which is filled with cerebrospinal fluid. The **pia mater** closely invests the medulla spinalis and sends delicate septa into its substance; a narrow band, the **ligamentum denticulatum**, extends along each of its lateral surfaces and is attached by a series of pointed processes to the inner surface of the **dura mater**.

Thirty-one pairs of spinal nerves spring from the medulla spinalis, each nerve having an anterior or ventral, and a posterior or dorsal root, the latter being distinguished by the presence of an oval swelling, the **spinal ganglion**, which contains numerous nerve cells. Each root consists of several bundles of nerve fibres, and at its attachment extends for some distance along the side of the medulla spinalis. The pairs of spinal nerves are grouped as follows: cervical 8, thoracic 12, lumbar 5, sacral 5, coccygeal 1, and, for convenience of description, the medulla spinalis is divided into cervical, thoracic, lumbar and sacral regions, corresponding with the attachments of the different groups of nerves.

Although no trace of transverse segmentation is visible on the surface of the medulla spinalis, it is convenient to regard it as being built up of a series of superimposed **spinal segments** or **neuromeres**, each of which has a length equivalent to the extent of attachment of a pair of spinal nerves. Since the extent of attachment of the successive pairs of nerves varies in different parts, it follows that the spinal segments are of varying lengths; thus, in the cervical region they average about 13 mm., in the mid-thoracic region about 26 mm., while in the lumbar and sacral regions they diminish rapidly from about 15 mm. at the level of the first pair of lumbar nerves to about 4 mm. opposite the attachments of the lower sacral nerves.

As a consequence of the relative inequality in the rates of growth of the medulla spinalis and vertebral column, the nerve roots, which in the early embryo passed transversely outward to reach their respective intervertebral foramina, become more and more oblique in direction from above downward, so that the lumbar and sacral nerves descend almost vertically to reach their points of exit. From the appearance these nerves present at their attachment to the medulla spinalis and from their great length they are collectively termed the **cauda equina** (Fig. 682).

The **filum terminale** is a delicate filament, about 20 cm. in length, prolonged downward from the apex of the **conus medullaris**. It consists of two parts, an upper and a lower. The upper part, or **filum terminale internum**, measures about 15 cm. in length and reaches as far as the lower border of the second sacral vertebra. It is contained within the tubular sheath of **dura mater**, and is surrounded by the nerves forming the **cauda equina**, from which it can be readily recognized by its bluish-white color. The lower part, or **filum terminale externum**, is closely invested by, and is adherent to, the **dura mater**; it extends downward from the apex of the tubular sheath

FIG. 682.—Cauda equina and filum terminale seen from behind. The **dura mater** has been opened and spread out, and the arachnoid has been removed.

FIG. 683.—Diagrams of the medulla spinalis.

and is attached to the back of the first segment of the coccyx. The filum terminale consists mainly of fibrous tissue, continuous above with that of the pia mater. Adhering to its outer surface, however, are a few strands of nerve fibres which probably represent rudimentary second and third coccygeal nerves; further, the central canal of the medulla spinalis extends downward into it for 5 or 6 cm.

Enlargements.—The medulla spinalis is not quite cylindrical, being slightly flattened from before backward; it also presents two swellings or enlargements, an upper or cervical, and a lower or lumbar (Fig. 683).

The **cervical enlargement** is the more pronounced, and corresponds with the attachments of the large nerves which supply the upper limbs. It extends from about the third cervical to the second thoracic vertebra, its maximum circumference (about 38 mm.) being on a level with the attachment of the sixth pair of cervical nerves.

The **lumbar enlargement** gives attachment to the nerves which supply the lower limbs. It commences about the level of the ninth thoracic vertebra, and reaches its maximum circumference, of about 33 mm., opposite the last thoracic vertebra, below which it tapers rapidly into the conus medullaris.

Fissures and Sulci (Fig. 684).—An anterior median fissure and a posterior median sulcus incompletely divide the medulla spinalis into two symmetrical parts, which are joined across the middle line by a commissural band of nervous matter.

The **Anterior Median Fissure** (*fissura mediana anterior*) has an average depth of about 3 mm., but this is increased in the lower part of the medulla spinalis. It contains a double fold of pia mater, and its floor is formed by a transverse band of white substance, the **anterior white commissure**, which is perforated by blood-vessels on their way to or from the central part of the medulla spinalis.

The **Posterior Median Sulcus** (*sulcus medianus posterior*) is very shallow; from it a septum of neuroglia reaches rather more than half-way into the substance of the medulla spinalis; this septum varies in depth from 4 to 6 mm., but diminishes considerably in the lower part of the medulla spinalis.

On either side of the posterior median sulcus, and at a short distance from it, the posterior nerve roots are attached along a vertical furrow named the **postero-lateral sulcus**. The portion of the medulla spinalis which lies between this and the posterior median sulcus is named the **posterior funiculus**. In the cervical and upper thoracic regions this funiculus presents a longitudinal furrow, the **postero-intermediate sulcus**; this marks the position of a septum which extends into the posterior funiculus and subdivides it into two fasciculi—a medial, named the **fasciculus gracilis** (*tract of Goll*); and a lateral, the **fasciculus cuneatus** (*tract of Burdach*) (Fig. 690). The portion of the medulla spinalis which lies in front of the postero-lateral sulcus is termed the **antero-lateral region**. The anterior nerve roots, unlike the posterior, are not attached in linear series, and their position of exit is not marked by a sulcus. They arise by separate bundles which spring from the anterior column of gray substance and, passing forward through the white substance, emerge over an area of some slight width. The most lateral of these bundles is generally taken as a dividing line which separates the antero-lateral region into two parts, viz., an **anterior funiculus**, between the anterior median fissure and the most lateral of the anterior nerve roots; and a **lateral funiculus**, between the exit of these roots and the postero-lateral sulcus. In the upper part of the cervical region a series of nerve roots passes outward through the lateral funiculus of the medulla spinalis; these unite to form the spinal portion of the accessory nerve, which runs upward and enters the cranial cavity through the foramen magnum.

The Internal Structure of the Medulla Spinalis.—On examining a transverse section of the medulla spinalis (Fig. 684) it is seen to consist of gray and white nervous substance, the former being enclosed within the latter.

Gray Substance (*substantia grisea centralis*).—The gray substance consists of two symmetrical portions, one in each half of the medulla spinalis: these are joined across the middle line by a transverse commissure of gray substance, through which runs a minute canal, the **central canal**, just visible to the naked eye. In a transverse section each half of the gray substance is shaped like a comma or crescent, the concavity of which is directed laterally; and these, together with the intervening gray commissure, present the appearance of the letter H. An imaginary coronal plane through the central canal serves to divide each crescent into an **anterior or ventral**, and a **posterior or dorsal column**.

The **Anterior Column** (*columna anterior; anterior cornu*), directed forward, is broad and of a rounded or quadrangular shape. Its posterior part is termed the **base**, and its anterior part the **head**, but these are not differentiated from each other by any well-defined constriction. It is separated from the surface of the medulla spinalis by a layer of white substance which is traversed by the bundles of the anterior nerve roots. In the thoracic region, the postero-lateral part of the anterior column projects lateralward as a triangular field, which is named the **lateral column** (*columna lateralis; lateral cornu*).

Posterior median sulcus

*Pos
neru*

Anterior nerve roots Anterior median fissure

FIG. 684.—Transverse section of the medulla spinalis in the mid-thoracic region.

The **Posterior Column** (*columna posterior; posterior cornu*) is long and slender, and is directed backward and lateralward: it reaches almost as far as the postero-lateral sulcus, from which it is separated by a thin layer of white substance, the **tract of Lissauer**. It consists of a **base**, directly continuous with the base of the anterior horn, and a **neck** or slightly constricted portion, which is succeeded by an oval or fusiform area, termed the **head**, of which the **apex** approaches the postero-lateral sulcus. The apex is capped by a V-shaped or crescentic mass of translucent, gelatinous neuroglia, termed the **substantia gelatinosa of Bolando**, which contains both neuroglia cells, and small nerve cells. Between the anterior and posterior columns the gray substance extends as a series of processes into the lateral funiculus, to form a net-work called the **formatio reticularis**.

The quantity of gray substance, as well as the form which it presents on transverse section, varies markedly at different levels. In the thoracic region it is small, not only in amount but relatively to the surrounding white substance. In the

cervical and lumbar enlargements it is greatly increased: in the latter, and especially in the conus medullaris, its proportion to the white substance is greatest (Fig. 685).

C.1.

In the cervical region its posterior column is comparatively narrow, while its anterior is broad and expanded; in the thoracic region, both columns are attenuated, and the lateral column is evident; in the lumbar enlargement, both are expanded; while in the conus medullaris the gray substance assumes the form of two oval masses, one in each half of the cord, connected together by a broad gray commissure.

C.2.

The **Central Canal** (*canalis centralis*) runs throughout the entire length of the medulla spinalis. The portion of gray substance in front of the canal is named the **anterior gray commissure**; that behind it, the **posterior gray commissure**. The former is thin, and is in contact anteriorly with the anterior white commissure: it contains a couple of longitudinal veins, one on either side of the middle line. The posterior gray commissure reaches from the central canal to the posterior median septum, and is thinnest in the thoracic region, and thickest in the conus medullaris. The central canal is continued upward through the lower part of the medulla oblongata, and opens into the fourth ventricle of the brain; below, it reaches for a short distance into the filum terminale. In the lower part of the conus medullaris it exhibits a fusiform dilatation, the **terminal ventricle**; this has a vertical measurement of from 8 to 10 mm., is triangular on cross-section with its base directed forward, and tends to undergo obliteration after the age of forty years.

C.5.

Throughout the cervical and thoracic regions the central canal is situated in the anterior third of the medulla spinalis; in the lumbar enlargement it is near the middle, and in the conus medullaris it approaches the posterior surface. It is filled with cerebrospinal fluid, and lined by ciliated, columnar epithelium, outside of which is an encircling band of gelatinous substance, the **substantia gelatinosa centralis**. This gelatinous substance consists mainly of neuroglia, but contains a few nerve cells and fibres; it is traversed by processes from the deep ends of the columnar ciliated cells which line the central canal (Fig. 686).

C.8.

Structure of the Gray Substance.—The gray substance consists of numerous nerve cells and nerve fibres held together by neuroglia. Throughout the greater part of the gray substance the neuroglia presents the appearance of a sponge-like net-work, but around the central canal and on the apices of the posterior columns it consists of the gelatinous substance already referred to. The nerve cells are multipolar, and vary greatly in size and shape. They consist of (1) motor cells of large size, which are

Coc.

FIG. 685.—Transverse sections of the medulla spinalis at different levels.

situated in the anterior horn, and are especially numerous in the cervical and lumbar enlargements; the axons of most of these cells pass out to form the anterior nerve roots, but before leaving the white substance they frequently give off collaterals, which reënter and ramify in the gray substance.¹ (2) Cells of small or medium size, whose axons pass into the white matter, where some pursue an ascending, and others a descending course, but most of them divide in a T-shape manner into descending and ascending processes. They give off collaterals which enter and ramify in the gray substance, and the terminations of the axons behave in a similar manner. The lengths of these axons vary greatly: some are short and pass only between adjoining spinal segments, while others are longer and connect more distant segments. These cells and their processes constitute a series of **association or intersegmental neurons** (Fig. 687), which link together the different parts of the medulla spinalis. The axons of most of these cells are confined to that side of the medulla spinalis in which the nerve cells are situated, but some cross to the opposite side through the anterior commissure, and are termed **crossed commissural fibres**. Some of these latter end directly in the gray substance, while others enter the white

Neu

FIG. 687 —Cells of medulla spinalis. (Poirier.) Diagram showing in longitudinal section the intersegmental neurons of the medulla spinalis. The gray and white parts correspond respectively to the gray and white substance of the medulla spinalis.

substance, and ascend or descend in it for varying distances, before finally terminating in the gray substance. (3) Cells of the type II of Golgi, limited to the posterior column, are found in the substantia gelatinosa of Rolando; their axons are short and entirely confined to the gray substance, in which they break up into numerous fine filaments. Most of the nerve cells are arranged in longitudinal column, and appear as groups on transverse section (Figs. 688, 689).

Nerve Cells in the Anterior Column.—The nerve cells in the anterior column are arranged in columns of varying length. The longest occupies the medial part of

¹ Lenhossek and Cajal found that in the chick embryo the axons of a few of these nerve cells passed backward through the posterior column, and emerged as the motor fibres of the posterior nerve roots. These fibres are said to control the peristaltic movements of the intestine. Their presence, in man, has not yet been determined.

the anterior column, and is named the **antero-medial column**: it is absent only in the fifth lumbar, the first sacral and the upper part of the second sacral segments (Bruce).¹ Behind it is a **dorso-medial column** of small cells, which extends from the second thoracic to the first lumbar segment, and is also present in the first, sixth, and seventh cervical segments.

11 12 13.

FIG. 638.—Mode of distribution of the nerve cells in the gray substance. (Schematic.) (Testut.) 1, 2. Medial and lateral groups of nerve cells in anterior column. 3. Cells of origin of the superficial antero-lateral fasciculus. 11. Anterior root. 12. Posterior root. 13. Spinal ganglion.

In the cervical and lumbar enlargements, where the anterior column is expanded in a lateral direction, the following additional columns are present, viz.: (a) **antero-lateral**, in the fourth, fifth, and sixth cervical and the second thoracic segments, and in the lower four lumbar and upper two sacral segments; (b) **postero-lateral**, in the lower five cervical, lower four lumbar, and upper three sacral segments; (c) **post-postero-lateral**, in the last cervical, first thoracic, and upper three sacral segments; and (d) a **central**, in the lower four lumbar and upper two sacral segments. Throughout the base of the anterior column are scattered solitary cells, the axons of some of which form crossed commissural fibres, while others constitute the motor fibres of the posterior nerve roots. (See footnote, page 811.)

Nerve Cells in the Lateral Column.—These form a column which is best marked where the lateral gray column is differentiated, viz., in the thoracic region;² but it can be traced throughout the entire length of the medulla spinalis in the form of groups of small cells which are situated in the anterior part of the formatio reticularis. The cells of this column are fusiform or star-shaped, and of a medium size: the axons of some of them pass into the anterior nerve roots, by which they are carried to the sympathetic nerves; while the axons of others pass into the anterior and lateral funiculi, where they become longitudinal.

¹ Topographical Atlas of the Spinal Cord, 1901.

² According to Bruce and Pirie (B. M. J., November 17, 1906) this column extends from the middle of the eighth cervical segment to the lower part of the second lumbar or the upper part of the third lumbar segment.

Nerve Cells in the Posterior Column.—1. The dorsal nucleus (*nucleus dorsalis; column of Clarke*) occupies the medial part of the base of the posterior column, and appears on the transverse section as a well-defined oval area. It begins below at the level of the second or third lumbar nerve, and reaches its maximum size opposite the twelfth thoracic nerve. Above the level of the ninth thoracic nerve its size diminishes, and the column ends opposite the last cervical or first thoracic nerve. It is represented, however, in the other regions by scattered cells, which become aggregated to form a **cervical nucleus** opposite the third cervical nerve, and a **sacral nucleus** in the middle and lower part of the sacral region. Its cells are of medium size, and of an oval or pyriform shape; their axons pass into the peripheral part of the lateral funiculus of the same side, and there ascend, under the name of the **cerebellospinal (direct cerebellar) fasciculus**. 2. The nerve cells in the **substantia gelatinosa of Rolando** are arranged in three zones: a posterior or marginal, of large angular or fusiform cells; an intermediate, of small fusiform cells; and an anterior, of star-shaped cells. The axons of these cells pass into the lateral and posterior funiculi, and there assume a vertical course. In the anterior zone some Golgi cells are found whose short axons ramify in the gray substance. 3. **Solitary cells** of varying form and size are scattered throughout the posterior column. Some of these are grouped to form the **posterior basal column** in the base of the posterior column, lateral to the dorsal nucleus; the posterior basal column is well-marked in the gorilla (Waldeyer), but is ill-defined in man. The axons of its cells pass partly to the posterior and lateral funiculi of the same side, and partly through the anterior white commissure to the lateral funiculus of the opposite side. Before leaving the gray substance, a considerable number run longitudinally for a varying distance in the head of the posterior column, forming what is termed the **longitudinal fasciculus** of the posterior column.

FIG. 689.—Transverse sections of the medulla spinalis at different levels to show the arrangement of the principal cell columns.

A few star-shaped or fusiform nerve cells of varying size are found in the *substantia gelatinosa centralis*. Their axons pass into the lateral funiculus of the same, or of the opposite side.

The nerve fibres in the gray substance form a dense interlacement of minute fibrils among the nerve cells. This interlacement is formed partly of axons which pass from the cells in the gray substance to enter the white funiculi or nerve roots; partly of the axons of Golgi's cells which ramify only in the gray substance; and partly of collaterals from the nerve fibres in the white funiculi which, as already stated, enter the gray substance and ramify within it.

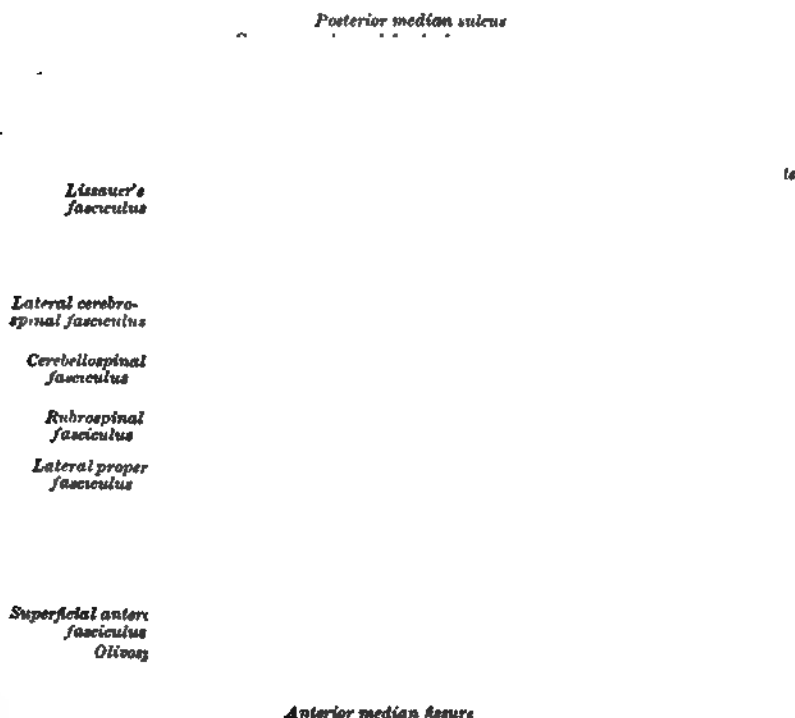

FIG. 690.—Diagram of the principal fasciculi in the medulla spinalis.

White Substance (*substantia alba*).—The white substance of the medulla spinalis consists of medullated nerve fibres imbedded in a sponge-like net-work of neuroglia, and is arranged in three funiculi: anterior, lateral, and posterior. The anterior funiculus lies between the anterior median fissure and the most lateral of the anterior nerve roots: the lateral funiculus between these nerve roots and the postero-lateral sulcus; and the posterior funiculus between the postero-lateral and the posterior median sulci (Fig. 690). The fibres vary greatly in thickness, the smallest being found in the fasciculus gracilis, the tract of Lissauer, and inner part of the lateral funiculus; while the largest are situated in the anterior funiculus, and in the peripheral part of the lateral funiculus. Some of the nerve fibres assume a more or less transverse direction, as for example those which cross from side to side in the anterior white commissure, but the majority pursue a longitudinal course and are divisible into (1) those connecting the medulla spinalis with the brain and conveying impulses to or from the latter, and (2) those which are confined to the medulla spinalis and link together its different segments, *i. e.*, intersegmental or association fibres.

Nerve Fasciculi.—The longitudinal fibres are grouped into more or less definite bundles or fasciculi. These are not recognizable from each other in the normal

state, and their existence has been determined by the following methods: (1) A. Waller discovered that if a bundle of nerve fibres be cut, the portions of the fibres which are separated from their cells rapidly degenerate and become atrophied, while the cells and the parts of the fibres connected with them undergo little alteration.¹ This is known as **Wallerian degeneration**. Similarly, if a group of nerve cells be destroyed, the fibres arising from them undergo degeneration. Thus, if the motor cells of the cerebral cortex be destroyed, or if the fibres arising from these cells be severed, a **descending degeneration** from the seat of injury takes place in the fibres. In the same manner, if a spinal ganglion be destroyed, or the fibres which pass from it into the medulla spinalis be cut, an **ascending degeneration** will extend along these fibres. (2) By tracing the development of the nervous system, it has been observed that at first the nerve fibres are merely naked axis-cylinders, and that they do not all acquire their medullary sheaths at the same time; hence the fibres can be grouped into different bundles according to the dates at which they receive their medullary sheaths. (3) Various methods of staining nervous tissue are of great value in tracing the course and mode of termination of the axis-cylinder processes.

Fasciculi in the Anterior Funiculus.—The principal fasciculus is the **anterior cerebrospinal** (*fasciculus cerebrospinalis anterior; direct pyramidal tract*), which is usually small, but varies inversely in size with the lateral cerebrospinal fasciculus. It lies close to the anterior median fissure, and is present only in the upper part of the medulla spinalis; gradually diminishing in size as it descends, it ends about the middle of the thoracic region. It consists of descending fibres which arise from cells in the motor area of the cerebral hemisphere of the same side, and which, as they run downward in the medulla spinalis, cross in succession through the anterior white commissure to the opposite side, where they end by arborizing around the motor cells in the anterior column.

In addition to the anterior cerebrospinal fasciculus there are strands of fibres in the anterior funiculus connecting certain ganglia in the brain with the gray substance of the medulla spinalis. The most important of these is the **vestibulospinal**, situated chiefly in the marginal part of the funiculus and mainly derived from the cells of Deiters' nucleus, *i. e.*, the chief terminal nucleus of the vestibular division of the acoustic nerve. Of the other descending fibres some pass downward from the corpora quadrigemina (**tectospinal**) and others are continuous with the medial longitudinal fasciculus.

The remaining fibres of the anterior funiculus constitute what is termed the **anterior proper fasciculus** (*fasciculus anterior proprius; anterior basis bundle*). It consists of (a) longitudinal intersegmental fibres which arise from cells in the gray substance, more especially from those of the medial group of the anterior column, and, after a longer or shorter course, reënter the gray substance; (b) fibres which cross in the anterior white commissure from the gray substance of the opposite side; (c) fibres arising from cells of the cerebellum and extending down the medulla spinalis to end around the cells of the anterior column—these fibres constitute an irregular tract, **cerebellospinal tract of Lowenthal**, disposed in the peripheral portions of the anterior and lateral proper fasciculi; and (d) fibres of the anterior nerve roots, which run obliquely forward to reach the surface of the medulla spinalis.

Fasciculi in the Lateral Funiculus.—1. **Descending Fasciculi.**—(a) The **lateral cerebrospinal fasciculus** (*fasciculus cerebrospinalis lateralis; crossed pyramidal tract*) extends throughout the entire length of the medulla spinalis, and on transverse section appears as an oval area in front of the posterior column and medial

¹ Somewhat later a change, termed *chromatolysis*, takes place in the nerve cells, and consists of a breaking down and an ultimate disappearance of the Nissl bodies. Further, the body of the cell is swollen, the nucleus displaced toward the periphery, and the part of the axon still attached to the altered cell is diminished in size and somewhat atrophied. Under favorable conditions the cell is capable of reassuming its normal appearance, and its axon may grow again.

to the cerebellospinal. Its fibres arise from cells in the motor area of the cerebral hemisphere of the opposite side. They pass downward in company with those of the anterior cerebrospinal fasciculus through the same side of the brain as that from which they originate, but they cross to the opposite side in the medulla oblongata and descend in the lateral funiculus of the medulla spinalis; they end by arborizing around the motor cells in the anterior column.¹

The anterior and lateral cerebrospinal fasciculi constitute the motor fasciculi of the medulla spinalis and have their origins in the motor cells of the cerebral cortex. They descend through the internal capsule of the cerebrum, traverse the cerebral peduncles and pons and enter the pyramid of the medulla oblongata. In the lower part of the latter about two-thirds of them cross the middle line and run downward in the lateral funiculus as the lateral cerebrospinal fasciculus, while the remaining fibres do not cross the middle line, but are continued into the same side of the medulla spinalis, where they form the anterior cerebrospinal fasciculus. The fibres of the latter, however, cross the middle line in the anterior white commissure, and thus all the motor fibres from one side of the brain ultimately reach the opposite side of the medulla spinalis. The proportion of fibres which cross in the medulla oblongata is not a constant one, and thus the anterior and lateral cerebrospinal fasciculi vary inversely in size. Sometimes the former is absent, and in such cases it may be presumed that the decussation of the motor fibres in the medulla oblongata has been complete. The fibres of these two fasciculi do not acquire their medullary sheaths until after birth. In some animals the motor fibres are situated in the posterior funiculus.

(b) The **rubrospinal fasciculus** (Monakow) (*prepyramidal tract*), lies on the ventral aspect of the lateral cerebrospinal fasciculus and on transverse section appears as a somewhat triangular area. Its fibres descend from the mid-brain, where they have their origin in the red nucleus of the tegmentum of the opposite side.

(c) The **tectospinal fasciculus** originates in the superior colliculus (upper quadrigeminal body) of the opposite side, and its fibres are partly intermingled with those of the rubrospinal fasciculus, and are partly contained in the anterior funiculus.

(d) The **olivospinal fasciculus** (Helweg) arises in the vicinity of the inferior olivary nucleus in the medulla oblongata, and is seen only in the cervical region of the medulla spinalis, where it forms a small triangular area at the periphery, close to the most lateral of the anterior nerve roots. Its exact origin and its mode of ending have not yet been definitely made out.

2. **Ascending Fasciculi.**—(a) The **cerebellospinal fasciculus** (*fasciculus cerebello-spinalis*; *direct cerebellar tract of Flechsig*) is situated at the periphery of the posterior part of the lateral funiculus, and on transverse section appears as a flattened band reaching as far forward as a line drawn transversely through the central canal. Medially, it is in contact with the lateral cerebrospinal fasciculus, behind, with the fasciculus of Lissauer. It begins about the level of the second or third lumbar nerve and, increasing in size as it ascends, passes to the cerebellum through the restiform body. Its fibres are generally regarded as being formed by the axons of the cells of the dorsal nucleus (Clarke's column); they receive their medullary sheaths about the sixth or seventh month of fetal life.

(b) The **superficial antero-lateral fasciculus** (*fasciculus anterolateralis superficialis*; *tract of Gowers*) skirts the periphery of the lateral funiculus in front of the cerebellospinal fasciculus. In transverse section it is shaped somewhat like a comma, the expanded end of which lies in front of the lateral cerebrospinal fasciculus while the tail reaches forward into the anterior funiculus. Its fibres come from the oppo-

¹ It is probable (Schäfer, Proc. Physiolog. Soc., 1899) that the fibres of the anterior and lateral cerebrospinal fasciculi are not related in this direct manner with the cells of the anterior column, but terminate by arborizing around the cells at the base of the posterior column and the cells of Clarke's column, which in turn link them to the motor cells in the anterior column, usually of several segments of the cord. In consequence of these interposed neurons the fibres of the cerebrospinal fasciculi correspond not to individual muscles, but to associated groups of muscles.

site side of the medulla spinalis and cross in the anterior white commissure; they are derived from the cells of the dorsal nucleus and from other cells of the posterior column. The superficial antero-lateral fasciculus begins about the level of the third pair of lumbar nerves, and, increasing in size as it ascends, can be followed into the medulla oblongata and pons. It consists of three fasciculi: (1) the **ventral spinocerebellar**, the largest of the three, passes to the cerebellum by way of the brachia conjunctiva; (2) the **spinothalamic** ends in the thalamus, and is sometimes termed the **secondary sensory fasciculus**; and (3) the **spinotectal** passes to the corpora quadrigemina.

(c) The **fasciculus of Lissauer** is a small strand situated in relation to the tip of the posterior column close to the entrance of the posterior nerve roots. It consists of fine fibres which do not receive their medullary sheaths until toward the close of fetal life. It is usually regarded as being formed by some of the fibres of the posterior nerve roots, which ascend for a short distance in the tract and then enter the posterior column, but since its fibres are myelinated later than those of the posterior nerve roots, and do not undergo degeneration in locomotor ataxia, they are probably intersegmental in character.

(d) The **lateral proper fasciculus** (*fasciculus lateralis proprius*; *lateral basis bundle*) constitutes the remainder of the lateral column, and is continuous in front with the anterior proper fasciculus. It consists chiefly of intersegmental fibres which arise from cells in the gray substance, and, after a longer or shorter course, reënter the gray substance and ramify in it. Some of its fibres are, however, continued upward into the brain under the name of the **medial longitudinal fasciculus**.

Fasciculi in the Posterior Funiculus.—This funiculus comprises two main fasciculi, viz., the **fasciculus gracilis**, and the **fasciculus cuneatus**. These are separated from each other in the cervical and upper thoracic regions by the postero-intermediate septum, and consist mainly of ascending fibres derived from the posterior nerve roots.

The **fasciculus gracilis** (*tract of Goll*) is wedge-shaped on transverse section, and lies next the posterior median septum, its base being at the surface of the medulla spinalis, and its apex directed toward the posterior gray commissure. It increases in size from below upward, and consists of long thin fibres which are derived from the posterior nerve roots, and ascend as far as the medulla oblongata, where they end in the nucleus gracilis.

The **fasciculus cuneatus** (*tract of Burdach*) is triangular on transverse section, and lies between the fasciculus gracilis and the posterior column, its base corresponding with the surface of the medulla spinalis. Its fibres, larger than those of the fasciculus gracilis, are mostly derived from the same source, viz., the posterior nerve roots. Some ascend for only a short distance in the tract, and, entering the gray matter, come into close relationship with the cells of the dorsal nucleus; while others can be traced as far as the medulla oblongata, where they end in the gracile and cuneate nuclei.

Occupying the ventral part of the posterior funiculus is a strand of fibres termed the **cornu-commissural fasciculus**. It is somewhat triangular on transverse section, and occupies the angle between the posterior gray commissure and the posterior column. It is best marked in the lumbar region, but can be traced into the thoracic and cervical regions. Its fibres, derived from the cells of the posterior column, divide into ascending and descending branches which reënter and ramify in the gray substance. It has been found to preserve its integrity in certain cases of locomotor ataxia.

Descending Fibres in the Posterior Funiculus (Fig. 692).—The posterior funiculus contains some descending fibres which occupy different parts at different levels. In the cervical and upper thoracic regions, they appear as a **comma-shaped fasciculus** in the lateral part of the fasciculus cuneatus, the blunt end of the comma being

directed toward the posterior gray commissure; in the lower thoracic region they form a **dorsal peripheral band** on the posterior surface of the funiculus; in the lumbar region, they are situated by the side of the posterior median septum, and appear on section as a semi-elliptical bundle, which, together with the corresponding bundle of the opposite side, forms the **oval area of Flechsig**; while in the conus medullaris they assume the form of a **triangular strand** in the postero-medial part

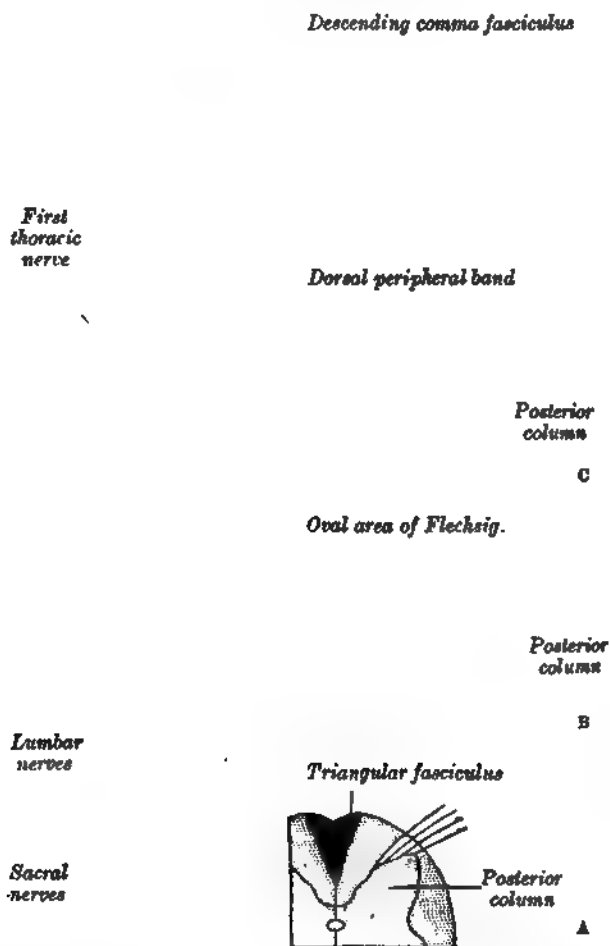

FIG. 691. —Formation of the fasciculus gracilis. (Poirier) Medulla spinalis viewed from behind. To the left, the fasciculus gracilis is shaded. To the right, the drawing shows that the fasciculus gracilis is formed by the long fibres of the posterior roots, and that in this tract the sacral nerves lie next the median plane, the lumbar to their lateral side, and the thoracic still more laterally.

FIG. 692. —Descending fibres in the posterior funiculi, shown at different levels. (After Testut.) A. In the conus medullaris. B. In the lumbar region. C. In the lower thoracic region. D. In the upper thoracic region.

of the fasciculus gracilis. These descending fibres are mainly intersegmental in character and derived from cells in the posterior column, but some consist of the descending branches of the posterior nerve roots. The comma-shaped fasciculus was supposed to belong to the second category, but against this view is the fact that it does not undergo descending degeneration when the posterior nerve roots are destroyed.

Roots of the Spinal Nerves.—As already stated, each spinal nerve possesses two roots, an anterior and a posterior, which are attached to the surface of the

medulla spinalis opposite the corresponding column of gray substance (Fig. 693); their fibres become medullated about the fifth month of fetal life.

The **Anterior Nerve Root** (*radix anterior*) consists of efferent fibres, which are the axons of the nerve cells in the ventral part of the anterior column. A short distance from their origins, these axons are invested by medullary sheaths and, passing forward, emerge in two or three irregular rows over an area which measures about 3 mm. in width.

The **Posterior Root** (*radix posterior*) comprises some six or eight fasciculi, attached in linear series along the postero-lateral sulcus. It consists of afferent fibres which arise from the nerve cells in a spinal ganglion. Each ganglion cell gives off a single fibre which divides in a T-shaped manner into two processes, medial and lateral. The medial processes of the ganglion cells grow into the medulla spinalis as the posterior roots of the spinal nerves, while the lateral are directed toward the periphery.

FIG. 694.—Posterior roots entering medulla spinalis and dividing into ascending and descending branches. (Van Gehuchten.) a. Stem fibre. b, b. Ascending and descending limbs of bifurcation. c. Collateral arising from stem fibre.

The posterior nerve root enters the medulla spinalis in three chief bundles, medial, intermediate, and lateral. The **medial** strand passes directly into the fasciculus cuneatus: it consists of coarse fibres, which acquire their medullary sheaths about the fifth month of intrauterine life; the **intermediate** strand consists of coarse fibres, which enter the gelatinous substance of Rolando; the **lateral** is composed of fine fibres, which assume a longitudinal direction in the tract of Lissauer, and do not acquire their medullary sheaths until after birth.

Having entered the medulla spinalis, all the fibres of the posterior nerve roots divide into ascending and descending branches, and these in their turn give off collaterals which enter the gray substance (Fig. 694). The descending fibres are short, and soon enter the gray substance. The ascending fibres are grouped into long, short, and intermediate: the long fibres ascend in the fasciculus cuneatus and fasciculus gracilis as far as the medulla oblongata, where they end by arborizing around the cells of the cuneate and gracile nuclei; the short fibres run upward for a distance of only 5 or 6 mm. and enter the gray substance; while the inter-

mediate fibres, after a somewhat longer course, have a similar destination. All fibres entering the gray substance end by arborizing around its nerve cells, those of intermediate length being especially associated with the cells of the dorsal nucleus.

The fibres of the posterior nerve roots pursue an oblique course upward, being situated at first in the lateral part of the fasciculus cuneatus: higher up, they occupy the middle of this fasciculus, having been displaced by the accession of other entering fibres; while still higher, they ascend in the fasciculus gracilis. The upper cervical fibres do not reach this fasciculus, but are entirely confined to the fasciculus cuneatus. The localization of these fibres is very precise: the sacral nerves lie in the medial part of the fasciculus gracilis and near its periphery, the lumbar nerves lateral to them, the thoracic nerves still more laterally; while the cervical nerves are confined to the fasciculus cuneatus (Fig. 691).

The development of the medulla spinalis is described in the section on Embryology (pages 117 to 120).

Applied Anatomy.—Several cases have been recorded¹ in which a local doubling of the medulla spinalis has taken place. The condition is probably due to some interference with the development of the neural tube in the embryo; in a few it was associated with spina bifida, while in one recent case² the two parts were separated by a dermoid tumor. Other *congenital abnormalities* of the medulla spinalis occur in connection with spina bifida (see p. 214), and also in *syringomyelia*. In this latter chronic condition an abnormal proliferation of the neuroglia takes place, generally near the central canal and in the cervical enlargement, and later this mass becomes absorbed, leaving an irregular cavity in its place. This gives rise to a number of interesting signs and symptoms, such as analgesia (or insensitiveness to pain), inability to distinguish between cold and heat, progressive atrophy in the muscles of the hands and arms, trophic changes in the bones and joints, and painless whitlows. Severe *injuries* to the medulla spinalis may occur in fractures or fracture-dislocations of the vertebral column anywhere above the second lumbar vertebra. If the medulla spinalis is completely crushed or torn across, total paralysis and anesthesia of all parts of the body drawing their nerve supply from below the injured spot will follow, with loss of control over the actions of the bladder and rectum. The higher up such a lesion occurs, the worse the prognosis. Thus, when the medulla spinalis is crushed by fracture of the atlas or axis, the vital centres in the medulla oblongata are injured, and death occurs at once. If the origin of the phrenic nerve—mainly the fourth cervical—just escape in a case where the neck is broken, respiration will have to be carried on by the Diaphragma alone, and death is likely to ensue before long from pulmonary complications. When the back is broken in the lower thoracic region, life is not immediately threatened; but unless the patient is carefully nursed, death may follow at any time from the development of bed-sores in the anesthetic area, or from septic infection spreading up the ureters into the kidneys and secondary to the cystitis that is so prone to occur in patients who have no control over the bladder. *Inflammation* of the medulla spinalis, or *spinal myelitis*, sometimes follows influenza or one of the acute specific fevers. A transverse patch of such myelitis extending completely across the medulla spinalis produces more or less complete interruption of the passage of nervous impulses through it. Hence it will occasion more or less complete paralysis and anesthesia of the parts of the body obtaining their nerve supply from below it, and, in addition, a zone of cutaneous hyperesthesia at its level, in consequence of the irritation of the sensory fibres entering the inflamed region of the medulla spinalis. The disease mainly attacking children, and known as *infantile spinal paralysis*, or *acute anterior poliomyelitis*, is a bacterial infection of the pia mater that spreads into the medulla spinalis along the bloodvessels, and destroys groups of the motor neurons aggregated in the anterior column. Destruction of the cells causes rapid and permanent paralysis of the muscles innervated, and groups of muscles in one or more of the limbs are commonly picked out for attack. The affected limbs are thus partially paralyzed, and their subsequent growth and nutrition both suffer. Further, the muscles that normally antagonize the affected groups of muscles, finding their actions unopposed, tend to assume a state of spastic contraction. In consequence, much dwarfing and deformity follow later, and may demand for their relief such operations as tenotomy, the transplantation of tendons, or even amputation.

Inflammation of the ganglia on one or more of any of the posterior nerve roots is the cause of *shingles*³ or herpes zoster, in which there is a painful eruption of groups of cutaneous vesicles corresponding to the distribution of the nerves derived from the affected ganglia. It is com-

¹ For an analysis of these cases consult paper by Bruce, Stuart McDonald, and Pirie, *Review of Neurology and Psychiatry*, January, 1906.

² Harriehausen, *D. Ztschrift. f. Nervenheilk.*, Band xxxvi, Heft 3 and 4, S. 268.

³ From Lat. *cingulum*, a belt.

monest along the course of the intercostal nerves; the eruption is often preceded and followed, as well as accompanied, by girdle pains, and in old people these may be prolonged and serious in character. Herpes is the analogue on the sensory side to anterior poliomyelitis on the motor side of the nervous system.

THE ENCEPHALON OR BRAIN.

Dissection.—To examine the brain with its membranes, the skull-cap must be removed. In order to effect this, saw through the external table, the section commencing, in front, about 2 cm. ($\frac{3}{4}$ inch) above the margin of the orbits, and extending, behind, to a little above the level of the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen and forcibly detach the skull-cap, and the dura will be exposed. The adhesion between the bone and the dura often is very intimate, particularly along the sutures.

General Considerations and Divisions.—The encephalon, or brain, is contained within the cranium, and constitutes the upper, greatly expanded part of the central nervous system. In its early embryonic condition it consists of three hollow vesicles, termed the **rhombencephalon** or **hind-brain**, the **mesencephalon** or **mid-brain**, and the **prosencephalon** or **fore-brain**; and the parts derived from each of these can be recognized in the adult (Fig. 695). Thus in the process of development the wall of the rhombencephalon undergoes modification to form the medulla oblongata, the pons, and cerebellum, while its cavity is expanded to form the fourth ventricle. The mesencephalon forms only a small part of the adult brain; its cavity becomes the **cerebral aqueduct** (*aqueduct of Sylvius*), which serves as a tubular communication between the third and fourth ventricles; while its walls are thickened to form the corpora quadrigemina and cerebral peduncles. The prosencephalon undergoes great modification: its anterior part or **telencephalon** expands laterally in the form of two hollow vesicles, the cavities of which become the lateral ventricles, while the surrounding walls form the cerebral hemispheres and their commissures; the cavity of the posterior part or **diencephalon** forms the greater part of the third ventricle, and from its walls are developed most of the structures which bound that cavity. Further details regarding these important changes are given in the section on Embryology (pages 120 to 132).

FIG. 695.—Scheme showing the connections of the several parts of the brain. (After Schwalbe.)

THE RHOMBENCEPHALON OR HIND-BRAIN.

The **rhombencephalon** or **hind-brain** occupies the posterior fossa of the cranial cavity and lies below a fold of dura mater, the **tentorium cerebelli**. It consists of (a) the **myelencephalon**, comprising the medulla oblongata and the lower part of the fourth ventricle; (b) the **metencephalon**, consisting of the pons, cerebellum, and the intermediate part of the fourth ventricle; and (c) the **isthmus rhombencephali**, a constricted portion immediately adjoining the mesencephalon and includ-

ing the brachia, conjunctiva of the cerebellum, the anterior medullary velum, and the upper part of the fourth ventricle.

The Medulla Oblongata (*spinal bulb*).—The medulla oblongata is the lowest and smallest division of the brain; its structure, however, is extremely complex, since it gives attachment to many of the cerebral nerves, and forms the connecting link between the medulla spinalis below and the cerebrum and cerebellum above.

It extends from the lower margin of the pons to a plane passing transversely below the pyramidal decussation and above the first pair of cervical nerves; this plane corresponds with the upper border of the atlas behind, and the middle of the odontoid process of the epistropheus or axis in front; at this level the medulla oblongata is continuous with the medulla spinalis. Its anterior surface is separated from the basilar part of the occipital bone and the upper part of the odontoid process by the membranes of the brain and the occipitoaxial ligaments. Its posterior surface is received into the fossa between the hemispheres of the cerebellum, and the upper portion of it forms the lower part of the floor of the fourth ventricle. The vertebral arteries pass upward and forward in relation to its lateral surfaces; they then curve forward on to its anterior surface and unite at the lower border of the pons to form the basilar artery.

The medulla oblongata is pyramidal in shape, its broad extremity being directed upward toward the pons, while its narrow, lower end is continuous with the medulla spinalis. It measures about 3 cm. in length, about 2 cm. in breadth at its widest part, and about 1.25 cm. in thickness. The central canal of the medulla spinalis is prolonged into its lower half, and then opens into the cavity of the fourth ventricle; the medulla oblongata may therefore be divided into a lower *closed part* containing the central canal, and an upper *open part* corresponding with the lower portion of the fourth ventricle. Its anterior and posterior surfaces are marked by median fissures.

The **Anterior Median Fissure** (*fissura mediana anterior; ventral or ventromedian fissure*) contains a fold of pia mater, and extends along the entire length of the medulla oblongata: it ends at the lower border of the pons in a small triangular expansion, termed the **foramen caecum**. Its lower part is interrupted by bundles of fibres which cross obliquely from one side to the other, and constitute the **pyramidal decussation**. Some fibres, termed the **anterior external arcuate fibres**, emerge from the fissure above this decussation and curve lateralward and upward over the surface of the medulla oblongata.

The **Posterior Median Fissure** (*fissura mediana posterior; dorsal or dorsomedian fissure*) is a narrow groove; and exists only in the closed part of the medulla oblongata; it becomes gradually shallower from below upward, and finally ends about the middle of the medulla oblongata, where the central canal expands into the cavity of the fourth ventricle.

These two fissures divide the closed part of the medulla oblongata into symmetrical halves, each presenting elongated eminences which, on surface view, are continuous with the funiculi of the medulla spinalis. In the open part the halves are separated by the anterior median fissure, and by a median **raphe** which extends from the bottom of the fissure to the floor of the fourth ventricle. Further, certain of the cerebral nerves pass through the substance of the medulla oblongata, and are attached to its surface in series with the roots of the spinal nerves; thus, the fibres of the hypoglossal nerve represent the upward continuation of the anterior nerve roots, and emerge in linear series from a furrow termed the **antero-lateral sulcus**. Similarly, the accessory, vagus, and glossopharyngeal nerves correspond with the posterior nerve roots, and are attached to the bottom of a sulcus named the **postero-lateral sulcus**. Advantage is taken of this arrangement to subdivide each half of the medulla oblongata into three districts, **anterior, middle, and posterior**. Although these three districts appear to be directly continuous

with the corresponding funiculi of the medulla spinalis, they do not necessarily contain the same fibres, since some of the fasciculi of the medulla spinalis end in the medulla oblongata, while others alter their course in passing through it.

The anterior district (Fig. 696) is named the **pyramid** (*pyramis medullae oblongatae*) and lies between the anterior median fissure and the antero-lateral sulcus. Its upper end is slightly constricted, and between it and the pons the fibres of the abducent nerve emerge; a little below the pons it becomes enlarged and prominent, and finally tapers into the anterior funiculus of the medulla spinalis, with which, at first sight, it appears to be directly continuous.

The two pyramids contain the motor fibres which pass from the brain to the medulla spinalis. When these pyramidal fibres are traced downward it is found that some two-thirds or more of them

leave the pyramids in successive bundles, and decussate in the anterior median fissure, forming what is termed the **pyramidal decussation**. Having crossed the middle line, they pass down in the posterior part of the lateral funiculus as the lateral cerebrospinal fasciculus. The remaining fibres—i. e., those which occupy the lateral part of the pyramid—do not cross the middle line, but are carried downward as the anterior cerebrospinal fasciculus (Fig. 697) into the anterior funiculus of the same side.

The greater part of the anterior proper fasciculus of the medulla spinalis is continued upward through the medulla oblongata under the name of the **medial longitudinal fasciculus**.

The **lateral district** (Fig. 698) is limited in front by the antero-lateral sulcus and the roots of the hypoglossal nerve, and behind by the postero-lateral sulcus and the roots of the accessory, vagus, and glossopharyngeal nerves. Its upper part consists of a prominent oval mass which is named the **olive**, while its lower part

is of the same width as the lateral funiculus of the medulla spinalis, and appears on the surface to be a direct continuation of it. As a matter of fact, only a portion of the lateral funiculus is continued upward into this district, for the lateral cerebro-spinal fasciculus passes into the pyramid of the opposite side, and the cerebello-spinal fasciculus is carried into the restiform body in the posterior district. The remainder of the lateral funiculus, which consists chiefly of the lateral proper fasciculus and the superficial antero-lateral fasciculus can be traced into the lateral district. Most of these fibres dip beneath the olive and disappear from the surface; but a small strand remains superficial, and ascends between the olive and the postero-lateral sulcus. In a depression at the upper end of this strand is the acoustic nerve.

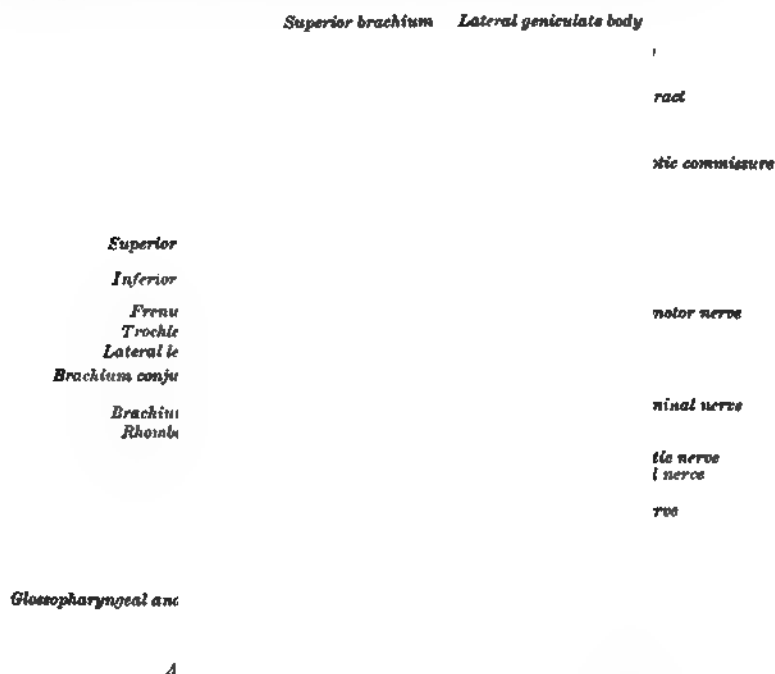

FIG. 698.—Hind- and mid-brains; postero-lateral view.

The **olive** (*oliva*; *olivary body*) is situated lateral to the pyramid, from which it is separated by the antero-lateral sulcus, and the fibres of the hypoglossal nerve. Behind, it is separated from the postero-lateral sulcus by the small superficial strand of the lateral funiculus already referred to. It measures about 1.25 cm. in length, and between its upper end and the pons there is a slight depression to which the roots of the facial nerve are attached. The external arcuate fibres wind across the lower part of the pyramid and olive and enter the restiform body.

The **posterior district** (Fig. 699) lies behind the postero-lateral sulcus and the roots of the accessory, vagus, and the glossopharyngeal nerves, and, like the lateral district, is divisible into a lower and an upper portion.

The **lower part** is limited behind by the posterior median fissure, and consists of the **fasciculus gracilis** and the **fasciculus cuneatus**. The fasciculus gracilis is placed parallel to and along the side of the posterior median fissure, and separated from the fasciculus cuneatus by the postero-intermediate sulcus and septum. The gracile and cuneate fasciculi are at first vertical in direction; but at the lower part of the rhomboid fossa they diverge from the middle line in a V-shaped manner, and each presents an elongated swelling. That on the fasciculus gracilis is named the **clava**, and is produced by a subjacent nucleus of gray matter, the **nucleus**

gracilis; that on the fasciculus cuneatus is termed the **cuneate tubercle**, and is likewise caused by a gray nucleus, named the **nucleus cuneatus**. The fibres of these fasciculi terminate by arborizing around the cells in their respective nuclei. A third elevation, produced by the substantia gelatinosa of Rolando, is present in the lower part of the posterior district of the medulla oblongata. It lies on the lateral aspect of the fasciculus cuneatus, and is separated from the surface of the medulla oblongata by a band of nerve fibres which form the spinal tract (spinal root) of the trigeminal nerve. Narrow below, this elevation gradually expands above, and ends, about 1.25 cm. below the pons, in a tubercle, the **tubercle of Rolando** (*tuber cinereum*).

FIG. 699.—Upper part of medulla spinalis and hind- and mid-brains; posterior aspect, exposed *in situ*.

The upper part of the posterior district of the medulla oblongata is occupied by the **restiform body**, a thick rope-like strand situated between the lower part of the fourth ventricle and the roots of the glossopharyngeal and vagus nerves. The restiform bodies connect the medulla spinalis and medulla oblongata with the cerebellum, and are sometimes named the **inferior peduncles of the cerebellum**. As they pass upward, they diverge from each other, and assist in forming the lower part of the lateral boundaries of the fourth ventricle; higher up, they are directed backward, each passing to the corresponding cerebellar hemisphere. Near their entrance into the cerebellum they are crossed by several strands of fibres, which run to the median sulcus of the rhomboid fossa, and are named the **striae medullares**.

The restiform body appears to be the upward continuation of the fasciculus gracilis and fasciculus cuneatus; this, however, is not so, as the fibres of these fasciculi end in the gracile and cuneate nuclei. The constitution of the restiform body will be subsequently discussed.

Internal Structure of the Medulla Oblongata.—Although the external form of the medulla oblongata bears a certain resemblance to that of the upper part of the medulla spinalis, its internal structure differs widely from that of the latter, and this for the following principal reasons: (1) certain fasciculi which extend from the medulla spinalis to the brain, and *vice versa*, undergo a rearrangement in their passage through the medulla oblongata; (2) others which exist in the medulla spinalis end in the medulla oblongata; (3) new fasciculi originate in the gray substance of the medulla oblongata and pass to different parts of the brain; (4) the gray substance, which in the medulla spinalis forms a continuous H-shaped column, becomes greatly modified and subdivided in the medulla oblongata, where also new masses of gray substance are added; (5) on account of the opening out of the central canal

Fig. 700.—Section of the medulla oblongata through the lower part of the decussation of the pyramids. (Testut.) 1. Anterior median fissure. 2. Posterior median sulcus. 3. Anterior column (in red), with 3', anterior root. 4. Posterior column (in blue), with 4', posterior root. 5. Lateral cerebrospinal fasciculus. 6. Posterior funiculus. The red arrow, *a*, *a'*, indicates the course the lateral cerebrospinal fasciculus takes at the level of the decussation of the pyramids; the blue arrow, *b*, *b'*, indicates the course which the sensory fibres take.

Fig. 701.—Section of the medulla oblongata at the level of the decussation of the pyramids. (Testut.) 1. Anterior median fissure. 2. Posterior median sulcus. 3. Motor roots. 4. Sensory roots. 5. of the medulla spinalis, certain parts of the gray substance, which in the medulla spinalis were more or less centrally situated, are displayed in the rhomboid fossa; (6) the medulla oblongata is intimately associated with many of the cerebral nerves, some arising from, and others ending in, nuclei within its substance.

The internal structure of the medulla oblongata is best studied in series of transverse (Figs. 704, 705) and of longitudinal sections. A short description of the course taken by the principal fasciculi, and of the arrangement of the gray substance, will now be given.

The Cerebrospinal Fasciculi.—The downward course of these fasciculi from the pyramids of the medulla oblongata and their partial decussation have already been described (page 816). In crossing to reach the lateral funiculus of the opposite side, the fibres of the lateral cerebrospinal fasciculi extend backward through the anterior columns, and separates the head of each of these columns from its base (Figs. 700, 701). The base retains its position in relation to the ventral aspect of the central canal, and, when the latter opens into the fourth ventricle, appears in the rhomboid fossa close to the middle line, where it forms the nuclei of the hypoglossal and abducent nerves; while above the level of the ventricle it exists as the nuclei of the trochlear and oculomotor nerves in relation to the floor of the cerebral aqueduct. The head of the column is pushed lateralward and forms the *nucleus ambiguus*, which gives origin from below upward to the cerebral part

of the accessory and the motor fibres of the vagus and glossopharyngeal, and still higher to the motor fibres of the facial and trigeminal nerves.

The *fasciculus gracilis* and *fasciculus cuneatus* constitute the posterior sensory fasciculi of the medulla spinalis; they are prolonged upward into the lower part of the medulla oblongata, where they end respectively in the nucleus gracilis and nucleus cuneatus. These two nuclei are continuous with the central gray substance of the medulla spinalis, and may be regarded as dorsal projections of this, each being covered superficially by the fibres of the corresponding fasciculus. On

transverse section (Fig. 704) the nucleus gracilis appears as a single, more or less quadrangular mass, while the nucleus cuneatus consists of two parts: a larger, somewhat triangular, **medial nucleus**, composed of small or medium-sized cells, and a smaller **lateral nucleus** containing large cells.

The fibres of the *fasciculus gracilis* and *fasciculus cuneatus* end by arborizing

around the cells of these nuclei (Fig. 702). From the cells of the nuclei new fibres arise; some of these are continued as the posterior external arcuate fibres into the restiform body, and through it to the cerebellum, but most of them pass forward through the neck of the posterior column, thus cutting off its head from its base (Fig. 703). Curving forward, they decussate in the middle line with the corresponding fibres of the opposite side, and run upward immediately behind the cerebrospinal fibres, as a flattened band, named the **lemniscus** or **fillet**. The decussation of these sensory fibres is situated above that of the motor fibres, and is named the **decussation of the lemniscus** or **sensory decussation**. The **lemniscus** is joined by the spinothalamic fasciculus (page 817), the fibres of which are derived from the cells of the gray substance of the opposite side of the medulla spinalis.

The base of the posterior column at first lies on the dorsal aspect of the central canal, but when the latter opens into the fourth ventricle, it appears in the lateral part of the rhomboid fossa. It forms the terminal nuclei of the sensory fibres of the vagus and glossopharyngeal nerves, and is associated with the vestibular part of the acoustic nerve and the sensory root of the facial nerve. Still higher, it forms a mass of pigmented cells—the **locus coeruleus**—in which some of the sensory fibres

of the trigeminal nerve appear to end. The head of the posterior column forms a long nucleus, in which the fibres of the spinal tract of the trigeminal nerve largely end.

FIG. 705.—Transverse section of medulla oblongata below the middle of the olive.

The **cerebellospinal fasciculus** (*fasciculus cerebellospinalis*; *direct cerebellar tract*) leaves the lateral district of the medulla oblongata; most of its fibres are carried backward into the restiform body of the same side, and through it are conveyed

to the cerebellum; but some run upward with the fibres of the lemniscus, and, reaching the inferior colliculus, undergo decussation, and are carried to the cerebellum through the brachium conjunctivum.

The **proper fasciculi** (*basis bundles*) of the anterior and lateral funiculi largely consist of intersegmental fibres, which link together the different segments of the medulla spinalis; they assist in the production of the formatio reticularis of the medulla oblongata, and many of them are accumulated into a fasciculus which runs up close to the median raphé between the lemniscus and the rhomboid fossa; this strand is named the **medial longitudinal fasciculus**, and will be again referred to.

Gray Substance of the Medulla Oblongata (Figs. 704, 705).—In addition to the gracile and cuneate nuclei, there are several other nuclei to be considered. Some of these are traceable from the gray substance of the medulla spinalis, while others are unrepresented in it.

1. The **hypoglossal nucleus** is derived from the base of the anterior column; in the lower closed part of the medulla oblongata it is situated on the ventrolateral aspect of the central canal; but in the upper part it approaches the rhomboid fossa, where it lies close to the middle line, under an eminence named the **trigonum hypoglossi** (Fig. 719). The nucleus measures about 2 cm. in length, and consists of large multipolar nerve cells, whose axons constitute the roots of the hypoglossal nerve. These nerve roots pass forward between the anterior and lateral districts of the medulla oblongata, and emerge from the antero-lateral sulcus.

2. The **motor nucleus** (Figs. 706, 707), common to the *glossopharyngeal*, *vagus*, and cerebral part of the *accessory nerves*, is named the **nucleus ambiguus**. It represents the head of the anterior column, lies deeply in the formatio reticularis grisea, and extends throughout nearly the whole length of the medulla oblongata.

3. The **sensory nucleus** (Figs. 706, 708), or terminal nucleus of the sensory fibres of the *glossopharyngeal* and *vagus*, represents the base of the posterior column. It measures about 2 cm. in length, and in the lower, closed part of the medulla oblongata is situated behind the hypoglossal nucleus; whereas in the upper, open part it lies lateral to that nucleus, and corresponds to an eminence, named the **ala cinerea** (*trigonum vagi*), in the rhomboid fossa.

FIG. 706.—The cerebral nerve nuclei schematically represented; dorsal view. Motor nuclei in red; sensory in blue. (The olfactory and optic centres are not represented.)

4. The **nuclei of the acoustic nerve** are described on page 836.

5. The **olivary nuclei** (Fig. 704) are three in number on either side of the middle line, viz., the inferior olivary nucleus, and the medial and dorsal accessory olivary nuclei; they consist of small, round, yellowish cells and numerous fine nerve fibres. (a) The **inferior olivary nucleus** is the largest, and is situated within the olive. It consists of a gray folded lamina arranged in the form of an incomplete capsule, opening medially by an aperture called the **hilus**; emerging from the hilus are numerous fibres which collectively constitute the **peduncle of the olive**. (b) The **medial accessory olivary nucleus** lies between the inferior olivary nucleus and the pyramid, and forms a curved lamina, the concavity of which is directed laterally. The fibres of the hypoglossal nerve, as they traverse the medulla, pass between the medial accessory and the inferior olivary nuclei. (c) The **dorsal accessory olivary nucleus** is the smallest, and appears on transverse section as a curved lamina behind the inferior olivary nucleus.

FIG. 707.—Nuclei of origin of cerebral motor nerves schematically represented; lateral view.

The inferior olivary nucleus is connected (1) with that of the opposite side by fibres which cross through the raphé; (2) with the anterior column of the same side of the medulla spinalis by the **spinoolivary fasciculus**; (3) with the thalamus of the cerebrum by the **cerebroolivary fasciculus** which passes through the pons and tegmentum; (4) with the opposite cerebellar hemisphere by the **cerebello-olivary fasciculus**, the fibres of which cross the raphé and turn backward to enter the deep part of the restiform body. Removal of one cerebellar hemisphere is followed by atrophy of the opposite olivary nucleus.

6. The **nucleus arcuatus** is described below with the anterior external arcuate fibres.

Restiform Bodies (*corpus restiformes*).—The position of the restiform bodies has already been described (page 825). Each comprises: (1) the cerebellospinal

fasciculus, which ascends from the lateral funiculus of the medulla spinalis; (2) descending cerebellar fibres, many of which are disseminated throughout the peripheral part of the anterior and lateral funiculi of the medulla spinalis, while others are conducted to the motor nuclei of the cerebral nerves; and (3) the arcuate fibres, which are arranged in three sets, viz., internal, and anterior and posterior external.

The **internal arcuate fibres** form the deeper and larger part of the restiform body. They decussate in the middle line of the medulla oblongata, and having reached the opposite side, terminate partly in the gracile and cuneate nuclei, while many of them enter the hilus of the inferior olivary nucleus, and constitute the cerebelloolivary tract already described (Fig. 709).

FIG. 708.—Primary terminal nuclei of the afferent (sensory) cerebral nerves schematically represented; lateral view. The olfactory and optic centres are not represented.

The **anterior external arcuate fibres** vary as to their prominence in different cases: in some they form an almost continuous layer covering the pyramid and olive, while in others they are barely visible on the surface. They arise from the cells of the gracile and cuneate nuclei, and passing forward through the formatio reticularis, decussate in the middle line. Most of them reach the surface by way of the anterior median fissure, and arch backward over the pyramid. Reinforced by others which emerge between the pyramid and olive, they pass backward over the olive and lateral district of the medulla oblongata, and enter the restiform body. They thus connect the cerebellum with the gracile and cuneate nuclei of the opposite side. As the fibres arch across the pyramid, they enclose a small nucleus which lies in front of and medial to the pyramid. This is named the **nucleus arcuatus**, and is serially continuous above with the nuclei pontis in the pons; it contains small fusiform cells, around which some of the arcuate fibres end, and from which others arise.

The posterior external arcuate fibres also take origin in the gracile and cuneate nuclei; they pass to the restiform body of the same side.

Formatio Reticularis (Fig. 710).—This term is applied to the coarse reticulum which occupies the anterior and lateral districts of the medulla oblongata. It

is situated behind the pyramid and olive, extending laterally as far as the restiform bodies, and dorsally to within a short distance of the rhomboid fossa. The reticulum is caused by the intersection of bundles of fibres running at right angles to each other, some being longitudinal, others more or less transverse in direction. The *formatio reticularis* presents a different appearance in the anterior district from what it does in the lateral; in the former, there is an almost entire absence of nerve cells, and hence this part is known as the *reticularis alba*; whereas in the lateral district nerve cells are numerous, and as a consequence it presents a gray appearance, and is termed the *reticularis grisea*.

In the substance of the *formatio reticularis* are two small nuclei of gray matter: one, the *inferior central nucleus* (*nucleus of Roller*), near the dorsal aspect of the hilus of the inferior olivary nucleus; the other, the *nucleus lateralis*, between the olive and the spinal tract of the trigeminal nerve.

In the *reticularis alba* the longitudinal fibres form two well-defined fasciculi, viz.: (1) the *lemniscus*, which lies close to the *raphé*, immediately behind the fibres of the pyramid; and (2) the *medial longitudinal fasciculus*, which is continued upward from the anterior and lateral proper fasciculi of the medulla spinalis, and, in the upper part of the medulla oblongata, lies between the *lemniscus* and the gray substance of the rhomboid fossa. The longitudinal fibres in the *reticularis grisea* are derived from the lateral funiculus of the medulla spinalis after the lateral cerebrospinal fasciculus has passed over to the opposite side, and the cerebello-spinal fasciculus has entered the restiform body. They form indeterminate fibres, with the exception of a bundle named the *fasciculus solitarius*, which is made up of descending fibres of the vagus and glossopharyngeal nerves. The transverse fibres of the *formatio reticularis* are the arcuate fibres already described (page 831).

Applied Anatomy.—In *bulbar paralysis*, i. e., paralysis of the medulla oblongata, which is really a special form of a progressive degeneration affecting the whole efferent or motor tract, the disease begins with impairment of the movements of the lips, tongue, pharynx, and larynx, due to degeneration of the motor cells in the nuclei of the medulla oblongata. Speech and swallowing become difficult, and the saliva dribbles from the open mouth. Other groups of muscles soon become involved, and death often occurs from “aspiration pneumonia,” set up by food that has accidentally passed down the trachea.

The Pons (*pons Varoli*). — The pons or forepart of the rhombencephalon is situated in front of the cerebellum. From its superior surface the cerebral peduncles emerge, one on either side of the middle line. Curving around each peduncle, close to the upper surface of the pons, a thin white band, the *taenia pontis*, is frequently seen; it enters the cerebellum between the *brachium pontis* and *brachium conjunctivum*. Behind and below, the pons is continuous with the medulla oblongata, but is separated from it in front by a furrow in which the abducent, facial, and acoustic nerves appear.

Its *ventral or anterior surface* (*pars basilaris pontis*) is very prominent, markedly convex from side to side, less so from above downward. It consists of transverse fibres arched like a bridge across the middle line, and gathered on either side into a compact mass which forms the *brachium pontis*. It rests upon the clivus of the sphenoidal bone, and is limited above and below by well-defined borders. In the middle line is the *sulcus basilaris* for the lodgement of the basilar artery; this sulcus is bounded on either side by an eminence caused by the descent of the cerebrospinal fibres through the substance of the pons. Outside these eminences, near the upper border of the pons, the trigeminal nerves make their exit, each consisting of a smaller, medial, motor root, and a larger, lateral, sensory root; vertical lines drawn immediately beyond the trigeminal nerves, may be taken as the boundaries between the ventral surface of the pons and the *brachia pontis*.

Its **dorsal or posterior surface** (*pars dorsalis pontis*), triangular in shape, is hidden by the cerebellum, and is bounded laterally by the brachia conjunctiva; it forms the upper part of the rhomboid fossa, with which it will be described.

Structure (Fig. 711).—Transverse sections of the pons show it to be composed of two parts which differ in appearance and structure: thus, the basilar or ventral portion consists for the most part of fibres arranged in transverse and longitudinal bundles, together with a small amount of gray substance; while the dorsal tegmental portion is a continuation of the reticular formation of the medulla oblongata, and most of its constituents are continued into the tegmenta of the cerebral peduncles.

FIG. 711.—Coronal section of the pons, at its upper part. (Testut.) 1. Fourth ventricle; its ependyma in yellow. 2. Anterior medullary velum, with 2', its white stratum, and 2'', its gray stratum. 3. Medial lemniscus. 9'. Lateral lemniscus. 10, 10. Transverse fibres of pons. 11, 11. Cerebrospinal fasciculi. 12. Raphe. V. Trigeminal.

The **basilar part** of the pons consists of—(a) superficial and deep transverse fibres, (b) longitudinal fasciculi, and (c) some small nuclei of gray substance, termed the nuclei pontis.

The **superficial transverse fibres** (*fibrae pontis superficiales*) constitute a rather thick layer on the ventral surface of the pons, and are collected into a large rounded bundle on either side of the middle line. This bundle, with the addition of some transverse fibres from the deeper part of the pons, forms the greater part of the brachium pontis.

The **deep transverse fibres** (*fibrae pontis profundae*) partly intersect and partly lie on the dorsal aspect of the cerebrospinal fibres. They course to the lateral border of the pons, and form part of the brachium pontis; the further connections of this brachium will be discussed with the anatomy of the cerebellum.

The **longitudinal fasciculi** (*fasciculi longitudinales*) are derived from the cerebral peduncles, and enter the upper surface of the pons. They stream downward on either side of the middle line in larger or smaller bundles, separated from each other by the deep transverse fibres; these longitudinal bundles cause a forward projection of the superficial transverse fibres, and thus give rise to the eminences on the anterior surface. Some of these fibres end in the nuclei pontis, and others,

after decussating, in the motor nuclei of the trigeminal, abducent, facial, and hypoglossal nerves; but most of them are carried through the pons, and at its lower surface are collected into the pyramids of the medulla. The fibres which end in the motor nuclei of the cerebral nerves are derived from the cells of the cerebral cortex, and bear the same relation to the motor cells of the cerebral nerves that the cerebro-spinal fibres bear to the motor cells in the anterior column of the medulla spinalis.

The **nuclei pontis** are serially continuous with the arcuate nuclei in the medulla, and consist of small groups of multipolar nerve cells which are scattered between the bundles of transverse fibres.

The **dorsal or tegmental part** of the pons is chiefly composed of an upward continuation of the reticular formation and gray substance of the medulla oblongata. It consists of transverse and longitudinal fibres and also contains important gray nuclei, and is subdivided by a median raphé, which, however, does not extend into the basilar part, being obliterated by the transverse fibres. The transverse fibres in the lower part of the pons are collected into a distinct strand, named the **trapezoid body**. This consists of fibres which arise from the cells of the ventral or accessory acoustic nucleus, and will be referred to in connection with the cochlear division of the acoustic nerve. In the substance of the trapezoid body is a collection of nerve cells, which constitutes the **trapezoid nucleus**. The longitudinal fibres, which are continuous with those of the medulla oblongata, are mostly collected into two fasciculi on either side. One of these lies between the trapezoid body and the reticular formation, and forms the upward prolongation of the lemniscus; the second is situated near the floor of the fourth ventricle, and is the **medial longitudinal fasciculus**. Other longitudinal fibres, more diffusely distributed, arise from the cells of the gray substance of the pons.

The rest of the dorsal part of the pons is a continuation upward of the formatio reticularis of the medulla oblongata, and, like it, presents the appearance of a network, in the meshes of which are numerous nerve cells. Besides these scattered nerve cells, there are some larger masses of gray substance, viz., the superior olivary nucleus and the nuclei of the trigeminal, abducent, facial, and acoustic nerves (Fig. 706).

1. The **superior olivary nucleus** (*nucleus olivaris superior*) is a small mass of gray substance situated on the dorsal surface of the lateral part of the trapezoid body. Rudimentary in man, but well developed in certain animals, it exhibits the same structure as the inferior olivary nucleus, and is situated immediately above it. Some of the fibres of the trapezoid body end by arborizing around the cells of this nucleus, while others arise from these cells.

2. The **nuclei of the trigeminal nerve** (*nuclei n. trigemini*) in the pons are two in number: a motor and a sensory. The **motor nucleus** is situated in the upper part of the pons, close to its posterior surface and along the line of the lateral margin of the fourth ventricle. The axis-cylinder processes of its cells form a portion of the motor root of the trigeminal nerve: the remaining fibres of the motor root of this nerve consist of a fasciculus which arises from the gray substance of the floor of the cerebral aqueduct, and hence is named the **mesencephalic root**. The **sensory nucleus** is lateral to the motor one, and beneath the brachium conjunctivum. Some of the sensory fibres of the trigeminal nerve end in this nucleus; but the greater number descend, under the name of the spinal tract of the trigeminal nerve, to end in the substantia gelatinosa of Rolando. The roots, motor and sensory, of the trigeminal nerve pass through the substance of the pons and emerge near the upper margin of its anterior surface.

3. The **nucleus of the abducent nerve** (*nucleus n. abducentis*) is a circular mass of gray substance situated close to the floor of the fourth ventricle, above the striae medullares and subjacent to the medial eminence: it lies a little lateral to the ascending part of the facial nerve. The fibres of the abducent nerve pass forward

through the entire thickness of the pons on the medial side of the superior olivary nucleus, and between the lateral fasciculi of the cerebrospinal fibres, and emerge in the furrow between the lower border of the pons and the pyramid of the medulla oblongata.

4. The **nucleus of the facial nerve** (*nucleus n. facialis*) is situated deeply in the reticular formation of the pons, on the dorsal aspect of the superior olivary nucleus, and the roots of the nerve derived from it pursue a remarkably tortuous course in the substance of the pons. At first they pass backward and medialward until they reach the rhomboid fossa, close to the median sulcus, where they are collected into a round bundle; this passes upward and forward, producing an elevation, the **colliculus facialis**, in the rhomboid fossa, and then takes a sharp bend, and arches lateralward through the substance of the pons to emerge at its lower border in the interval between the olive and the restiform body of the medulla oblongata.

5. The **nuclei of the acoustic nerve** (*nuclei n. acustici*) consists of a cochlear and a vestibular division. The fibres of the cochlear division end in two nuclei: (a) the **lateral cochlear nucleus**, corresponding to the tuberculum acusticum on the dorso-lateral surface of the restiform body; and (b) the **ventral or accessory cochlear nucleus**, placed between the two divisions of the nerve, on the ventral aspect of the restiform body. The nuclei in which the vestibular division ends are (a) the **dorsal or chief vestibular nucleus**, corresponding to the lower part of the area acustica in the rhomboid fossa; the caudal end of this nucleus is sometimes termed the **descending or spinal vestibular nucleus**; (b) the **nucleus of Deiters**, consisting of large cells and situated in the lateral angle of the rhomboid fossa; the dorso-lateral part of this nucleus is sometimes termed the **nucleus of Bechterew**.

Applied Anatomy.—Injury to the pons, such as may occur on the occlusion or rupture of one of its bloodvessels, often gives rise to a special train of symptoms that is almost diagnostic. Pontine lesions are characterized mainly by "alternate paralyses;" that is to say, by paralysis of one of the motor cerebral nerves on one side, and of the limbs on the other side of the body. Thus a hemorrhage into the lower part of the pons might cause paralysis of the face, *lower segment paralysis*, on the same side, from destruction of the facial nucleus or nerve root, and paralysis of the arm and leg on the opposite side from injury to the adjacent cerebrospinal tract. In the same way, paralysis of the Rectus lateralis of one eye and of the Rectus medialis of the other, *conjugate paralysis*, of the muscles turning the two eyes in one direction, and often paralysis of one side of the face as well, together with palsy of the limbs on the opposite side of the body, may be found when the lesion occurs about the nucleus of the abducent nerve. Hearing is often unaffected in pontine lesions, possibly because the central acoustic tract occupies a ventral and lateral position in the pons.

The Cerebellum.—The cerebellum constitutes the largest part of the hind-brain. It lies behind the pons and medulla oblongata; between its central portion and these structures is the cavity of the fourth ventricle. It rests on the inferior occipital fossæ, while above it is the tentorium cerebelli, a fold of dura mater which separates it from the tentorial surface of the cerebrum. It is somewhat oval in form, but constricted medially and flattened from above downward, its greatest diameter being from side to side. Its surface is not convoluted like that of the cerebrum, but is traversed by numerous curved furrows or sulci, which vary in depth at different parts, and separate the laminae of which it is composed. Its average weight in the male is about 150 gms. In the adult the proportion between the cerebellum and cerebrum is about 1 to 8, in the infant about 1 to 20.

Lobes of the Cerebellum.—The cerebellum consists of three parts, a median and two lateral, which are continuous with each other, and are substantially the same in structure. The median portion is constricted, and is called the **vermis**, from its annulated appearance which it owes to the transverse ridges and furrows upon it; the lateral expanded portions are named the **hemispheres**. On the upper surface of the cerebellum the vermis is elevated above the level of the hemispheres, but on the under surface it is sunk almost out of sight in the bottom of a deep depres-

sion between them; this depression is called the *vallecula cerebelli*, and lodges the posterior part of the medulla oblongata. The part of the vermis on the upper surface of the cerebellum is named the *superior vermis*; that on the lower surface, the *inferior vermis*. The hemispheres are separated below and behind by a deep notch, the *posterior cerebellar notch*, and in front by a broader shallower notch, the *anterior cerebellar notch*. The anterior notch lies close to the pons and upper part of the medulla, and its superior edge encircles the inferior colliculi and the *brachia conjunctiva cerebelli*. The posterior notch contains the upper part of the *falx cerebelli*, a fold of *dura mater*.

The cerebellum is characterized by its laminated or foliated appearance; it is marked by deep, somewhat curved fissures, which extend for a considerable distance into its substance, and divide it into a series of layers or leaves. The largest and deepest fissure is named the *horizontal sulcus*. It commences in front of the pons, and passes horizontally around the free margin of the hemisphere to the middle line behind, and divides the cerebellum into an upper and a lower portion. Several secondary but deep fissures separate the cerebellum into lobes, and these are further subdivided by shallower sulci, which separate the individual *folia* or *laminæ* from each other. Sections across the *laminæ* show that the *folia*, though differing in appearance from the convolutions of the cerebrum, are analogous to them, inasmuch as they consist of central white substance covered by gray substance.

Ala lobuli centralis

Præclival fissure

E

FIG. 712.—Upper surface of the cerebellum. (Schäfer.)

The cerebellum is connected to the cerebrum, pons, and medulla oblongata; to the cerebrum by the *brachia conjunctiva*, to the pons by the *brachia pontis*, and to the medulla oblongata by the *restiform bodies*.

The *upper surface of the cerebellum* (Fig. 712) is elevated in the middle and sloped toward the circumference, the hemispheres being connected together by the *superior vermis*, which assumes the form of a raised median ridge, most prominent in front, but not sharply defined from the hemispheres. The *superior vermis* is subdivided from before backward into the *lingula*, the *lobulus centralis*, the *monticulus* and the *folium vermis*, and each of these, with the exception of the *lingula*, is continuous with the corresponding parts of the hemispheres—the *lobulus centralis* with the *alae*, the *monticulus* with the *quadrangular lobules*, and the *folium vermis* with the *superior semilunar lobules*.

The *lingula* (*lingula cerebelli*) is a small tongue-shaped process, consisting of four or five *folia*; it lies in front of the *lobulus centralis*, and is concealed by it. Anteriorly, it rests on the dorsal surface of the anterior medullary velum, and its white substance is continuous with that of the velum.

The Lobulus Centralis and Alae.—The *lobulus centralis* is a small square lobule, situated in the anterior cerebellar notch. It overlaps the *lingula*, from which it is separated by the *precentral fissure*; laterally, it extends along the upper and anterior part of each hemisphere, where it forms a wing-like prolongation, the *ala lobuli centralis*.

The Monticulus and Quadrangular Lobules.—The *monticulus* is the largest part of the superior vermis. Anteriorly, it overlaps the *lobulus centralis*, from which it is separated by the *postcentral fissure*; laterally, it is continuous with the *quadrangular lobule* in the hemispheres. It is divided by the *preclival fissure* into an anterior, raised part, the *culmen* or summit, and a posterior sloped part, the *clivus*; the quadrangular lobule is similarly divided. The *culmen* and the anterior parts of the quadrangular lobules form the *lobus culminis*; the *clivus* and the posterior parts, the *lobus clivi*.

The Folium Vermis and Superior Semilunar Lobule.—The *folium vermis* (*folium cacuminis*; *cacuminal lobe*) is a short, narrow, concealed band at the posterior extremity of the vermis, consisting apparently of a single folium, but in reality marked on its upper and under surfaces by secondary fissures. Laterally, it expands in either hemisphere into a considerable lobule, the *superior semilunar lobule* (*lobulus semilunaris superior*; *postero-superior lobules*), which occupies the posterior third of the upper surface of the hemisphere, and is bounded below by the *horizontal sulcus*. The superior semilunar lobules and the *folium vermis* form the *lobus semilunaris*.

Ala lobuli centralis *Flocculus*

Tuber vermis

FIG. 713.—Under surface of the cerebellum. (Schäfer.)

The under surface of the cerebellum (Fig. 713) presents, in the middle line, the *inferior vermis*, buried in the *vallecula*, and separated from the hemisphere on either side by a deep groove, the *sulcus vallecule*. Here, as on the upper surface, there are deep fissures, dividing it into separate segments or lobules; but the arrangement is more complicated, and the relation of the segments of the vermis to those of the hemispheres is less clearly marked. The inferior vermis is subdivided from before backward, into (1) the *nodule*, (2) the *uvula*, (3) the *pyramid*, and (4) the *tuber vermis*; the corresponding parts on the hemispheres are (1) the *flocculus*, (2) the *tonsilla cerebelli*, (3) the *biventral lobule*, and (4) the *inferior semilunar lobule*. The three main fissures are (1) the *postnodular fissure*, which runs transversely across the vermis, between the *nodule* and the *uvula*. In the hemispheres this fissure passes in front of the *tonsil*, crosses between the *flocculus* in front and the *biventral lobule* behind, and joins the anterior end of the *horizontal sulcus*. (2) The *pre-*

pyramidal fissure crosses the vermis between the uvula in front and the pyramid behind, then curves forward between the tonsil and the biventral lobe, to join the postnodular fissure. (3) The **postpyramidal fissure** passes across the vermis between the pyramid and the tuber vermis, and, in the hemispheres, courses behind the tonsil and biventral lobules, and then along the lateral border of the biventral lobule to the postnodular sulcus; in the hemisphere it forms the anterior boundary of the inferior semilunar lobule.

The Nodule and Flocculus.—The **nodule** (*nodulus vermis; nodular lobe*), or anterior end of the inferior vermis, abuts against the roof of the fourth ventricle, and can only be distinctly seen after the cerebellum has been separated from the medulla oblongata and pons. On either side of the nodule is a thin layer of white substance, named the **posterior medullary velum**. It is semilunar in form, its convex border being continuous with the white substance of the cerebellum; it extends on either side as far as the flocculus. The **flocculus** is a prominent, irregular lobule, situated in front of the biventral lobule, between it and the brachium pontis cerebelli. It is subdivided into a few small laminae, and is connected to the inferior medullary velum by its central white core. The flocculi, together with the posterior medullary velum and nodule, constitute the **lobus noduli**.

The Uvula and Tonsilla.—The **uvula** (*uvula vermis; uvular lobe*) forms a considerable portion of the inferior vermis; it is separated on either side from the tonsil by the **sulcus valleculae**, at the bottom of which it is connected to the tonsil by a ridge of gray matter, indented on its surface by shallow furrows, and hence called the **furrowed band**. The **tonsilla** (*tonsilla cerebelli; amygdaline nucleus*) is a rounded mass, situated in the hemispheres. Each lies in a deep fossa, termed the **bird's nest** (*nidus avis*), between the uvula and the biventral lobule. The uvula and tonsillae form the **lobus uvulae**.

The Pyramid and Biventral lobules constitute the **lobus pyramidis**. The **pyramid** is a conical projection, forming the largest prominence of the inferior vermis. It is separated from the hemispheres by the **sulcus valleculae**, across which it is connected to the biventral lobule by an indistinct gray band, analogous to the furrowed band already described. The **biventral lobule** is triangular in shape; its apex points backward, and is joined by the gray band to the pyramid. The lateral border is separated from the inferior semilunar lobule by the postpyramidal fissure. The base is directed forward, and is on a line with the anterior border of the tonsil, and is separated from the flocculus by the postnodular fissure.

The Tuber Vermis (*tuber valvulae*) and the **Inferior Semilunar Lobule** (*lobulus semilunaris inferior; postero-superior lobule*) collectively form the **lobus tuberus** (*tuberae lobe*). The **tuber vermis**, the most posterior division of the inferior vermis, is of small size, and laterally spreads out into the large inferior semilunar lobules, which comprise at least two-thirds of the inferior surface of the hemisphere.

Internal Structure of the Cerebellum.—The cerebellum consists of white and gray substance.

White Substance.—If a sagittal section (Fig. 714) be made through either hemisphere, the interior will be found to consist of a central stem of white substance, in the middle of which is a gray mass, the **dentate nucleus**. From the surface of this central white stem a series of plates are prolonged; these are covered with gray substance and form the laminae. In consequence of the main branches from the central stem dividing and subdividing, a characteristic appearance, named the **arbor vitae**, is presented. If the sagittal section be made through the middle of the vermis, it will be found that the central stem divides into a vertical and a horizontal branch. The **vertical** branch passes upward to the culmen monticuli, where it subdivides freely, one of its ramifications passing forward and upward to the central lobule. The **horizontal** branch passes backward to the folium vermis, greatly diminished in size in consequence of having given off large secondary

branches; one, from its upper surface, ascends to the clivus monticuli; the others descend, and enter the lobes in the inferior vermis, viz., the tuber vermis, the pyramid, the uvula, and the nodule.

FIG. 715.—Dissection showing the projection fibres of the cerebellum. (After E. B. Jamieson.)

The white substance of the cerebellum includes two sets of nerve fibres: (1) projection fibres, (2) *fibræ propriae*.

Projection Fibres.—The cerebellum is connected to the other parts of the brain by three large bundles of projection fibres, viz., to the cerebrum by the brachia conjunctiva, to the pons by the brachia pontis, and to the medulla oblongata by the restiform bodies (Fig. 715).

The **brachia conjunctiva** (*superior cerebellar peduncles*), two in number, emerge from the upper and medial part of the white substance of the hemispheres and are placed under cover of the upper part of the cerebellum. They are joined to each other across the middle line by the anterior medullary velum, and can be followed upward as far as the inferior colliculi, under which they disappear. Below, they form the upper lateral boundaries of the fourth ventricle, but as they ascend they converge on the dorsal aspect of the ventricle and thus assist in roofing it in.

The fibres of the *brachium conjunctivum* are mainly derived from the cells of the dentate nucleus of the cerebellum and emerge from the hilus of this nucleus; a few arise from the cells of the smaller gray nuclei in the cerebellar white substance, and others from the cells of the cerebellar cortex. They are continued upward beneath the corpora quadrigemina, and the fibres of the two brachia undergo a complete decussation ventral to the Sylvian aqueduct. Having crossed the middle line they divide into ascending and descending groups of fibres, the former ending in the red nucleus, the thalamus, and the nucleus of the oculomotor nerve, while the descending fibres can be traced as far as the dorsal part of the pons; Cajal believes them to be continued into the anterior funiculus of the medulla spinalis.

As already stated (page 816), the majority of the fibres of the superficial antero-lateral fasciculi of the medulla spinalis pass to the cerebellum, which they reach by way of the brachia conjunctiva.

The **brachia pontis** (*middle cerebellar peduncles*) (Fig. 715) are composed entirely of centripetal fibres, which arise from the cells of the nuclei pontis of the opposite side and end in the cerebellar cortex; the fibres are arranged in three fasciculi, superior, inferior, and deep. The **superior fasciculus**, the most superficial, is derived from the upper transverse fibres of the pons; it is directed backward and lateralward superficial to the other two fasciculi, and is distributed mainly to the lobules on the inferior surface of the cerebellar hemisphere and to the parts of the superior surface adjoining the posterior and lateral margins. The **inferior fasciculus** is formed by the lowest transverse fibres of the pons; it passes under cover of the superior fasciculus and is continued downward and backward more or less parallel with it, to be distributed to the folia on the under surface close to the vermis.

The **deep fasciculus** comprises most of the deep transverse fibres of the pons. It is at first covered by the superior and inferior fasciculi, but crosses obliquely and appears on the medial side of the superior, from which it receives a bundle; its fibres spread out and pass to the upper anterior cerebellar folia. The fibres of this fasciculus cover those of the restiform body.¹

The **restiform bodies** (*corpus restiformes; inferior cerebellar peduncles*) pass at first upward and lateralward, forming part of the lateral walls of the fourth ventricle, and then bend abruptly backward to enter the cerebellum between the brachia conjunctiva and brachia pontis. Each contains the following fasciculi: (1) the cerebellospinal fasciculus of the medulla spinalis, which ends mainly in the superior vermis; (2) fibres from the gracile and cuneate nuclei of the same and of the opposite sides; (3) fibres from the opposite olivary nuclei; (4) crossed and uncrossed fibres from the reticular formation of the medulla oblongata; (5) vestibular fibres, derived partly from the vestibular division of the acoustic nerve and partly from the nuclei in which this division ends—these fibres occupy the medial segment of the restiform body and divide into ascending and descending groups of fibres; the ascending fibres partly end in the roof nucleus of the opposite side of the cerebellum; (6) cerebellobulbar fibres which come from the opposite roof nucleus and probably from the dentate nucleus, and are said to end in the nucleus of Deiters and in the *formatio reticularis* of the medulla oblongata.

¹ See article by E. B. Jamieson, *Journal of Anatomy and Physiology*, vol. xlv.

The **anterior medullary velum** (*velum medullare anterius*; *valve of Vieussens*; *superior medullary velum*) is a thin, transparent lamina of white substance, which stretches between the brachial conjunctiva; on the dorsal surface of its lower half the folia and lingula are prolonged. It forms, together with the brachia conjunctiva, the roof of the upper part of the fourth ventricle; it is narrow above, where it passes beneath the inferior colliculi, and broader below, where it is continuous with the white substance of the superior vermis. A slightly elevated ridge, the **fraenulum veli**, descends upon its upper part from between the inferior colliculi, and on either side of this the trochlear nerve emerges.

The **posterior medullary velum** (*velum medullare posterius*; *inferior medullary velum*) is a thin layer of white substance, prolonged from the white centre of the cerebellum, above and on either side of the nodule; it forms a part of the roof of the fourth ventricle. Somewhat semilunar in shape, its convex edge is continuous with the white substance of the cerebellum, while its thin concave margin is apparently free; in reality, however, it is continuous with the epithelium of the ventricle, which is prolonged downward from the posterior medullary velum to the ligulae.

The two medullary vela are in contact with each other along their line of emergence from the white substance of the cerebellum; and this line of contact forms the summit of the roof of the fourth ventricle, which, in a vertical section through the cavity, appears as a pointed angle.

The **Fibrae Propriae** of the cerebellum are of two kinds: (1) **commissural fibres**, which cross the middle line at the anterior and posterior parts of the vermis and connect the opposite halves of the cerebellum; (2) **arcuate or association fibres**, which connect adjacent laminae with each other.

Gray Substance.—The gray substance of the cerebellum is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the anterior.

(1) The **gray substance of the cortex** presents a characteristic foliated appearance, due to the series of laminae which are given off from the central white substance; these in their turn give off secondary laminae, which are covered by gray substance. Externally, the cortex is covered by pia mater; internally is the medullary centre, consisting mainly of nerve fibres.

Microscopic Appearance of the Cortex (Fig. 716).—The cortex consists of two layers, viz., an external gray molecular layer, and an internal rust-colored nuclear layer; between these is an incomplete stratum of cells which are characteristic of the cerebellum, viz., the **cells of Purkinje**.

The **external gray or molecular layer** consists of fibres and cells. The nerve fibres are delicate fibrillae, and are derived from the following sources: (a) the dendrites and axon collaterals of Purkinje's cells; (b) fibres from cells in the nuclear layer; (c) fibres from the central white substance of the cerebellum; (d) fibres derived from cells in the molecular layer itself. In addition to these are other fibres, which have a vertical direction, and are the processes of large neuroglia cells, situated in the nuclear layer. They pass outward to the periphery of the gray matter, where they expand into little conical enlargements which form a sort of limiting membrane beneath the pia mater, analogous to the *membrana limitans interna* in the retina, formed by the sustentacular fibres of Müller.

The **cells of the molecular layer** are small, and are arranged in two strata, an outer and an inner. They all possess branched axons; those of the inner layer are termed **basket cells**; they run for some distance parallel with the surface of the folium—giving off collaterals which pass in a vertical direction toward the bodies of Purkinje's cells, around which they become enlarged, and form basket-like net-works.

The **cells of Purkinje** form a single stratum of large, flask-shaped cells at the junction of the molecular and nuclear layers, their bases resting against the latter; in fishes and reptiles they are arranged in several layers. The cells are flattened

in a direction transverse to the long axis of the folium, and thus appear broad in sections carried across the folium, and fusiform in sections parallel to the long axis of the folium. From the neck of the flask one or more dendrites arise and pass into the molecular layer, where they subdivide and form an extremely rich arborescence, the various subdivisions of the dendrites being covered by lateral spine-like processes. This arborescence is not circular, but, like the cell, is flattened at right angles to the long axis of the folium; in other words, it does not resemble a round bush, but has been aptly compared by Obersteiner to the branches of a fruit tree trained against a trellis or a wall. Hence, in sections carried across the folium the arborescence is broad and expanded; whereas in those which are parallel to the long axis of the folium, the arborescence, like the cell itself, is seen in profile, and is limited to a narrow area.

FIG. 716.—Transverse section of a cerebellar folium. (Diagrammatic, after Cajal and Kölliker.)

From the bottom of the flask-shaped cell the axon arises; this passes through the nuclear layer, and, becoming medullated, is continued as a nerve fibre in the subjacent white substance. As this axon traverses the granular layer it gives off fine collaterals, some of which run back into the molecular layer.

The **internal rust-colored** or **nuclear layer** (Fig. 716) is characterized by containing numerous small nerve cells of a reddish-brown color, together with many nerve

fibrils. Most of the cells are nearly spherical and provided with short dendrites which spread out in a spider-like manner in the nuclear layer. Their axons pass outward into the molecular layer, and, bifurcating at right angles, run for some distance parallel with the surface. In the outer part of the nuclear layer are some larger cells, of the type II of Golgi. Their axons undergo frequent division as soon as they leave the nerve cells, and pass into the nuclear layer; while their dendrites ramify chiefly in the molecular layer.

Finally, in the gray substance of the cerebellar cortex there are fibres which come from the white centre and penetrate the cortex. The cell-origin of these fibres is unknown, though it is believed that it is probably in the gray substance of the medulla spinalis. Some of these fibres end in the nuclear layer by dividing into numerous branches, on which are to be seen peculiar moss-like appendages; hence they have been termed by Ramón y Cajal the **moss fibres**; they form an arborescence around the cells of the nuclear layer. Other fibres, the **clinging or tendril fibres**, derived from the medullary centre can be traced into the molecular layer, where their branches cling around the dendrites of Purkinje's cells.

(2) The **independent centres of gray substance** in the cerebellum are four in number on either side: one is of large size, and is known as the **nucleus dentatus**; the other three, much smaller, are situated near the middle of the cerebellum, and are known as the **nucleus emboliformis**, **nucleus globosus**, and **nucleus fastigii**.

Nucleus dentatus Brachium conjunctivum Vermis

FIG. 717.—Sagittal section through right cerebellar hemisphere. The right olive has also been cut sagittally.

The **nucleus dentatus** (Fig. 717) is situated a little to the medial side of the centre of the stem of the white substance of the hemisphere. It consists of an irregularly folded lamina, of a grayish-yellow color, containing white fibres, and presenting on its antero-medial aspect an opening, the **hilus**, from which most of the fibres of the brachium conjunctiva emerge (page 841).

The **nucleus emboliformis** lies immediately to the medial side of the nucleus dentatus, and partly covering its hilus. The **nucleus globosus** is an elongated mass, directed antero-posteriorly, and placed medial to preceding. The **nucleus fastigii** is somewhat larger than the other two, and is situated close to the middle line at the anterior end of the superior vermis, and immediately over the roof of the fourth ventricle, from which it is separated by a thin layer of white substance.

Applied Anatomy.—The general functions of the cerebellum in the human economy appear to be the coördination of movements and equilibration. The exact functions of its different parts are still quite uncertain, owing to the contradictory nature of the evidence furnished by

(1) ablation experiments upon animals, and (2) clinical observations in man of the effects produced by abscesses or tumors affecting different portions of the organ. According to W. Aldren Turner, "The following localizing symptoms would therefore indicate the presence of a tumor implicating the right cerebellar hemisphere and middle peduncle; deafness in the right ear, unassociated with middle-ear complications; an unsteady and uncertain gait, with a tendency to fall more particularly to the right side; coarse nystagmoid oscillations on looking to the right; movements resembling those of disseminated sclerosis on volitional effort of the right arm; an awkward uncertain action of the right leg; a slight increase of the right knee-jerk; and, perhaps, slight blunting of sensibility over the right cornea and side of the face."

The Fourth Ventricle (*ventriculus quartus*).—The fourth ventricle, or cavity of the rhombencephalon, is situated in front of the cerebellum and behind the pons and upper half of the medulla oblongata. Developmentally considered, the fourth ventricle consists of three parts: a **superior** belonging to the isthmus rhombencephali, an **intermediate**, to the metencephalon, and an **inferior**, to the myelencephalon. It is lined by ciliated epithelium, and is continuous below with the central canal of the medulla oblongata;¹ above, it communicates, by means of a passage termed the cerebral aqueduct, with the cavity of the third ventricle. It presents four **angles**, and possesses a **roof** or dorsal wall, a **floor** or ventral wall, and **lateral boundaries**.

Angles.—The **superior angle** is on a level with the upper border of the pons, and is continuous with the lower end of the cerebral aqueduct. The **inferior angle** is on a level with the lower end of the olive, and opens into the central canal of the medulla oblongata. Each **lateral angle** corresponds with the point of meeting of the brachia and restiform body. A little below the lateral angles, on a level with the striae medullares, the ventricular cavity is prolonged outward in the form of two narrow **lateral recesses**, one on either side; these are situated between the restiform bodies and the flocculi, and reach as far as the attachments of the glossopharyngeal and vagus nerves.

Lateral Boundaries.—The lower part of each lateral boundary is constituted by the clava, the fasciculus cuneatus, and the restiform body; the upper part by the brachium pontis and the brachium conjunctivum.

Roof or Dorsal Wall (Fig. 718).—The upper portion of the roof is formed by the brachia conjunctiva and the anterior medullary velum; the lower portion, by the posterior medullary velum, the epithelial lining of the ventricle covered by the tela chorioidea inferior, the tæniæ of the fourth ventricle, and the obex.

The **brachia conjunctiva** (page 841), on emerging from the central white substance of the cerebellum, pass upward and forward, forming at first the lateral boundaries of the upper part of the cavity; on approaching the inferior colliculi, they converge, and their medial portions overlap the cavity and form part of its roof.

The **anterior medullary velum** (page 842) fills in the angular interval between the brachia conjunctiva, and is continuous behind with the central white substance of the cerebellum; it is covered on its dorsal surface by the lingula of the superior vermis.

The **posterior medullary velum** (page 842) is continued downward and forward from the central white substance of the cerebellum in front of the nodule and tonsils, and ends inferiorly in a thin, concave, somewhat ragged margin. Below this margin the roof is devoid of nervous matter except in the immediate vicinity of the lower lateral boundaries of the ventricle, where two narrow white bands, the **tæniæ of the fourth ventricle** (*ligulae*), appear; these bands meet over the inferior angle of the ventricle in a thin triangular lamina, the **obex**. The non-nervous part of the roof is formed by the **epithelial lining of the ventricle**, which is prolonged downward as a thin membrane, from the deep surface of the posterior medullary

¹ J. T. Wilson (Journal of Anatomy and Physiology, vol. xl) has pointed out that the central canal of the medulla oblongata, immediately below its entrance into the fourth ventricle, retains the cleft-like form presented by the fetal medulla spinalis, and that it is marked by dorso- and ventro-lateral sulci.

velum to the corresponding surface of the obex and taeniae, and thence on to the floor of the ventricular cavity; it is covered and strengthened by a portion of the pia mater, which is named the **tela chorioidea of the fourth ventricle**.

The **taeniae of the fourth ventricle** (*taenia ventriculi quarti; ligula*) are two narrow bands of white matter, one on either side, which complete the lower part of the roof of the cavity. Each consists of a vertical and a horizontal part. The vertical part is continuous below the obex with the clava, to which it is adherent by its lateral border. The horizontal portion extends transversely across the restiform body, below the striae medullares, and roofs in the lower and posterior part of the lateral recess; it is attached by its lower margin to the restiform body, and partly encloses the choroid plexus, which, however, projects beyond it like a cluster of grapes; and hence this part of the taenia has been termed the **cornucopia** (Bochdalek). The **obex** is a thin, triangular, gray lamina, which roofs in the lower angle of the ventricle and is attached by its lateral margins to the clavae.¹ The **tela chorioidea of the fourth ventricle** is the name applied to the triangular fold of pia mater which is carried upward between the cerebellum and the medulla oblongata. It consists of two

FIG. 718.—Scheme of roof of fourth ventricle. The arrow is in the foramen of Majendie.

layers, which are continuous with each other in front, and are more or less adherent throughout. The posterior layer covers the antero-inferior surface of the cerebellum, while the anterior is applied to the structures which form the lower part of the roof of the ventricle, and is continuous inferiorly with the pia mater on the restiform bodies and closed part of the medulla.

Choroid Plexuses.—These consist of two highly vascular inflexions of the tela chorioidea, which invaginate the lower part of the roof of the ventricle and are everywhere covered by the epithelial lining of the cavity. Each consists of a vertical and a horizontal portion: the former lies close to the middle line, and the latter passes into the lateral recess and projects beyond its apex. The vertical parts of the plexuses are distinct from each other, but the horizontal portions are joined in the middle line; and hence the entire structure presents the form of the letter T, the vertical limb of which, however, is double.

¹ J. T. Wilson, op. cit., recognizes two forms of obex: (a) the *true* obex, constituted by a medullary thickening of the roof plate, and (b) a *false* or *membranous* obex, where the medullary thickening fails to take place, and where the roof plate is represented only by the ependymal layer clothing the ventral surface of a pial reduplication which forms the main substance of the membranous fold in question.

Openings in the Roof.—In the roof of the fourth ventricle there are three openings, a medial and two lateral: the **medial aperture** (*foramen Majendii*), is situated immediately above the inferior angle of the ventricle; the **lateral apertures** are found at the extremities of the lateral recesses. By means of these three openings the ventricle communicates with the subarachnoid cavity, and the cerebrospinal fluid can circulate from the one to the other.

Rhomboid Fossa (*fossa rhomboidea*; “*floor*” of the fourth ventricle) (Fig. 719).—The anterior part of the fourth ventricle is named, from its shape, the **rhomboid fossa**, and its anterior wall, formed by the back of the pons and medulla oblongata, constitutes the floor of the fourth ventricle. It is covered by a thin layer of gray substance continuous with that of the medulla spinalis; superficial to this is a thin lamina of neuroglia which constitutes the ependyma of the ventricle and supports a layer of ciliated epithelium. The fossa consists of three parts, superior, inter-

Tænia p

Superior fc
Colliculus fau
Striae me
Area
Trigonum h
A
Tænia of four

FIG. 719.—Rhomboid fossa.

mediate, and inferior. The **superior part** is triangular in shape and limited laterally by the brachia conjunctiva cerebelli; its apex, directed upward, is continuous with the cerebral aqueduct; its base is represented by an imaginary line at the level of the upper ends of the superior foveæ. The **intermediate part** extends from this level to that of the horizontal portions of the tæniæ of the ventricle; it is narrow above where it is limited laterally by the brachia pontis, but widens below and is prolonged into the lateral recesses of the ventricle. The **inferior part** is triangular, and its downwardly directed apex, named the **calamus scriptorius**, is continuous with the central canal of the closed part of the medulla oblongata.

The rhomboid fossa is divided into symmetrical halves by a **median sulcus** which reaches from the upper to the lower angles of the fossa and is deeper below than above. On either side of this sulcus is an elevation, the **medial eminence**, bounded laterally by a sulcus, the **sulcus limitans**. In the superior part of the fossa the medial eminence has a width equal to that of the corresponding half of the

fossa, but opposite the superior fovea it forms an elongated swelling, the **colliculus facialis**, which overlies the nucleus of the abducent nerve, and is, in part at least, produced by the ascending portion of the root of the facial nerve. In the inferior part of the fossa the medial eminence assumes the form of a triangular area, the **trigonum hypoglossi**. When examined under water with a lens this trigone is seen to consist of a medial and a lateral area separated by a series of oblique furrows; the medial area corresponds with the upper part of the nucleus of the hypoglossal nerve, the lateral with a small nucleus, the **nucleus intercalatus**.

The **sulcus limitans** forms the lateral boundary of the medial eminence. In the superior part of the rhomboid fossa it corresponds with the lateral limit of the fossa and presents a bluish-gray area, the **locus coeruleus**, which owes its color to an underlying patch of deeply pigmented nerve cells, termed the **substantia ferruginea**. At the level of the colliculus facialis the sulcus limitans widens into a flattened depression, the **superior fovea**, and in the inferior part of the fossa appears as a distinct dimple, the **inferior fovea**. Lateral to the foveæ is a rounded elevation named the **area acustica**, which extends into the lateral recess and there forms a feebly marked swelling, the **tuberculum acusticum**. Winding around the restiform body and crossing the area acustica and the medial eminence are a number of white strands, the **striae medullares**, which form a portion of the cochlear division of the acoustic nerve and disappear into the median sulcus. Below the inferior fovea, and between the trigonum hypoglossi and the lower part of the area acustica is a triangular dark field, the **ala cinerea**, which corresponds to the sensory nucleus of the vagus and glossopharyngeal nerves. The lower end of the ala cinerea is crossed by a narrow translucent ridge, the **funiculus separans**, and between this funiculus and the clava, is a small tongue-shaped area, the **area postrema**. On section it is seen that the funiculus separans is formed by a strip of thickened ependyma, and the area postrema by loose, highly vascular, neuroglial tissue containing nerve cells of moderate size.

THE MESENCEPHALON OR MID-BRAIN.

The **mesencephalon** or **mid-brain** (Fig. 725) is the short, constricted portion which connects the pons and cerebellum with the thalamencephalon and cerebral hemispheres. It is directed upward and forward, and consists of (1) a ventro-lateral portion, composed of a pair of cylindrical bodies, named the **cerebral peduncles**; (2) a dorsal portion, consisting of four rounded eminences, named the **corpora quadrigemina**; and (3) an intervening passage or tunnel, the **cerebral aqueduct**, which represents the original cavity of the mid-brain and connects the third with the fourth ventricle (Fig. 720).

The **cerebral peduncles** (*pedunculus cerebri*; *crus cerebri*) are two cylindrical masses situated at the base of the brain, and largely hidden by the temporal lobes of the cerebrum, which must be drawn aside or removed in order to expose them. They emerge from the upper surface of the pons, one on either side of the middle line, and, diverging as they pass upward and forward, disappear into the substance of the cerebral hemispheres. The depressed area between the crura is termed the **interpeduncular fossa**, and consists of a layer of grayish substance, the **posterior perforated substance**, which is pierced by small apertures for the transmission of bloodvessels; its lower part lies on the ventral aspect of the medial portions of the tegmenta, and contains a nucleus named the **interpeduncular ganglion** (page 850); its upper part assists in forming the floor of the third ventricle. The ventral surface of each peduncle is crossed from the medial to the lateral side by the superior cerebellar and posterior cerebral arteries; its lateral surface is in relation to the gyrus hippocampi of the cerebral hemisphere and is crossed from behind forward

by the trochlear nerve. Close to the point of disappearance of the peduncle into the cerebral hemisphere, the optic tract winds forward around its ventro-lateral surface. The medial surface of the peduncle forms the lateral boundary of the interpeduncular fossa, and is marked by a longitudinal furrow, the **oculomotor sulcus**, from which the roots of the oculomotor nerve emerge. On the lateral surface of each peduncle there is a second longitudinal furrow, termed the **lateral sulcus**; the fibres of the lateral lemniscus come to the surface in this sulcus, and pass backward and upward, to disappear under the inferior colliculus.

Structure of the Cerebral Peduncles (Figs. 721, 722).—On transverse section, each peduncle is seen to consist of a dorsal and a ventral part, separated by a deeply pigmented lamina of gray substance, termed the **substantia nigra**. The dorsal part is named the **tegmentum**; the ventral, the **base** or **crusta**; the two bases are separated from each other, but the tegmenta are joined in the median plane by a forward prolongation of the raphé of the pons. Laterally, the tegmenta are free; dorsally, they blend with the corpora quadrigemina.

FIG. 721.—Transverse section of mid-brain at level of inferior colliculi.

The **base** (*basis pedunculi*; *crusta* or *pes*) is semilunar on transverse section, and consists almost entirely of longitudinal bundles of efferent fibres, which arise from the cells of the cerebral cortex and are grouped into three principal sets, viz., cerebrospinal, frontopontine, and temporopontine (Fig. 720). The **cerebrospinal**

fibres, derived from the cells of the motor area of the cerebral cortex, occupy the middle three-fifths of the base; they are continued partly to the nuclei of the motor cerebral nerves, but mainly into the pyramids of the medulla oblongata. The **frontopontine fibres** are situated in the medial fifth of the base; they arise from the cells of the frontal lobe and end in the nuclei of the pons. The **temporopontine fibres** are lateral to the cerebrospinal fibres; they originate in the temporal lobe and end in the nuclei pontis.¹

aqueduct

*of oculomotor nerve
longitudinal
sacculus*

FIG. 722.—Transverse section of mid-brain at level of superior colliculi.

The **substantia nigra** (*intercalatum*) is a layer of gray substance containing numerous deeply pigmented, multipolar nerve cells. It is semilunar on transverse section, its concavity being directed toward the tegmentum; from its convexity, prolongations extend between the fibres of the base of the peduncle. Thicker medially than laterally, it reaches from the oculomotor sulcus to the lateral sulcus, and extends from the upper surface of the pons to the subthalamic region; its medial part is traversed by the fibres of the oculomotor nerve as these stream forward to reach the oculomotor sulcus. The connections of the cells of the substantia nigra have not been definitely established.

The **tegmentum** is continuous below with the reticular formation of the pons, and, like it, consists of longitudinal and transverse fibres, together with a considerable amount of gray substance. The principal gray masses of the tegmentum are the red nucleus and the interpeduncular ganglion; of its fibres the chief longitudinal tracts are the brachium conjunctivum, the medial longitudinal fasciculus, and the lemniscus.

GRAY SUBSTANCE.—The **red nucleus** is situated in the anterior part of the tegmentum, and is continued upward into the posterior part of the subthalamic region. In sections at the level of the superior colliculus it appears as a circular mass which is traversed by the fibres of the oculomotor nerve. Most of the fibres of the brachium conjunctivum end in it (page 847). The axons of its larger cells cross the middle line and are continued downward into the lateral funiculus of the medulla spinalis as the rubrospinal tract (page 816); those of its smaller cells end mainly in the thalamus.

The **interpeduncular ganglion** is a median collection of nerve cells situated in the ventral part of the tegmentum. The fibres of the fasciculus retroflexus of

¹ A band of fibres, the *tractus peduncularis transversus*, is sometimes seen emerging from in front of the superior colliculus; it passes around the ventral aspect of the peduncle about midway between the pons and the optic tract, and dips into the oculomotor sulcus. This band is a constant structure in many mammals, but is only present in about 30 per cent. of human brains. Since it undergoes atrophy after enucleation of the eyeballs, it may be considered as forming a path for visual sensations.

Meynert, which have their origin in the cells of the ganglion habenulæ (page 859), end in it.

Besides the two nuclei mentioned, there are small collections of cells which form the dorsal and ventral nuclei and the central nucleus or nucleus of the raphé.

WHITE SUBSTANCE.—(1) The origin and course of the *brachium conjunctivum* have already been described (page 841).

(2) The **medial (posterior) longitudinal fasciculus** (Fig. 723) is continuous below with the proper fasciculi of the anterior and lateral funiculi of the medulla spinalis, and has been traced by Edinger as far as a nucleus, the **nucleus of the medial longitudinal fasciculus**, situated in the hypothalamus, immediately in front of the cerebral aqueduct. In the medulla oblongata and pons it runs close to the middle line, near the floor of the fourth ventricle; in the mesencephalon it is situated on the

FIG. 723.—Scheme of the medial longitudinal fasciculus; motor fibres in red, sensory in blue.

ventral aspect of the cerebral aqueduct, below the nuclei of the oculomotor and trochlear nerves. Its connections are imperfectly known, but it consists largely of ascending and descending intersegmental or association fibres, which connect the nuclei of the rhombencephalon and mesencephalon to each other. Many of the descending fibres arise in the superior colliculus, and, after decussating in the middle line, end in the motor nuclei of the pons and medulla oblongata. The ascending fibres arise from the cells of the gray substance of the upper part of the medulla spinalis, and from the nuclei in the medulla oblongata and pons, and pass

without undergoing decussation to the higher nuclei. Fibres are also carried through the medial longitudinal fasciculus from the nucleus of the abducent nerve into the oculomotor nerve of the opposite side, and through this nerve to the Rectus medialis oculi. Again, fibres are said to be prolonged through this fasciculus from the nucleus of the oculomotor nerve into the facial nerve, and are distributed to the Orbicularis oculi, the Corrugator, and the Frontalis.¹

FIG. 724.—Scheme showing the course of the fibres of the lemniscus; medial lemniscus in blue, lateral in red.

(3) The **lemniscus** or **fillet** (Fig. 724).—The fibres of the lemniscus take origin in the gracile and cuneate nuclei of the medulla oblongata, and cross to the opposite side in the sensory decussation (page 827). They then pass upward through the medulla oblongata, in which they are situated behind the cerebrospinal fibres and between the olives. Here they are joined by the fibres of the superficial antero-lateral fasciculus, these having already undergone decussation in the medulla spinalis. As the lemniscus ascends, it receives additional fibres from the terminal nuclei of the sensory cerebral nerves of the opposite side. In the pons, it assumes a flattened, ribbon-like appearance, and is placed dorsal to the trapezium. In

¹ A. Bruce and J. H. Harvey Pirrie, "On the Origin of the Facial Nerve," *Review of Neurology and Psychiatry*, December, 1908, No. 12, vol. vi, produce weighty evidence against the view that the facial nerve derives fibres from the nucleus of the oculomotor nerve.

the mesencephalon, its lateral part is folded backward and forms nearly a right angle with its medial portion; and hence it is customary to speak of the lemniscus as consisting of lateral and medial parts.

The **lateral lemniscus** (*lemniscus lateralis*) comes to the surface of the mesencephalon along its lateral sulcus, and disappears under the inferior colliculus. It consists of fibres from the terminal nuclei of the cochlear division of the acoustic nerve, together with others from the superior olivary and trapezoid nuclei. Most of these fibres are crossed, but some are uncrossed. Many of them pass to the inferior colliculus of the same or opposite side, but others are prolonged to the thalamus, and thence through the occipital part of the internal capsule to the middle and superior temporal gyri.

The **medial lemniscus** (*lemniscus medialis*) begins in the gracile and cuneate nuclei of the opposite side, and is joined by the superficial antero-lateral fasciculus of the medulla spinalis and by fibres from the terminal nuclei of the sensory cerebral nerves of the opposite side, excepting the cochlear division of the acoustic. In the cerebral peduncle, a few of its fibres pass upward in the lateral part of the base of the peduncle, on the dorsal aspect of the temporo-pontine fibres, and reach the lentiform nucleus and the insula. The greater part of the medial lemniscus, on the other hand, is prolonged through the tegmentum, and most of its fibres end in the thalamus; probably some are continued directly through the occipital part of the internal capsule to the cerebral cortex. From the cells of the thalamus a relay of fibres is prolonged to the cerebral cortex.

In the tegmentum there are, besides these three tracts, the **tectospinal fasciculus** from the superior colliculus and the **rubrospinal fasciculus** from the red nucleus; these cross the middle line and are continued downward into the medulla spinalis.

The **corpora quadrigemina** (Fig. 729) are four rounded eminences which form the dorsal part of the mesencephalon. They are situated above and in front of the anterior medullary velum and brachia conjunctiva, and below and behind the third ventricle and posterior commissure. They are covered by the splenium of the corpus callosum, and are partly overlapped on either side by the medial angle, or **pulvinar**, of the posterior end of the thalamus; on the lateral aspect, under cover of the pulvinar, is an oval eminence, named the **medial geniculate body**. The corpora quadrigemina are arranged in pairs (**superior and inferior colliculi**), and are separated from one another by a crucial sulcus. The longitudinal part of this sulcus expands superiorly to form a slight depression which supports the **pineal body**, a cone-like structure which projects backward from the thalamencephalon and partly obscures the superior colliculi. From the inferior end of the longitudinal sulcus, a white band, termed the **frinulum veli**, is prolonged downward to the anterior medullary velum; on either side of this band the trochlear nerve emerges, and passes forward on the lateral aspect of the cerebral peduncle to reach the base of the brain. The **superior colliculi** are larger and darker in color than the inferior, and are oval in shape. The **inferior colliculi** are hemispherical, and somewhat more prominent than the superior. The superior colliculi are associated with the sense of sight, the inferior with that of hearing.

From the lateral aspect of each colliculus a white band, termed the **brachium**,

FIG. 725.—Transverse section passing through the sensory decussation. Schematic. (Testut.) 1. Anterior median fissure. 2. Posterior median sulcus. 3, 3'. Head and base of anterior column sulcus. 4. is prolonged upward and forward. The **superior brachium** extends lateralward from the superior colliculus, and, passing between the pulvinar and medial geniculate body, is partly continued into an eminence called the **lateral geniculate body**, and partly into the optic tract. The **inferior brachium** passes forward and upward from the inferior colliculus and disappears under cover of the **medial geniculate body**.

In close relationship with the corpora quadrigemina are the brachia conjunctiva, which emerge from the upper and medial parts of the cerebellar hemispheres. They run upward and forward, and, passing under the inferior colliculi, enter the tecta as already described (page 841).

Structure of the Corpora Quadrigemina.—The **inferior colliculus** (*colliculus inferior; inferior quadrigeminal body; postgemina*) consists of a compact nucleus of gray substance containing large and small multipolar nerve cells, and more or less completely surrounded by white fibres derived from the lateral lemniscus. Most of these fibres end in the gray nucleus of the same side, but some cross the middle line and end in that of the opposite side. From the cells of the gray nucleus, fibres are prolonged through the inferior brachium into the tegmentum of the cerebral peduncle, and are carried to the thalamus and the cortex of the temporal lobe; other fibres cross the middle line and end in the opposite colliculus.

The **superior colliculus** (*colliculus superior; superior quadrigeminal body; pregemina*) is covered by a thin stratum (**stratum zonale**) of white fibres, the majority of which are derived from the optic tract. Beneath this is the **stratum cinereum**, a cap-like layer of gray substance, thicker in the centre than at the circumference, and consisting of numerous small multipolar nerve cells, imbedded in a fine network of nerve fibres. Still deeper is the **stratum opticum**, containing large multipolar nerve cells, separated by numerous fine nerve fibres. Finally, there is the **stratum lemnisci**, consisting of fibres derived partly from the lemniscus and partly from the cells of the stratum opticum; interspersed among these fibres are many large multipolar nerve cells. The two last-named strata are sometimes termed the **gray-white layers**, from the fact that they consist of both gray and white substance. Of the afferent fibres which reach the superior colliculus, some are derived from the lemniscus, but the majority have their origins in the retina and are conveyed to it through the superior brachium; all of them end by arborizing around the cells of the gray substance. Of the efferent fibres, some cross the middle line to the opposite colliculus; many ascend through the superior brachium, and finally reach the cortex of the occipital lobe of the cerebrum; while others, after undergoing decussation (**decussation of Meynert**) form the tectospinal fasciculus which descends through the formatio reticularis of the mesencephalon, pons, and medulla oblongata into the medulla spinalis, where it is found partly in the anterior funiculus and partly intermingled with the fibres of the rubrospinal tract.

The corpora quadrigemina are larger in the lower animals than in man. In fishes, reptiles, and birds they are hollow, and only two in number (*corpora bigemina*); they represent the superior colliculi of mammals, and are frequently termed the optic lobes, because of their intimate connection with the optic tracts.

The **cerebral aqueduct** (*aqueductus cerebri; aqueduct of Sylvius*) is a narrow canal, about 15 mm. long, situated between the corpora quadrigemina and tecta, and connecting the third with the fourth ventricle. Its shape, as seen in transverse section, varies at different levels, being T-shaped, triangular above, and oval in the middle; the central part is slightly dilated, and was named by Retzius the **ventricle of the mid-brain**. It is lined by ciliated columnar epithelium, and is surrounded by a layer of gray substance named the **central gray stratum**: this is continuous below with the gray substance in the rhomboid fossa, and above with that of the third ventricle. Dorsally, it is partly separated from the gray

substance of the quadrigeminal bodies by the fibres of the lemniscus; ventral to it are the medial longitudinal fasciculus, and the *formatio reticularis* of the tegmentum. Scattered throughout the central gray stratum are numerous nerve cells of various sizes, interlaced, by a net-work of fine fibres. Besides these scattered cells it contains three groups which constitute the nuclei of the oculomotor and trochlear nerves, and the nucleus of the mesencephalic root of the trigeminal nerve. The **nucleus of the trigeminal nerve** extends along the entire length of the aqueduct, and occupies the lateral part of the gray stratum, while the nuclei of the oculomotor and trochlear nerves are situated in its ventral part. The **nucleus of the oculomotor nerve** is about 10 cm. long, and lies under the superior colliculus, beyond which, however, it extends for a short distance into the gray substance of the third ventricle. The **nucleus of the trochlear nerve** is small and nearly circular, and is on a level with a plane carried transversely through the upper part of the inferior colliculus.

THE PROSENCEPHALON OR FORE-BRAIN.

The **prosencephalon** or **fore-brain** consists of: (1) the **diencephalon**, corresponding in a large measure to the third ventricle and the structures which bound it; and (2) the **telencephalon**, comprising the largest part of the brain, viz., the cerebral hemispheres; these hemispheres are intimately connected with each other across the middle line, and each contains a large cavity, named the lateral ventricle. The lateral ventricles communicate through the interventricular foramen with the third ventricle, but are separated from each other by a medial septum, the *septum pellucidum*; this contains a slit-like cavity, which does not communicate with the ventricles.

The Diencephalon.—The diencephalon is connected above and in front with the cerebral hemispheres; behind with the mesencephalon. Its upper surface is concealed by the corpus callosum, and is covered by a fold of pia mater, named the *tela chorioidea* of the third ventricle; inferiorly it reaches to the base of the brain.

The diencephalon comprises: (1) the **thalamencephalon**; (2) the **pars mamillaria hypothalami**; and (3) the **posterior part of the third ventricle**. For descriptive purposes, however, it is more convenient to consider the whole of the third ventricle and its boundaries together; this necessitates the inclusion, under this heading, of the *pars optica hypothalami* and the corresponding part of the third ventricle—structures which properly belong to the telencephalon.

The Thalamencephalon.—The thalamencephalon comprises: (1) the **thalamus**; (2) the **metathalamus** or **corpora geniculata**; and (3) the **epithalamus**, consisting of the *trigonum habenulae*, the pineal body, and the posterior commissure.

The Thalami (*optic thalamus*) (Figs. 726, 727) are two large ovoid masses, situated one on either side of the third ventricle and reaching for some distance behind that cavity. Each measures about 4 cm. in length, and presents two extremities, an anterior and a posterior, and four surfaces, superior, inferior, medial, and lateral.

The **anterior extremity** is narrow; it lies close to the middle line and forms the posterior boundary of the interventricular foramen.

The **posterior extremity** is expanded, directed backward and lateralward, and overlaps the superior colliculus. Medially it presents an angular prominence, the **pulvinar**, which is continued laterally into an oval swelling, the **lateral geniculate body**, while beneath the pulvinar, but separated from it by the superior brachium, is a second oval swelling, the **medial geniculate body**.

The **superior surface** is free, slightly convex, and covered by a layer of white substance, termed the **stratum zonale**. It is separated laterally from the caudate nucleus by a white band, the **stria terminalis**, and by the terminal vein. It is divided into a medial and a lateral portion by an oblique shallow furrow which runs from

behind forward and medialward and corresponds with the lateral margin of the fornix; the lateral part forms a portion of the floor of the lateral ventricle, and is covered by the epithelial lining of this cavity; the medial part is covered by the tela chorioidea of the third ventricle, and is destitute of an epithelial covering. In front, the superior is separated from the medial surface by a salient margin, the *taenia thalami*, along which the epithelial lining of the third ventricle is reflected on to the under surface of the tela chorioidea. Behind, it is limited medially by a groove, the *sulcus habenulae*, which intervenes between it and a small triangular area, termed the *trigonum habenulae*.

The *inferior surface* rests upon and is continuous with the upward prolongation of the tegmentum (*subthalamie tegmental region*), in front of which it is related to the *substantia innominata* of Meynert.

FIG. 726.—Dissection showing the ventricles of the brain.

The *medial surface* constitutes the upper part of the lateral wall of the third ventricle, and is connected to the corresponding surface of the opposite thalamus by a flattened gray band, the *massa intermedia* (*middle or gray commissure*). This mass averages about 1 cm. in its antero-posterior diameter: it sometimes consists of two parts and occasionally is absent. It contains nerve cells and nerve fibres; a few of the latter may cross the middle line, but most of them pass toward the middle line and then curve lateralward on the same side.

The *lateral surface* is in contact with a thick band of white substance which forms the occipital part of the internal capsule and separates the thalamus from the lentiform nucleus of the corpus striatum.

Structure.—The thalamus consists chiefly of gray substance, but its upper surface is covered by a layer of white substance, named the *stratum zonale*, and its lateral surface by a similar layer termed the *lateral medullary lamina*. Its gray

substance is incompletely subdivided into three parts—**anterior**, **medial**, and **lateral**—by a white layer, the **medial medullary lamina**. The anterior part comprises the anterior tubercle, the medial part lies next the lateral wall of the third ventricle while the lateral and largest part is interposed between the medullary laminae and includes the pulvinar. The lateral part is traversed by numerous fibres which radiate from the thalamus into the internal capsule, and pass through the latter to the cerebral cortex. These three parts are built up of numerous nuclei, the connections of many of which are imperfectly known.

Connections.—The thalamus may be regarded as a large ganglionic mass in which the ascending tracts of the tegmentum and a considerable proportion of the fibres of the optic tract end, and from the cells of which numerous fibres (thalamocortical) take origin, and radiate to almost every part of the cerebral cortex. The lemniscus, together with the other longitudinal strands of the tegmentum, enters its ventral part: the **thalamomamillary fasciculus** (*bundle of Vicq d'Azyr*), from the corpus mamillare, enters in its anterior tubercle, while many of the fibres of the optic tract terminate in its posterior end. The thalamus also receives numerous fibres (corticothalamic) from the cells of the cerebral cortex. The fibres that arise from the cells of the thalamus form four principal groups or stalks: (a) those of the **anterior stalk** pass through the frontal part of the internal capsule to the frontal lobe; (b) the fibres of the **posterior stalk** (*optic radiations*) arise in the pulvinar and are

conveyed through the occipital part of the internal capsule to the occipital lobe: 2 the fibres of the **inferior stalk** leave the under and medial surfaces of the thalamus, and pass beneath the lentiform nucleus to the temporal lobe and insula: 3 those of the **parietal stalk** pass from the lateral nucleus of the thalamus to the parietal lobe. Fibres also extend from the thalamus into the corpus striatum—those destined for the caudate nucleus leave the lateral surface, and those for the lentiform nucleus, the inferior surface of the thalamus.

FIG. 728.—Coronal section of brain through intermediate mass of third ventricle.

The **Metathalamus** (Fig. 729) comprises the **geniculate bodies**, which are two in number—a **medial** and a **lateral**—on each side.

The **medial geniculate body** (*corpus geniculatum mediale*; *internal geniculate body*; *postgeniculatum*) lies under cover of the pulvinar of the thalamus and on the lateral aspect of the corpora quadrigemina. Oval in shape, with its long axis directed forward and lateralward, it is lighter in color and smaller in size than the lateral. The inferior brachium from the inferior colliculus disappears under cover of it while from its lateral extremity a strand of fibres passes to join the optic tract. Entering it are many acoustic fibres from the lateral lemniscus. The medial geniculate bodies are connected with one another by the commissure of Gudden, which passes through the posterior part of the optic chiasma.

The **lateral geniculate body** (*corpus geniculatum laterale*; *external geniculate body*; *pregeniculatum*) is an oval elevation on the lateral part of the posterior end of the

thalamus, and is connected with the superior colliculus by the superior brachium. It is of a dark color, and presents a laminated arrangement consisting of alternate layers of gray and white substance. It receives numerous fibres from the optic tract, while other fibres of this tract pass over or through it into the pulvinar. Its cells are large and pigmented; their axons pass to the visual area in the occipital part of the cerebral cortex.

The superior colliculus, the pulvinar, and the lateral geniculate body receive many fibres from the optic tracts, and are therefore intimately connected with sight, constituting what are termed the **lower visual centres**. Extirpation of the eyes in a newly born animal entails an arrest of the development of these centres, but has no effect on the medial geniculate bodies or on the inferior colliculi. Moreover, the latter are well-developed in the mole, an animal in which the superior colliculi are rudimentary.

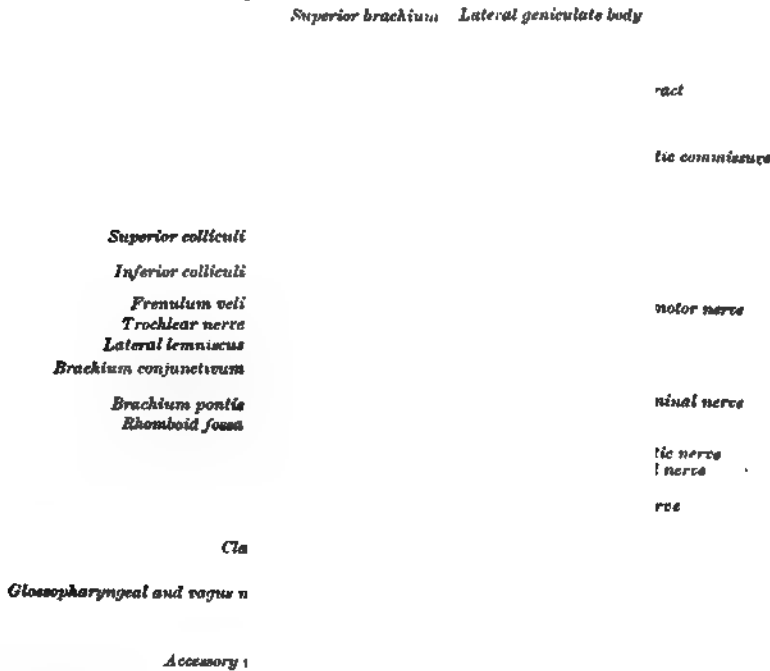

FIG. 729.—Hind- and mid-brains; postero-lateral view.

The **Epithalamus** comprises the **trigonum habenulae**, the **pineal body**, and the **posterior commissure**.

The **trigonum habenulae** is a small depressed triangular area situated in front of the superior colliculus and on the lateral aspect of the posterior part of the **taenia thalami**. It contains a group of nerve cells termed the **ganglion habenulae**. Fibres enter it from the stalk of the pineal body, and others, forming what is termed the **habenular commissure**, pass across the middle line to the corresponding ganglion of the opposite side. Most of its fibres are, however, directed downward and form a bundle, the **fasciculus retroflexus** of Meynert, which passes medial to the red nucleus, and, after decussating with the corresponding fasciculus of the opposite side, ends in the interpeduncular ganglion.

The **pineal body** (*corpus pineale*; *epiphysis*) is a small, conical, reddish-gray body which lies in the depression between the superior colliculi. It is placed beneath the **splenium** of the corpus callosum, but is separated from this by the **tela choriodea** of the third ventricle, the lower layer of which envelops it. It measures about 8 cm. in length, and its base, directed forward, is attached by a stalk or peduncle

of white substance. The **stalk** of the pineal body divides anteriorly into two laminae, a dorsal and a ventral, separated from one another by the pineal recess of the third ventricle. The ventral lamina is continuous with the posterior commissure; the dorsal lamina is continuous with the habenular commissure and divides into two strands the medullary striæ, which run forward, one on either side, along the junction of the medial and upper surfaces of the thalamus to blend in front with the columns of the fornix.

Structure.—The pineal body is destitute of nervous substance, and consists of follicles lined by epithelium and enveloped by connective tissue. These follicles contain a variable quantity of gritty material, composed of phosphate and carbonate of calcium, phosphate of magnesium and ammonia, and a little animal matter.

The pineal body is generally believed to be the homologue of the pineal eye of lizards. In these animals it is attached by an elongated stalk and projects through an aperture in the roof of the cranium. Its extremity lies immediately under the epidermis, and, on microscopic examination, presents in a rudimentary fashion structures similar to those found in the eyeball. Recent observations tend to the conclusion that the pineal body arises as a paired structure, probably serially homologous with the paired eyes.

The **posterior commissure** is a rounded band of white fibres crossing the middle line on the dorsal aspect of the upper end of the cerebral aqueduct. Its fibres acquire their medullary sheaths early, but their connections have not been definitely determined. Most of them have their origin in a nucleus, the **nucleus of the posterior commissure** (*nucleus of Darkschewitsch*), which lies in the central gray substance of the upper end of the cerebral aqueduct, in front of the nucleus of the oculomotor nerve. Some are probably derived from the posterior part of the thalamus and from the superior colliculus, while others are believed to be continued downward into the medial longitudinal fasciculus.

The **Hypothalamus** (Fig. 730) includes the **subthalamic tegmental region** and the structures forming the greater part of the floor of the third ventricle, viz., the **corpora mamillaria**, **tuber cinereum**, **infundibulum**, **hypophysis**, and **optic chiasma**.

The **subthalamic tegmental region** consists of the upward continuation of the tegmentum; it lies on the ventro-lateral aspect of the thalamus and separates it from the fibres of the internal capsule. The red nucleus and the substantia nigra are prolonged into its lower part; in front it is continuous with the substantia innominate of Meynert, medially with the gray substance of the floor of the third ventricle.

It consists from above downward of three strata: (1) **stratum dorsale**, directly applied to the under surface of the thalamus and consisting of fine longitudinal fibres; (2) **zona incerta**, a continuation forward of the formatio reticularis of the tegmentum; and (3) the **corpus subthalamicum** (*nucleus of Luys*), a brownish mass presenting a lenticular shape on transverse section, and situated on the dorsal aspect of the fibres of the base of the cerebral peduncle; it is encapsuled by a lamina of nerve fibres and contains numerous medium-sized nerve cells, the connections of which are as yet not fully determined.

The **corpora mamillaria** (*corpus albicantia*) are two round white masses, each about the size of a small pea, placed side by side below the gray substance of the floor of the third ventricle in front of the posterior perforated substance. They consist of white substance externally and of gray substance internally, the cells of the latter forming two nuclei, a **medial** of smaller and a **lateral** of larger cells. The white substance is mainly formed by the fibres of the columns of the fornix, which descend to the base of the brain and end partly in the corpora mamillaria. From the cells of the gray substance of each mamillary body two fasciculi arise: one, the **thalamomamillary fasciculus** (*bundle of Vicq d'Azyr*), passes upward into the anterior nucleus of the thalamus; the other is directed downward into the tegmentum. Afferent fibres are believed to reach the corpus mamillare from the medial lemniscus and from the tegmentum.

The **tuber cinereum** is a hollow eminence of gray substance situated between the corpora mamillaria behind, and the optic chiasma in front. Laterally it is

<i>Tela chorioidea of third ventricle</i>	<i>Posterior commissure</i>
<i>Intermediate mass</i>

FIG. 730.—Median sagittal section of brain. The relations of the pia mater are indicated by the red color.

continuous with the anterior perforated substances and anteriorly with a thin lamina, the **lamina terminalis**. From the under surface of the tuber cinereum a hollow conical process, the **infundibulum**, projects downward and forward and is attached to the posterior lobe of the hypophysis.

In the lateral part of the tuber cinereum is a nucleus of nerve cells, the *basal optic nucleus of Meynert*, while close to the cavity of the third ventricle are three additional nuclei. Between the tuber cinereum and the corpora mamillaria a small elevation, with a corresponding depression in the third ventricle, is sometimes seen. Retzius has named it the *eminentia sacularis*, and regards it as a representative of the saccus vasculosus found in this situation in some of the lower vertebrates.

FIG. 731.—The hypophysis cerebri, in position. Shown in sagittal section. (Festui.) 1. Anterior and posterior lobes of hypophysis. 2. Infundibulum. 3. Optic chiasma. 4. Lamina terminalis. 5. The **hypophysis** (*pituitary body*) (Fig. 731) is a reddish-gray, somewhat oval mass, measuring about 1.25 cm. in its transverse, and about 8 cm. in its antero-

posterior diameter. It is attached to the end of the infundibulum, and is situated in the fossa hypophyseos of the sphenoidal bone, where it is retained by a circular fold of dura mater, the **diaphragma sellæ**; this fold almost completely roofs in the fossa, leaving only a small central aperture through which the infundibulum passes.

The hypophysis consists of an anterior and a posterior lobe, which differ from one another in their mode of development and in their structure (Fig. 732). The **anterior lobe** is the larger, and is somewhat kidney-shaped, the concavity being directed backward and embracing the posterior lobe. It is developed from a diverticulum of the ectoderm of the primitive buccal cavity or stomodeum (see page 166) and consists of a pars anterior and a pars intermedia, separated from each other by a narrow cleft, the remnant of the pouch or diverticulum. The pars anterior is extremely vascular and consists of epithelial cells of varying size and shape, arranged in cord-like trabeculæ or alveoli and separated by large, thin-walled bloodvessels. The pars intermedia is a thin lamina closely applied to the body and neck of the posterior lobe and extending on to the neighboring parts of the brain; it contains few bloodvessels and consists of finely granular cells between which are small masses of colloid material. The **posterior lobe** is developed as a downgrowth from the floor of the embryonic brain, and during early fetal life contains a cavity continuous with that of the third ventricle. In some animals, *e. g.*,

FIG. 732.—Median sagittal section through the hypophysis of an adult monkey. Semidiagrammatic. (Herring.)

cat, this cavity persists throughout life. Although of nervous origin the posterior lobe contains no nerve cells or fibres. It consists of neuroglia cells and fibres and is invaded by columns which grow into it from the pars intermedia; imbedded in it are large quantities of a colloid substance histologically similar to that found in the thyroid gland. In certain of the lower vertebrates, *e. g.*, fishes, nervous structures are present, and the lobe is of large size.

Applied Anatomy.—Prof. Schäfer has isolated from the pars intermedia a substance, no doubt an internal secretion, that causes constriction of the bloodvessels, rise of arterial blood pressure, and increased secretion of urine, when injected subcutaneously. Enlargement of the hypophysis and of the cavity of the sella turcica are found in the rare disease *acromegaly*, which is characterized by gradual enlargement of the face, hands, and feet, with headache and often a peculiar type of blindness. This blindness is due to the pressure of the enlarging hypophysis on the optic chiasma (Fig. 731). The pressure causes atrophy, for the most part of the nerve fibres coming from the nasal sides of the retinae; with the result that the patient loses his two temporal fields of vision while retaining his nasal fields (bitemporal hemianopsy).

Optic Chiasma (*chiasma opticum*; *optic commissure*).—The optic chiasma is a flattened, somewhat quadrilateral band of fibres, situated at the junction of the floor and anterior wall of the third ventricle. Most of its fibres have their origins

in the retina, and reach the chiasma through the optic nerves, which are continuous with its antero-lateral angles. In the chiasma, they undergo a partial decussation (Fig. 733); the fibres from the nasal half of the retina decussate and enter the optic tract of the opposite side, while the fibres from the temporal half of the retina do not undergo decussation, but pass back into the optic tract of the same side. Occupying the posterior part of the commissure, however, is a strand of fibres, the **commissure of Gudden**, which is not derived from the optic nerves; it forms a connecting link between the medial geniculate bodies.

FIG. 733.—Scheme showing central connections of the optic nerves and optic tracts.

Optic Tracts.—The optic tracts are continued backward and lateralward from the postero-lateral angles of the optic chiasma. Each passes between the anterior perforated substance and the tuber cinereum, and, winding around the ventro-lateral aspect of the cerebral peduncle, divides into a medial and a lateral root. The former comprises the fibres of Gudden's commissure. The lateral root consists mainly of afferent fibres which arise in the retina and undergo partial decussation in the optic chiasma, as described; but it also contains a few fine efferent fibres which have their origins in the brain and their terminations in the retina. When traced backward, the afferent fibres of the lateral root are found to end in the lateral geniculate body and pulvinar of the thalamus, and in the superior colliculus; and

these three structures constitute the **lower visual centres**. Fibres arise from the nerve cells in these centres and pass through the occipital part of the internal capsule, under the name of the **optic radiations**, to the cortex of the occipital lobe of the cerebrum, where the **higher or cortical visual centre** is situated. Some of the fibres of the optic radiations take an opposite course, arising from the cells of the occipital cortex and passing to the lower visual centres. Some fibres are detached from the optic tract, and pass through the cerebral peduncle to the nucleus of the oculomotor nerve. These may be regarded as the afferent branches for the Sphincter pupillae and Ciliaris muscles. Other fibres have been described as reaching the cerebellum through the brachia conjunctiva; while others, again, are lost in the pons.

The Third Ventricle (*ventriculus tertius*) (Figs. 726, 730).—The third ventricle is a median cleft between the two thalami. Behind, it communicates with the fourth ventricle through the cerebral aqueduct, and in front with the lateral ventricles through the interventricular foramen. Somewhat triangular in shape, with the apex directed backward, it has a **roof**, a **floor**, an **anterior** and a **posterior boundary** and a pair of **lateral walls**.

FIG. 734.—Coronal section of lateral and third ventricles. (Diagrammatic.)

The **roof** (Fig. 734) is formed by a layer of epithelium, which stretches between the upper edges of the lateral walls of the cavity and is continuous with the epithelial lining of the ventricle. It is covered by and adherent to a fold of pia mater, named the **tela chorioidea** of the third ventricle, from the under surface of which a pair of vascular fringed processes, the **choroid plexuses of the third ventricle**, project downward, one on either side of the middle line, and invaginate the epithelial roof into the ventricular cavity.

The **floor** slopes downward and forward and is formed mainly by the structures which constitute the **hypothalamus**: from before backward these are: the optic chiasma, the tuber cinereum and infundibulum, and the corpora mamillaria. Behind the last, the floor is formed by the interpeduncular fossa and the tegmenta of the cerebral peduncles. The ventricle is prolonged downward as a funnel-shaped recess, the **recessus infundibuli**, into the infundibulum, and to the apex of the latter the hypophysis is attached.

The **anterior boundary** is constituted below by the **lamina terminalis**, a thin layer of gray substance stretching from the upper surface of the optic chiasma to the rostrum of the corpus callosum; above by the columns of the fornix and the anterior commissure. At the junction of the floor and anterior wall, immediately above the optic chiasma, the ventricle presents a small angular recess or diverticulum,

the **optic recess**. Between the columns of the fornix, and above the anterior commissure, is a second recess termed the **vulva**. At the junction of the roof and anterior wall of the ventricle, and situated between the thalami behind and the columns of the fornix in front, is the **interventricular foramen** (*foramen of Monro*) through which the third communicates with the lateral ventricles.

The **posterior boundary** is constituted by the pineal body, the posterior commissure and the cerebral aqueduct. A small recess, the **recessus pinealis**, projects into the stalk of the pineal body, while in front of and above the pineal body is a second recess, the **recessus suprapinealis**, consisting of a diverticulum of the epithelium which forms the ventricular roof.

Each **lateral wall** consists of an upper portion formed by the medial surface of the anterior two-thirds of the thalamus, and a lower consisting of an upward continuation of the gray substance of the ventricular floor. These two parts correspond to the alar and basal laminae respectively of the lateral wall of the fore-brain vesicle and are separated from each other by a furrow, the **sulcus of Monro**, which extends from the interventricular foramen to the cerebral aqueduct (pages 125 and 126). The lateral wall is limited above by the **taenia thalami**. The columns of the fornix curve downward in front of the interventricular foramen, and then run in the lateral walls of the ventricle, where, at first, they form distinct prominences, but subsequently are lost to sight. The lateral walls are joined to each other across the cavity of the ventricle by a band of gray matter, the **massa intermedia** (page 856).

Interpeduncular Fossa (Fig. 735).—This is a somewhat lozenge-shaped area of the base of the brain, limited in front by the optic chiasma, behind by the antero-superior surface of the pons, antero-laterally by the converging optic tracts, and postero-laterally by the diverging cerebral peduncles. The structures contained in it have already been described; from behind forward, they are the posterior perforated substance, corpora mamillaria, tuber cinereum, infundibulum, and hypophysis.

The Telencephalon.—The telencephalon includes: (1) the **cerebral hemispheres** with their cavities, the lateral ventricles; and (2) the **pars optica hypothalami** and the anterior portion of the third ventricle (already described under the diencephalon). As stated in the chapter on Embryology (page 128), each cerebral hemisphere may be divided into three fundamental parts, viz., the **rhinencephalon**, the **corpus striatum**, and the **neopallium**. The **rhinencephalon**, associated with the sense of smell, is the oldest part of the telencephalon, and forms almost the whole of the hemisphere in some of the lower animals, *e. g.*, fishes, amphibians, and reptiles. In man it is rudimentary, whereas the **neopallium** undergoes great development and forms the chief part of the hemisphere.

The Cerebral Hemispheres.—The cerebral hemispheres constitute the largest part of the encephalon, and, when viewed together from above, assume the form of an ovoid mass broader behind than in front, the greatest transverse diameter corresponding with a line connecting the two parietal eminences. The hemispheres are separated medially by a deep cleft, named the **longitudinal cerebral fissure**, and each possesses a central cavity, the lateral ventricle.

The **Longitudinal Cerebral Fissure** (*fissura cerebri longitudinalis*; *great longitudinal fissure*) contains a sickle-shaped process of dura mater, the **falx cerebri**. It front and behind, the fissure extends from the upper to the under surfaces of the hemispheres and completely separates them, but its middle portion only separates them for about one-half of their vertical extent; for at this part they are connected across the middle line by a great central white commissure, the **corpus callosum**.

In a median sagittal section (Fig. 730) the cut corpus callosum presents the appearance of a broad, arched band. Its thick posterior end, termed the **splenium**, overlaps the mid-brain, but is separated from it by the tela chorioidea of the third

ventricle and the pineal body. Its anterior curved end, termed the **genu**, gradually tapers into a thinner portion, the **rostrum**, which is continued downward and backward in front of the anterior commissure to join the lamina terminalis. Arching backward from immediately behind the anterior commissure to the under surface of the splenium is a second white band named the **fornix**: between this and the corpus callosum are the laminae and cavity of the septum pellucidum.

FIG. 735.—Base of brain.

Surfaces of the Cerebral Hemispheres.—Each hemisphere presents three surfaces: **lateral**, **medial**, and **inferior**.

The **lateral surface** is convex in adaptation to the concavity of the corresponding half of the vault of the cranium. The **medial surface** is flat and vertical, and is separated from that of the opposite hemisphere by the great longitudinal fissure and the falx cerebri. The **inferior surface** is of an irregular form, and may be divided into three areas: anterior, middle, and posterior. The anterior area, formed by the orbital surface of the frontal lobe, is concave, and rests on the roof of the orbit and nose; the middle area is convex, and consists of the under surface of the temporal lobe: it is adapted to the corresponding half of the middle cranial fossa. The posterior area is concave, directed medialward as well as downward, and is named the **tentorial surface**, since it rests upon the tentorium cerebelli, which intervenes between it and the upper surface of the cerebellum.

These three surfaces are separated from each other by the following borders:

(a) **supero-medial**, between the lateral and medial surfaces; (b) **infero-lateral**, between the lateral and inferior surfaces; the anterior part of this border separating the lateral from the orbital surface, is known as the **superciliary border**; (c) **medial occipital**, separating the medial and tentorial surfaces; and (d) **medial orbital**, separating the orbital from the medial surface. The anterior end of the hemisphere is named the **frontal pole**; the posterior, the **occipital pole**; and the anterior end of the temporal lobe, the **temporal pole**. About 5 cm. in front of the occipital pole on the infero-lateral border is an indentation or notch, named the **preoccipital notch**.

The surfaces of the hemispheres are moulded into a number of irregular eminences, named **gyri** or **convolutions**, and separated by furrows termed **fissures** and **sulci**. The furrows are of two kinds, *complete* and *incomplete*. The former appear early in fetal life, are few in number, and are produced by infoldings of the entire thickness of the brain wall, and give rise to corresponding elevations in the interior of the ventricle. They comprise the hippocampal fissure, and parts of the calcarine and collateral fissures. The incomplete furrows are very numerous, and only indent the subjacent white substance, without producing any corresponding elevations in the ventricular cavity.

The gyri and their intervening fissures and the sulci are fairly constant in their arrangement; at the same time they vary within certain limits, not only in different individuals, but on the two hemispheres of the same brain. The convoluted condition of the surface permits of a great increase of the gray matter without the sacrifice of much additional space. The number and extent of the gyri, as well as the depth of the intervening furrows, appear to bear a direct relation to the intellectual powers of the individual.

Certain of the fissures and sulci are utilized for the purpose of dividing the hemisphere into lobes, and are therefore termed **interlobular**; included under this category are the lateral cerebral, parietooccipital, calcarine, and collateral fissures, the central and cingulate sulci, and the sulcus circularis.

The **Lateral Cerebral Fissure** (*fissura cerebri lateralis* [Sylvii]; *fissure of Sylvius*) (Fig. 737) is a well-marked cleft on the inferior and lateral surfaces of the hemisphere, and consists of a short stem which divides into three rami. The stem is situated on the base of the brain, and commences in a depression at the lateral angle of the anterior perforated substance. From this point it extends between the anterior part of the temporal lobe and the orbital surface of the frontal lobe, and reaches the lateral surface of the hemisphere. Here it divides into three rami: an anterior horizontal, an anterior ascending, and a posterior. The **anterior horizontal ramus** passes forward for about 2.5 cm. into the inferior frontal gyrus, while the **anterior ascending ramus** extends upward into the same convolution for about an equal distance. The **posterior ramus** is the longest; it runs backward and slightly upward for about 7 cm., and ends by an upward inflexion in the parietal lobe.

FIG. 736.—Lateral surface of left cerebral hemisphere, viewed from above.

The **Central Sulcus** (*sulcus centralis* [Rolandi]; *fissure of Rolando*; *central fissure*) (Figs. 736, 737) is situated about the middle of the lateral surface of the hemisphere, and begins in or near the longitudinal cerebral fissure, a little behind its mid-point. It runs sinuously downward and forward, and ends a little above the posterior

FIG. 737.—Lateral surface of left cerebral hemisphere, viewed from the side.

ramus of the lateral fissure, and about 2.5 cm. behind the anterior ascending ramus of the same fissure. It described two chief curves: a **superior genu** with its concavity directed forward, and an **inferior genu** with its concavity directed backward. The central sulcus forms an angle opening forward of about 70° with the median plane.

FIG. 738.—Medial surface of left cerebral hemisphere.

The **Parietooccipital Fissure** (*fissura parietooccipitalis*).—Only a small part of this fissure is seen on the lateral surface of the hemisphere, its chief part being on the medial surface.

The **lateral part** of the parietooccipital fissure (Fig. 737) is situated about 5 cm. in front of the occipital pole of the hemisphere, and measures about 1.25 cm. in length.

The **medial part** of the parietooccipital fissure (Fig. 738) runs downward and forward as a deep cleft on the medial surface of the hemisphere, and joins the calcarine fissure below and behind the posterior end of the corpus callosum. In most cases it contains a submerged gyrus.

The **Calcarine Fissure** (*fissura calcarina*) (Fig. 738) is on the medial surface of the hemisphere. It begins near the occipital pole in two converging rami, and runs forward to a point a little below the splenium of the corpus callosum, where it is joined at an acute angle by the medial part of the parietooccipital fissure. The anterior part of this fissure gives rise to the prominence of the *calcar avis* in the posterior cornu of the lateral ventricle.

The **Cingulate Sulcus** (*sulcus cinguli*; *callosomarginal fissure*) (Fig. 738) is on the medial surface of the hemisphere; it begins below the anterior end of the corpus callosum and runs upward and forward nearly parallel to the rostrum of this body and, curving in front of the genu, is continued backward above the corpus callosum, and finally ascends to the supero-medial border of the hemisphere a short distance behind the upper end of the central sulcus. It separates the superior frontal from the cingulate gyrus.

The **Collateral Fissure** (*fissura collateralis*) (Fig. 738) is on the tentorial surface of the hemisphere and extends from near the occipital pole to within a short distance of the temporal pole. Behind, it lies below and lateral to the calcarine fissure, from which it is separated by the lingual gyrus; in front, it is situated between the hippocampal gyrus and the anterior part of the fusiform gyrus.

The **Sulcus Circularis** (*circuminsular fissure*) (Fig. 741) is on the lower and lateral surfaces of the hemisphere: it surrounds the insula and separates it from the frontal, parietal, and temporal lobes.

Lobes of the Hemispheres.—By means of these fissures and sulci, assisted by certain arbitrary lines, each hemisphere is divided into the following lobes: the **frontal**, the **parietal**, the **temporal**, the **occipital**, the **limbic**, and the **insula**.

Frontal Lobe (*lobus frontalis*).—On the lateral surface of the hemisphere this lobe extends from the frontal pole to the central sulcus, the latter separating it from the parietal lobe. Below, it is limited by the posterior ramus of the lateral fissure, which intervenes between it and the central lobe. On the medial surface, it is separated from the cingulate gyrus by the cingulate sulcus; and on the inferior surface, it is bounded behind by the stem of the lateral fissure.

The **lateral surface** of the frontal lobe (Fig. 737) is traversed by three sulci which divide it into four gyri: the sulci are named the precentral, and the superior and inferior frontal; the gyri are the anterior central, and the superior, middle, and inferior frontal. The **precentral sulcus** runs parallel to the central sulcus, and is usually divided into an upper and a lower part; between it and the central sulcus is the **anterior central gyrus**. From the precentral sulcus, the **superior** and **inferior frontal sulci** run forward and downward, and divide the remainder of the lateral surface of the lobe into three parallel gyri, named, respectively the **superior**, **middle**, and **inferior frontal gyri**.

The **anterior central gyrus** (*gyrus centralis anterior*; *ascending frontal convolution*; *precentral gyre*) is bounded in front by the precentral sulcus, behind by the central sulcus; it extends from the supero-medial border of the hemisphere to the posterior ramus of the lateral fissure.

The **superior frontal gyrus** (*gyrus frontalis superior*; *superfrontal gyre*) is situated above the superior frontal sulcus and is continued on to the medial surface of the hemisphere. The portion on the lateral surface of the hemisphere is usually more or less completely subdivided into an upper and a lower part by an antero-

posterior sulcus, the **paramedial sulcus**, which, however, is frequently interrupted by bridging gyri.

The **middle frontal gyrus** (*gyrus frontalis medius; medifrontal gyre*), between the superior and inferior frontal sulci, is continuous with the anterior orbital gyrus on the inferior surface of the hemisphere; it is frequently subdivided into two by a horizontal sulcus, the **medial frontal sulcus** of Eberstaller, which ends anteriorly in a wide bifurcation.

The **inferior frontal gyrus** (*gyrus frontalis inferior; subfrontal gyre*) lies below the inferior frontal sulcus, and extends forward from the lower part of the precentral sulcus; it is continuous with the lateral and posterior orbital gyri on the under surface of the lobe. It is subdivided by the anterior horizontal and ascending rami of the lateral fissure into three parts, viz., (1) the **orbital part**, below the anterior horizontal ramus of the fissure; (2) the **triangular part** (*cap of Broca*), between the ascending and horizontal rami; and (3) the **basilar part**, behind the anterior ascending ramus. The left inferior frontal gyrus is, as a rule, more highly developed than the right, and is named the **gyrus of Broca**, from the fact that Broca described it as the centre for articulate speech.

The **inferior or orbital surface** of the frontal lobe is concave, and rests on the orbital plate of the frontal bone (Fig. 739). It is divided into four orbital gyri by a well-

Fig. 739.—Orbital surface of left frontal lobe.

marked H-shaped **orbital sulcus**. These are named, from their position, the **medial**, **anterior**, **lateral**, and **posterior orbital gyri**. The medial orbital gyrus presents a well-marked antero-posterior sulcus, the **olfactory sulcus**, for the olfactory tract; the portion medial to this is named the **straight gyrus**, and is continuous with the superior frontal gyrus on the medial surface.

The **medial surface** of the frontal lobe is occupied by the medial part of the superior frontal gyrus (*marginal gyrus*) (Fig. 738). It lies between the cingulate sulcus and the supero-medial margin of the hemisphere. The posterior part of this gyrus is sometimes marked off by a vertical sulcus, and is distinguished as the **paracentral lobule**, because it is continuous with the anterior and posterior central gyri.

Parietal Lobe (*lobus parietalis*).—The parietal lobe is separated from the frontal lobe by the central sulcus, but its boundaries below and behind are not so definite. Posteriorly, it is limited by the parietooccipital fissure, and by a line carried across the hemisphere from the end of this fissure toward the preoccipital notch. Below, it is separated from the temporal lobe by the posterior ramus of the lateral fissure, and by a line carried backward from it to meet the line passing downward to the preoccipital notch.

The **lateral surface** of the parietal lobe (Fig. 737) is cleft by a well-marked furrow, the **intraparietal sulcus** of Turner, which consists of an oblique and a horizontal portion. The oblique part is named the **postcentral sulcus**, and commences below, about midway between the lower end of the central sulcus and the upturned end of the lateral fissure. It runs upward and backward, parallel to the central sulcus, and is sometimes divided into an *upper* and a *lower* ramus. It forms the hinder limit of the posterior central gyrus.

From about the middle of the postcentral sulcus, or from the upper end of its inferior ramus, the **horizontal portion** of the intraparietal sulcus is carried backward and slightly upward on the parietal lobe, and is prolonged, under the name of the

occipital ramus, on to the occipital lobe, where it divides into two parts, which form nearly a right angle with the main stem and constitute the **transverse occipital sulcus**. The part of the parietal lobe above the horizontal portion of the intraparietal sulcus is named the **superior parietal lobule**; the part below, the **inferior parietal lobule**.

The **posterior central gyrus** (*gyrus centralis posterior; ascending parietal convolution; postcentral gyre*) extends from the longitudinal fissure above to the posterior ramus of the lateral fissure below. It lies parallel with the anterior central gyrus, with which it is connected below, and also, sometimes, above, the central sulcus.

The **superior parietal lobule** (*lobulus parietalis superior*) is bounded in front by the upper part of the postcentral sulcus, but is usually connected with the posterior central gyrus above the end of the sulcus; behind it is the lateral part of the parietooccipital fissure, around the end of which it is joined to the occipital lobe by a curved gyrus, the **arcus parietooccipitalis**; below, it is separated from the inferior parietal lobule by the horizontal portion of the intraparietal sulcus.

The **inferior parietal lobule** (*lobulus parietalis inferior; subparietal district or lobule*) lies below the horizontal portion of the intraparietal sulcus, and behind the lower part of the postcentral sulcus. It is divided from before backward into two gyri. One, the **supramarginal**, arches over the upturned end of the lateral fissure; it is continuous in front with the postcentral gyrus, and behind with the superior temporal gyrus. The second, the **angular**, arches over the posterior end of the superior temporal sulcus, behind which it is continuous with the middle temporal gyrus.

The **medial surface** of the parietal lobe (Fig. 738) is bounded behind by the medial part of the parietooccipital fissure; in front, by the posterior end of the cingulate sulcus; and below, it is separated from the cingulate gyrus by the **subparietal sulcus**. It is of small size, and consists of a square-shaped convolution, which is termed the **precuneus** or **quadrate lobe**.

Occipital Lobe (*lobus occipitalis*).—The occipital lobe is small and pyramidal in shape; it presents three surfaces: **lateral**, **medial**, and **tentorial**.

The **lateral surface** is limited in front by the lateral part of the parietooccipital fissure, and by a line carried from the end of this fissure to the preoccipital notch; it is traversed by the transverse occipital and the lateral occipital sulci. The **transverse occipital sulcus** is continuous with the posterior end of the occipital ramus of the intraparietal sulcus, and runs across the upper part of the lobe, a short distance behind the parietooccipital fissure. The **lateral occipital sulcus** extends from behind forward, and divides the lateral surface of the occipital lobe into a **superior** and an **inferior gyrus**, which are continuous in front with the parietal and temporal lobes.¹

The **medial surface** of the occipital lobe is bounded in front by the medial part of the parietooccipital fissure, and is traversed by the calcarine fissure, which subdivides it into the cuneus and the lingual gyrus. The cuneus is a wedge-shaped area between the calcarine fissure and the medial part of the parietooccipital fissure. The **lingual gyrus** lies between the calcarine fissure and the posterior part of the collateral fissure; behind, it reaches the occipital pole; in front, it is continued on to the tentorial surface of the temporal lobe, and joins the hippocampal gyrus.

The **tentorial surface** of the occipital lobe is limited in front by an imaginary transverse line through the preoccipital notch, and consists of the posterior part of the **fusiform gyrus** (*occipitotemporal convolution*) and the lower part of the lingual gyrus, which are separated from each other by the posterior segment of the collateral fissure.

Temporal Lobe (*lobus temporalis*).—The temporal lobe presents **superior**, **lateral**, and **inferior surfaces**.

¹ Elliot Smith has named the lateral occipital sulcus the *sulcus lunatus*; he regards it as the representative, in the human brain, of the "Affenspalte" of the brain of the ape.

The **superior surface** forms the lower limit of the lateral fissure and overlaps the insula. On opening out the lateral fissure, three or four gyri will be seen springing from the depth of the hinder end of the fissure, and running obliquely forward and outward on the posterior part of the upper surface of the superior temporal gyrus; these are named the **transverse temporal gyri** (Heschl) (Fig. 740).

The **lateral surface** (Fig. 737) is bounded above by the posterior ramus of the lateral fissure, and by the imaginary line continued backward from it; below, it is limited by the infero-lateral border of the hemisphere. It is divided into superior, middle, and inferior gyri by the superior and middle temporal sulci. The **superior temporal sulcus** runs from before backward across the temporal lobe, some little distance below, but parallel with, the posterior ramus of the lateral fissure; and hence it is often termed the **parallel sulcus**. The **middle temporal sulcus** takes the same direction as the superior, but is situated at a lower level, and is usually subdivided into two or more parts. The **superior temporal gyrus** lies between

FIG. 740.—Section of brain showing upper surface of temporal lobe.

the posterior ramus of the lateral fissure and the superior temporal sulcus, and is continuous behind with the supramarginal and angular gyri. The **middle temporal gyrus** is placed between the superior and middle temporal sulci, and is joined posteriorly with the angular gyrus. The **inferior temporal gyrus** is placed below the middle temporal sulcus, and is connected behind with the inferior occipital gyrus; it also extends around the infero-lateral border on to the inferior surface of the temporal lobe, where it is limited by the inferior sulcus.

The **inferior surface** is concave, and is continuous posteriorly with the tentorial surface of the occipital lobe. It is traversed by the **inferior temporal sulcus**, which extends from near the occipital pole behind, to within a short distance of the temporal pole in front, but is frequently subdivided by bridging gyri. Lateral to this fissure is the narrow tentorial part of the inferior temporal gyrus, and medial to it the **fusiform gyrus**, which extends from the occipital to the temporal pole; this gyrus is limited medially by the collateral fissure, which separates it from the lingual gyrus behind and from the hippocampal gyrus in front.

The **Insula** (*island of Reil; central lobe*) (Fig. 741) lies deeply in the lateral or Sylvian fissure, and can only be seen when the lips of that fissure are widely separated, since it is overlapped and hidden by the gyri which bound the fissure. These gyri are termed the **opercula of the insula**; they are separated from each other by the three rami of the lateral fissure, and are named the orbital, frontal, fronto-parietal, and temporal opercula. The **orbital operculum** lies below the anterior horizontal ramus of the fissure, the **frontal** between this and the anterior ascending ramus, the **parietal** between the anterior ascending ramus and the upturned end of the posterior ramus, and the **temporal** below the posterior ramus. The frontal operculum is of small size in those cases where the anterior horizontal and ascending rami of the lateral fissure arise from a common stem. The insula is surrounded by a deep **circular sulcus** which separates it from the frontal, parietal, and temporal lobes. When the opercula have been removed, the insula is seen as a triangular eminence, the apex of which is directed toward the anterior perforated substance. It is divided into a larger anterior and a smaller posterior part by a deep sulcus, which runs backward and upward from the apex of the insula. The anterior part is subdivided by shallow sulci into three or four **short gyri**, while the posterior part is formed by one **long gyrus**, which is often bifurcated at its upper end. The cortical gray substance of the insula is continuous with that of the different opercula, while its deep surface corresponds with the lentiform nucleus of the corpus striatum.

FIG. 741.--The insula of the left side, exposed by removing the opercula.

Limbic Lobe (Fig. 738).—The term limbic lobe was introduced by Broca, and under it he included the cingulate and hippocampal gyri, which together arch around the corpus callosum and the hippocampal fissure. These he separated on the morphological ground that they are well-developed in animals possessing a keen sense of smell (osmatic animals), such as the dog and fox. They were thus regarded as a part of the rhinencephalon, but it is now recognized that they belong to the neopallium; the cingulate gyrus is therefore sometimes described as a part of the frontal lobe, and the hippocampal as a part of the temporal lobe.

The **cingulate gyrus** (*gyrus cinguli; callosal convolution*) is an arch-shaped convolution, lying in close relation to the superficial surface of the corpus callosum, from which it is separated by a slit-like fissure, the **callosal fissure**. It commences below the rostrum of the corpus callosum, curves around in front of the genu, extends along the upper surface of the body, and finally turns downward behind the splenium, where it is connected by a narrow **isthmus** with the hippocampal

gyrus. It is separated from the medial part of the superior frontal gyrus by the cingulate sulcus, and from the precuneus by the subparietal sulcus.

The **hippocampal gyrus** (*gyrus hippocampi*) is bounded above by the hippocampal fissure, and below by the anterior part of the collateral fissure. Behind, it is continuous superiorly, through the isthmus, with the cingulate gyrus and inferiorly with the lingual gyrus. Running in the substance of the cingulate and hippocampal gyri, and connecting them together, is a tract of arched fibres, named the **cingulum** (page 890). The anterior extremity of the hippocampal gyrus is recurved in the form of a hook (**uncus**), which is separated from the apex of the temporal lobe by a slight fissure, the **incisura temporalis**. Although superficially continuous with the hippocampal gyrus, the uncus forms morphologically a part of the rhinencephalon.

The **Hippocampal Fissure** (*fissura hippocampi*; *dentate fissure*) begins immediately behind the splenium of the corpus callosum, and runs forward between the hippocampal and dentate gyri to end in the uncus. It is a complete fissure (page 867), and gives rise to the prominence of the hippocampus in the inferior cornu of the lateral ventricle.

FIG. 742.—Scheme of rhinencephalon.

Rhinencephalon (Fig. 742).—The rhinencephalon comprises the **olfactory lobe**, the **uncus**, the **subcallosal** and **supracallosal gyri**, the **fascia dentata hippocampi**, the **septum pellucidum**, the **fornix**, and the **hippocampus**.

1. The **Olfactory Lobe** (*lobus olfactorius*) is situated under the inferior or orbital surface of the frontal lobe. In many vertebrates it constitutes a well-marked portion of the hemisphere and contains an extension of the lateral ventricle; but in man and some other mammals it is rudimentary. It consists of the **olfactory bulb** and **tract**, the **olfactory trigone**, the **parolfactory area of Broca**, and the **anterior perforated substance**.

(a) The **olfactory bulb** (*bulbus olfactorius*) is an oval, reddish-gray mass which rests on the cribriform plate of the ethmoid and forms the anterior expanded extremity of the olfactory tract. Its under surface receives the olfactory nerves, which pass upward through the cribriform plate from the olfactory region of the nasal cavity. Its minute structure is described on page 893.

(b) The **olfactory tract** (*tractus olfactorius*) is a narrow white band, triangular on coronal section, the apex being directed upward. It lies in the olfactory sulcus on the inferior surface of the frontal lobe, and divides posteriorly into two striae, a medial and a lateral. The **lateral stria** is directed across the lateral part of the

anterior perforated substance and then bends abruptly medialward toward the uncus of the hippocampal gyrus. The **medial stria** turns medialward behind the parolfactory area and ends in the subcallosal gyrus; in some cases a small **intermediate stria** is seen running backward to the anterior perforated substance.

(c) The **olfactory trigone** (*trigonum olfactorium*) is a small triangular area in front of the anterior perforated substance. Its apex, directed forward, occupies the posterior part of the olfactory sulcus, and is brought into view by throwing back the olfactory tract.

(d) The **parolfactory area of Broca** (*area parolfactoria*) is a small triangular field on the medial surface of the hemisphere in front of the subcallosal gyrus, from which it is separated by the posterior parolfactory sulcus; it is continuous below with the olfactory trigone, and above and in front with the cingulate gyrus; it is limited anteriorly by the anterior parolfactory sulcus.

(e) The **anterior perforated substance** (*substantia perforata anterior*) is an irregularly quadrilateral area in front of the optic tract and behind the olfactory trigone, from which it is separated by the **fissure prima**; medially and in front it is continuous with the subcallosal gyrus; laterally it is bounded by the lateral stria of the olfactory tract and is continued into the uncus. Its gray substance is confluent above with that of the corpus striatum, and is perforated anteriorly by numerous small bloodvessels.

2. The **Uncus** has already been described (page 874) as the recurved, hook-like portion of the hippocampal gyrus.

3. The **Subcallosal, Supracallosal, and Dentate Gyri** form a rudimentary arch-shaped lamina of gray substance extending over the corpus callosum and above the hippocampal gyrus from the anterior perforated substance to the uncus.

(a) The **subcallosal gyrus** (*gyrus subcallosus*; *peduncle of the corpus callosum*) is a narrow lamina on the medial surface of the hemisphere in front of the lamina terminalis, behind the parolfactory area, and below the rostrum of the corpus callosum. It is continuous around the genu of the corpus callosum with the supracallosal gyrus.

(b) The **supracallosal gyrus** (*indusium griseum*; *gyrus epicallosus*) consists of a thin layer of gray substance in contact with the upper surface of the corpus callosum and continuous laterally with the gray substance of the cingulate gyrus. It contains two longitudinally directed strands of fibres termed respectively the **medial** and **lateral longitudinal striæ**. The supracallosal gyrus is prolonged around the splenium of the corpus callosum as a delicate lamina, the **fasciola cinerea**, which is continuous below with the fascia dentata hippocampi.

(c) The **fascia dentata hippocampi** (*gyrus dentatus*) is a narrow band extending downward and forward above the hippocampal gyrus but separated from it by the hippocampal fissure; its free margin is notched and overlapped by the fimbria—the **fimbriodentate fissure** intervening. Anteriorly it is continued into the notch of the uncus, where it forms a sharp bend and is then prolonged as a delicate band, the **band of Giacomini**, over the incus, on the lateral surface of which it is lost.

The remaining parts of the rhinencephalon, viz., the septum pellucidum, fornix, and hippocampus, will be described in connection with the lateral ventricle.

Interior of the Cerebral Hemispheres.—If the upper part of either hemisphere be removed, at a level about 1.25 cm. above the corpus callosum, the central white substance will be exposed as an oval-shaped area, the **centrum ovale minus**, surrounded by a narrow convoluted margin of gray substance, and studded with numerous minute red dots (**puncta vasculosa**), produced by the escape of blood from divided bloodvessels. If the remaining portions of the hemispheres be slightly drawn apart a broad band of white substance, the **corpus callosum**, will be observed, connecting them at the bottom of the longitudinal fissure; the margins of the hemispheres which overlap the corpus callosum are called the **labia cerebri**. Each labium is

part of the cingulate gyrus already described; and the slit-like interval between it and the upper surface of the corpus callosum is termed the **callosal fissure** (Fig. 738). If the hemispheres be sliced off to a level with the upper surface of the corpus callosum, the white substance of that structure will be seen connecting the two hemispheres. The large expanse of medullary matter now exposed, surrounded by the convoluted margin of gray substance, is called the **centrum ovale majus**.

The **Corpus Callosum** (Fig. 743) is the great transverse commissure which unites the cerebral hemispheres and roofs in the lateral ventricles. A good conception of its position and size is obtained by examining a median sagittal section of the brain (Fig. 730), when it is seen to form an arched structure about 10 cm. long. Its anterior end is about 4 cm. from the frontal pole, and its posterior end about 6 cm. from the occipital pole of the hemisphere.

FIG. 743.—Corpus callosum from above.

The **anterior end** is named the **genu**, and is bent downward and backward in front of the septum pellucidum; diminishing rapidly in thickness, it is prolonged backward under the name of the **rostrum**, which is connected below with the lamina terminalis. The anterior cerebral arteries are in contact with the under surface of the rostrum; they then arch over the front of the genu, and are carried backward above the body of the corpus callosum.

The **posterior end** is termed the **splenium** and constitutes the thickest part of the corpus callosum. It overlaps the tela chorioidea of the third ventricle and the mesencephalon, and ends in a thick, convex, free border. A sagittal section of

the splenium shows that the posterior end of the corpus callosum is acutely bent forward, the upper and lower parts being applied to each other.

The **superior surface** is convex from before backward, and is about 2.5 cm. wide. Its medial part forms the bottom of the longitudinal fissure, and is in contact posteriorly with the lower border of the falx cerebri. Laterally it is overlapped by the cingulate gyrus, but is separated from it by the slit-like callosal fissure. It is traversed by numerous transverse ridges and furrows, and is covered by a thin layer of gray matter, the **supracallosal gyrus**, which exhibits on either side of the middle line the medial and lateral longitudinal striæ, already described (page 875).

The **inferior surface** is concave, and forms on either side of the middle line the roof of the lateral ventricle. Medially, this surface is attached in front to the septum pellucidum; behind this it is fused with the upper surface of the body of the fornix, while the splenium is in contact with the tela chorioidea.

On either side, the fibres of the corpus callosum radiate in the white substance and pass to the various parts of the cerebral cortex; those curving forward from the genu into the frontal lobe constitute the **forceps anterior**, and those curving backward into the occipital lobe, the **forceps posterior**. Between these two parts is the main body of the fibres which constitute the **tapetum** and extend laterally on either side into the temporal lobe, and cover in the central part of the lateral ventricle.

FIG. 744.—Scheme showing relations of the ventricles to the surface of the brain.

The Lateral Ventricles (*ventriculus lateralis*) (Fig. 744).—The two lateral ventricles are irregular cavities situated in the lower and medial parts of the cerebral hemispheres, one on either side of the middle line. They are separated from each other by a median vertical partition, the **septum pellucidum**, but communicate with the third ventricle and indirectly with each other through the **interventricular foramen**. They are lined by a thin, diaphanous membrane, the **ependyma**, covered by ciliated epithelium, and contain cerebrospinal fluid, which, even in health, may be secreted in considerable amount. Each lateral ventricle consists of a **central part** or **body**, and three prolongations from it, termed **cornua** (Figs. 745, 746).

The **central part** (*pars centralis ventriculi lateralis; cella*) (Fig. 747) of the lateral ventricle extends from the interventricular foramen to the splenium of the corpus

callosum. It is an irregularly curved cavity, triangular on transverse section, with a roof, a floor, and a medial wall. The roof is formed by the under surface of the corpus callosum; the floor by the following parts, enumerated in their order of position, from before backward: the caudate nucleus of the corpus striatum, the

cle

suprapineal recess

FIG. 745.—Drawing of a cast of the ventricular cavities, viewed from above. (Retzius.)

stria terminalis and the terminal vein, the lateral portion of the upper surface of the thalamus, the choroid plexus, and the lateral part of the fornix; the medial wall is the posterior part of the septum pellucidum, which separates it from the opposite ventricle.

Intersure

Su₁

ess

Ce

FIG. 746.—Drawing of a cast of the ventricular cavities, viewed from the side. (Retzius.)

The **anterior cornu** (*cornu anterius*; *anterior horn*; *precornu*) (Fig. 746) passes forward and lateralward, with a slight inclination downward, from the interventricular foramen into the frontal lobe, curving around the anterior end of the caudate nucleus. Its floor is formed by the upper surface of the reflected portion of the

corpus callosum, the **rostrum**. It is bounded medially by the anterior portion of the septum pellucidum, and laterally by the head of the caudate nucleus. Its apex reaches the posterior surface of the genu of the corpus callosum.

The **posterior cornu** (*cornu posterius; postcornu*) (Figs. 747, 748) passes into the occipital lobe, its direction being backward and lateralward, and then medialward. Its roof is formed by the fibres of the corpus callosum passing to the temporal and occipital lobes. On its medial wall is a longitudinal eminence, the **calcar avis** (*hippocampus minor*), which is an involution of the ventricular wall produced by the calcarine fissure. Above this the forceps posterior of the corpus callosum, sweeping around to enter the occipital lobe, causes another projection, termed the **bulb of the posterior cornu**. The calcar avis and bulb of the posterior cornu are extremely variable in their degree of development; in some cases they are ill-defined, in others prominent.

FIG. 747.—Central part and anterior and posterior cornua of lateral ventricles exposed from above.

The **inferior cornu** (*cornu inferior; descending horn; middle horn; medicornu*) (Fig. 749), the largest of the three, traverses the temporal lobe of the brain, forming in its course a curve around the posterior end of the thalamus. It passes at first backward, lateralward, and downward, and then curves forward to within 2.5 cm. of the apex of the temporal lobe, its direction being fairly well indicated on the surface of the brain by that of the superior temporal sulcus. Its roof is formed chiefly by the inferior surface of the tapetum of the corpus callosum, but the tail of the caudate nucleus and the stria terminalis also extend forward in the roof of the inferior cornu to its extremity, where they end in a mass of gray substance,

the **nucleus amygdalae**. Its floor presents the following parts: the hippocampus, the fimbria hippocampi, the collateral eminence, and the choroid plexus. When the

choroid plexus is removed, a cleft-like opening is left along the medial wall of the inferior cornu; this cleft constitutes the lower part of the choroidal fissure.

Choroid plexus

Hippocampus

FIG. 749.—Posterior and inferior cornua of left lateral ventricle exposed from the side.

The **hippocampus** (*hippocampus major*) (Figs. 749, 750) is a curved eminence, about 5 cm. long, which extends throughout the entire length of the floor of the

inferior cornu. Its lower end is enlarged, and presents two or three rounded elevations or digitations which give it a paw-like appearance, and hence it is named the *pes hippocampi*. If a transverse section be made through the hippocampus, it will be seen that this eminence is produced by the folding of the wall of the hemisphere to form the hippocampal fissure. The main mass of the hippocampus consists of gray substance, but on its ventricular surface is a thin white layer, the *alveus*, which is continuous with the fimbria hippocampi.

The *collateral eminence* (*eminencia collateralis*) (Fig. 750) is an elongated swelling lying lateral to and parallel with the hippocampus. It corresponds with the middle part of the collateral fissure, and its size depends on the depth and direction of this fissure. It is continuous behind with a flattened triangular area, the *trigonum collaterale*, situated between the posterior and inferior cornua.

The fimbria hippocampi is a continuation of the crus of the fornix, and will be discussed with that body; a description of the choroid plexus will be found on page 887.

The *corpus striatum* has received its name from the striped appearance which a section of its anterior part presents, in consequence of diverging white fibres being mixed with the gray substance which forms its chief mass. A part of the corpus striatum is imbedded in the white substance of the hemisphere, and is therefore external to the ventricle; it is termed the *extraventricular portion*, or the *lentiform nucleus*; the remainder, however, projects into the ventricle, and is named the *intraventricular portion*, or the *caudate nucleus* (Fig. 747).

The *caudate nucleus* (*nucleus caudatus; caudatum*) (Fig. 751) is a pear-shaped, highly arched gray mass; its broad extremity, or head, is directed forward into the anterior cornu of the lateral ventricle, and is continuous with the anterior perforated substance and with the anterior end of the lentiform nucleus; its narrow end, or tail, is directed backward on the lateral side of the thalamus, from which it is separated by the stria terminalis and the terminal vein. It is then continued downward into the roof of the inferior cornu, and ends in the *nucleus amygdalæ*, at the apex of the temporal lobe. It is covered by the lining of the ventricle, and crossed by some veins of considerable size. It is separated from the lentiform nucleus, in the greater part of its extent, by a thick lamina of white substance, called the *internal capsule*, but the two portions of the corpus striatum are united in front (Figs. 752, 753).

FIG. 750.—Inferior and posterior cornua, viewed from above.

The *lentiform nucleus* (*nucleus lentiformis; lenticular nucleus; lenticula*) is lateral to the caudate nucleus and thalamus, and is seen only in sections of the hemisphere. When divided horizontally, it exhibits, to some extent, the appearance of a biconvex lens (Fig. 751), while a coronal section of its central part presents a somewhat triangular outline. It is shorter than the caudate nucleus and does not extend as far forward. It is bounded laterally by a lamina of white substance called the *external capsule*, and lateral to this is a thin layer of gray substance termed the *claustrum*. Its anterior end is continuous with the lower part of the head of the caudate nucleus and with the anterior perforated substance.

In a coronal section through the middle of the lentiform nucleus, two *medullary laminae* are seen dividing it into three parts. The lateral and largest part is of a

reddish color, and is known as the **putamen**, while the medial and intermediate are of a yellowish tint, and together constitute the **globus pallidus**; all three are marked by fine radiating white fibres, which are most distinct in the putamen (Fig. 753).

The gray substance of the corpus striatum is traversed by nerve fibres, some of which originate in it. The cells are multipolar, both large and small; those of the lentiform nucleus contain yellow pigment. The caudate and lentiform nuclei are not only directly continuous with each other anteriorly, but are connected to each other by numerous fibres. The corpus striatum is also connected: (1) to the

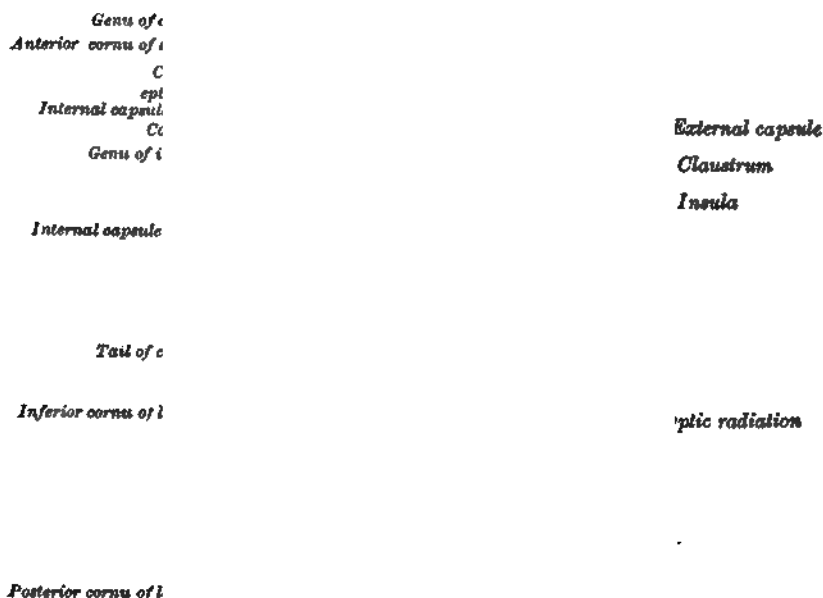

FIG. 751.—Horizontal section of right cerebral hemisphere.

cerebral cortex, by what are termed the **corticostriate fibres**; (2) to the thalamus, by fibres which pass through the internal capsule, and by a strand named the **ansa lentiformis**; (3) to the cerebral peduncle, by fibres which leave the lower aspect of the caudate and lentiform nuclei.

The **claustrum** (Figs. 751, 753) is a thin layer of gray substance, situated on the lateral surface of the external capsule. Its transverse section is triangular, with the apex directed upward. Its medial surface, contiguous to the external capsule, is smooth, but its lateral surface presents ridges and furrows corresponding with the gyri and sulci of the insula, with which it is in close relationship. The claustrum is regarded as a detached portion of the gray substance of the insula, from which

it is separated by a layer of white fibres, the **capsula extrema** (*band of Baillarger*). Its cells are small and spindle-shaped, and contain yellow pigment; they are similar to those of the deepest layer of the cortex.

The **nucleus amygdalæ** (*amygdala*) is an ovoid gray mass, situated at the lower end of the roof of the inferior cornu. It is merely a localized thickening of the gray cortex, continuous with that of the uncus; in front it is continuous with the putamen, behind with the stria terminalis and the tail of the caudate nucleus.

Inferior frontal gyrus

FIG. 752.—Coronal section through anterior cornua of lateral ventricles.

The **internal capsule** (*capsula interna*) (Fig. 754) is a flattened band of white fibres, between the lentiform nucleus on the lateral side and the caudate nucleus and thalamus on the medial side. In horizontal section (Figs. 751) it is seen to be somewhat abruptly curved, with its convexity inward; the prominence of the curve is called the **genu**, and projects between the caudate nucleus and the thalamus. The portion in front of the genu is termed the **frontal part**, and separates the lentiform from the caudate nucleus; the portion behind the genu is the **occipital part**, and separates the lentiform nucleus from the thalamus.

The **frontal part** of the internal capsule contains: (1) fibres running from the thalamus to the frontal lobe; (2) fibres connecting the lentiform and caudate nuclei; (3) fibres connecting the cortex with the corpus striatum; and (4) fibres passing from the frontal lobe through the medial fifth of the base of the cerebral peduncle to the nuclei pontis. The fibres in the region of the genu are named the **geniculate fibres**; they originate in the motor part of the cerebral cortex, and, after passing downward through the base of the cerebral peduncle with the cerebro-

spinal fibres, undergo decussation and end in the motor nuclei of the cerebral nerves of the opposite side. The anterior two-thirds of the occipital part of the internal capsule contains the **cerebrospinal fibres**, which arise in the motor area of the cerebral cortex and, passing downward through the middle three-fifths of the base of the cerebral peduncle, are continued into the pyramids of the medulla oblongata. The posterior third of the occipital part contains: (1) sensory fibres, largely derived from the thalamus, though some may be continued upward from the medial lemniscus; (2) the fibres of optic radiation, from the lower visual centres to the cortex of the occipital lobe; (3) acoustic fibres, from the lateral lemniscus to the temporal lobe; and (4) fibres which pass from the occipital and temporal lobes to the nuclei pontis.

FIG. 753. —Coronal section of brain through anterior commissure.

The fibres of the internal capsule radiate widely as they pass to and from the various parts of the cerebral cortex, forming the **corona radiata** (Fig. 754) and intermingling with the fibres of the corpus callosum.

The **external capsule** (*capsula externa*) (Fig. 751) is a lamina of white substance, situated lateral to the lentiform nucleus, between it and the claustrum, and continuous with the internal capsule below and behind the lentiform nucleus. It probably contains fibres derived from the thalamus, the anterior commissure, and the subthalamic region.

The **substantia innominata of Meynert** is a stratum consisting partly of gray and partly of white substance, which lies below the anterior part of the thalamus and lentiform nucleus. It consists of three layers, superior, middle, and inferior. The *superior* layer is named the **ansa lentiformis**, and its fibres, derived from the medullary lamina of the lentiform nucleus, pass medially to end in the thalamus

and subthalamie region, while others are said to end in the tegmentum and red nucleus. The *middle* layer consists of nerve cells and nerve fibres; fibres enter it from the parietal lobe through the external capsule, while others are said to connect it with the medial longitudinal fasciculus. The *inferior* layer forms the main part of the inferior stalk of the thalamus, and connects this body with the temporal lobe and the insula.

The *stria terminalis* (*taenia semicircularis*) is a narrow band of white substance situated in the depression between the caudate nucleus and the thalamus. Anteriorly, its fibres are partly continued into the column of the fornix; some, however, pass over the anterior commissure to the gray substance between the caudate nucleus and septum pellucidum, while others are said to enter the caudate nucleus. Posteriorly, it is continued into the roof of the inferior cornu of the lateral ventricle, at the extremity of which it enters the nucleus amygdalæ. Superficial to it is a

Use

FIG. 754.—Dissection showing the course of the cerebrospinal fibres. (E. B. Jamieson.)

large vein, the *terminal vein* (*vein of the corpus striatum*), which receives numerous tributaries from the corpus striatum and thalamus; it runs forward to the interventricular foramen and there joins with the vein of the choroid plexus to form the corresponding internal cerebral vein. On the surface of the terminal vein is a narrow white band, named the *lamina affixa*.

The *Fornix* (Figs. 730, 755) is a longitudinal, arch-shaped lamella of white substance, situated below the corpus callosum, and continuous with it behind, but separated from it in front by the septum pellucidum. It may be described as consisting of two symmetrical bands, one for either hemisphere. The two portions are not united to each other in front and behind, but their central parts are joined together in the middle line. The anterior parts are called the *columns of the fornix*; the intermediate united portions, the *body*; and the posterior parts, the *crura*.

The **body** (*corpus fornicis*) of the fornix is triangular, narrow in front, and broad behind. The medial part of its upper surface is connected to the septum pellucidum in front and to the corpus callosum behind. The lateral portion of this surface forms part of the floor of the lateral ventricle, and is covered by the ventricular epithelium. Its lateral edge overlaps the choroid plexus, and is continuous with the epithelial covering of this structure. The under surface rests upon the tela chorioidea of the third ventricle, which separates it from the epithelial roof of that cavity, and from the medial portions of the upper surfaces of the thalami. Below, the lateral portions of the body of the fornix are joined by a thin triangular lamina, named the **psalterium** (*lyra*). This lamina contains some transverse fibres which connect the two hippocampi across the middle line and constitute the **hippocampal commissure**. Between the psalterium and the corpus callosum a horizontal cleft, the so-called **ventricle of the fornix** (*ventricle of Verga*), is sometimes found.

FIG. 755.—The fornix and corpus callosum from below. (From a specimen in the Department of Human Anatomy of the University of Oxford.)

The **columns** (*columna fornicis*; *anterior pillars*; *fornicolumns*) of the fornix arch downward in front of the interventricular foramen and behind the anterior commissure, and each descends through the gray substance in the lateral wall of the third ventricle to the base of the brain, where it ends in the corpus mamillare. From the cells of the corpus mamillare the **thalamomamillary fasciculus** (*bundle of Vieq d' Azyr*) takes origin and is prolonged into the anterior nucleus of the thalamus. The column of the fornix and the thalamomamillary fasciculus together form a loop resembling the figure 8, but the continuity of the loop is broken in the corpus

mamillare. The column of the fornix is joined by the stria medullaris of the pineal body and by the superficial fibres of the stria terminalis, and is said to receive also fibres from the septum pellucidum. Zuckerkandl describes an **olfactory fasciculus** which becomes detached from the main portion of the column of the fornix, and passes downward in front of the anterior commissure to the base of the brain, where it divides into two bundles, one joining the medial stria of the olfactory tract; the other joins the subcallosal gyrus, and through it reaches the hippocampal gyrus.

The **crura** (*crus fornicis; posterior pillars*) of the fornix are prolonged backward from the body. They are flattened bands, and at their commencement are intimately connected with the under surface of the corpus callosum. Diverging from one another, each curves around the posterior end of the thalamus, and passes downward and forward into the inferior cornu of the lateral ventricle (Fig. 757). Here it lies along the concavity of the hippocampus, on the surface of which some of its fibres are spread out to form the **alveus**, while the remainder are continued as a narrow white band, the **fimbria hippocampi**, which is prolonged into the uncus of the hippocampal gyrus. The inner edge of the fimbria overlaps the **fascia dentata hippocampi** (*dentate gyrus*) (page 875), from which it is separated by the **fimbriodentate fissure**; from its lateral margin, which is thin and ragged, the ventricular epithelium is reflected over the choroid plexus as the latter projects into the chorioidal fissure.

Interventricular Foramen (*foramen of Monro*).—Between the columns of the fornix and the anterior ends of the thalami, an oval aperture is present on either side: this is the interventricular foramen, and through it the lateral ventricles communicate with the third ventricle. Behind the epithelial lining of the foramen the choroid plexuses of the lateral ventricles are joined across the middle line.

The **Anterior Commissure** (*precommissure*) is a bundle of white fibres, connecting the two cerebral hemispheres across the middle line, and placed in front of the columns of the fornix. On sagittal section it is oval in shape, its long diameter being vertical and measuring about 5 mm. Its fibres can be traced lateralward and backward on either side beneath the corpus striatum into the substance of the temporal lobe. It serves in this way to connect the two temporal lobes, but it also contains decussating fibres from the olfactory tracts.

The **Septum Pellucidum** (*septum lucidum*) (Fig. 730) is a thin, vertically placed partition consisting of two laminae, separated in the greater part of their extent by a narrow chink or interval, the **cavity of the septum pellucidum**. It is attached, above, to the under surface of the corpus callosum; below, to the anterior part of the fornix behind, and the reflected portion of the corpus callosum in front. It is triangular in form, broad in front and narrow behind; its inferior angle corresponds with the upper part of the anterior commissure. The lateral surface of each lamina is directed toward the body and anterior cornu of the lateral ventricle, and is covered by the ependyma of that cavity.

The **cavity of the septum pellucidum** (*cavum septi pellucidi; pseudocoele; fifth ventricle*) is generally regarded as part of the longitudinal cerebral fissure, which has become shut off by the union of the hemispheres in the formation of the corpus callosum above and the fornix below. Each half of the septum therefore forms part of the medial wall of the hemisphere, and consists of a medial layer of gray substance, derived from that of the cortex, and a lateral layer of white substance continuous with that of the cerebral hemispheres. This cavity is not developed from the cavity of the cerebral vesicles, and never communicates with the ventricles of the brain.

The **Choroid Plexus of the Lateral Ventricle** (*plexus chorioideus ventriculus lateralis; paraplexus*) (Fig. 757) is a highly vascular, fringe-like process of pia mater, which projects into the ventricular cavity. The plexus, however, is everywhere

covered by a layer of epithelium continuous with the epithelial lining of the ventricle. It extends from the interventricular foramen, where it is joined with the plexus of the opposite ventricle, to the end of the inferior cornu. The part in relation to the body of the ventricle forms the vascular fringed margin of a triangular process of pia mater, named the *tela chorioidea of the third ventricle*, and projects from under cover of the lateral edge of the fornix. It lies upon the upper surface of the thalamus, from which the epithelium is reflected over the plexus on to the edge of the fornix (Fig. 734). The portion in relation to the inferior cornu lies in the concavity of the hippocampus and overlaps the fimbria hippocampi: from the lateral edge of the fimbria the epithelium is reflected over the plexus on to the roof of the cornu (Fig. 756). It consists of minute and highly vascular villous processes, each with an afferent and an efferent vessel. The *arteries* of the plexus are: (*a*) the anterior choroidal, a branch of the internal carotid, which enters the plexus at the end of the inferior cornu; and (*b*) the posterior choroidal, one or two small branches of the posterior cerebral, which pass forward under the splenium. The *veins* of the choroid plexus unite to form a tortuous vein, which courses from behind forward to the interventricular foramen and there joins with the terminal vein to form the corresponding internal cerebral vein.

FIG. 756.—Coronal section of inferior horn of lateral ventricle. (Diagrammatic.)

When the choroid plexus is pulled away, the continuity between its epithelial covering and the epithelial lining of the ventricle is severed, and a cleft-like space is produced. This is named the *choroidal fissure*; like the plexus, it extends from the interventricular foramen to the end of the inferior cornu. The upper part of the fissure, *i. e.*, the part nearest the interventricular foramen is situated between the lateral edge of the fornix and the upper surface of the thalamus; farther back at the beginning of the inferior cornu it is between the commencement of the fimbria hippocampi and the posterior end of the thalamus, while in the inferior cornu it lies between the fimbria in the floor and the stria terminalis in the roof of the cornu.

The *tela chorioidea of the third ventricle* (*tela chorioidea ventriculi tertii; velum interpositum*) (Fig. 757) is a double fold of pia mater, triangular in shape, which lies beneath the fornix. The lateral portions of its lower surface rest upon the thalami, while its medial portion is in contact with the epithelial roof of the third ventricle. Its apex is situated at the interventricular foramen; its base corresponds with the splenium of the corpus callosum, and occupies the interval between that structure above and the corpora quadrigemina and pineal body below. This

interval, together with the lower portions of the choroidal fissures, is sometimes spoken of as the **transverse fissure of the brain**. At its base the two layers of the velum separate from each other, and are continuous with the pia mater investing the brain in this region. Its lateral margins are modified to form the highly vascular choroid plexuses of the lateral ventricles. It is supplied by the anterior and posterior choroidal arteries already described. The veins of the tela chorioidea are named the **internal cerebral veins** (*venae Galeni*); they are two in number, and run backward between its layers, each being formed at the interventricular foramen by the union of the terminal vein with the choroidal vein. The internal cerebral veins unite posteriorly in a single trunk, the **great cerebral vein** (*vena magna Galeni*), which passes backward beneath the splenium and ends in the straight sinus.

FIG. 757.—Tela chorioidea of the third ventricle, and the choroid plexus of the left lateral ventricle, exposed from above.

Structure of the Cerebral Hemispheres.—The cerebral hemispheres are composed of gray and white substance: the former covers their surface, and is termed the **cortex**; the latter occupies the interior of the hemispheres.

The **white substance** consists of medullated fibres, varying in size, and arranged in bundles separated by neuroglia. They may be divided, according to their course and connections, into three distinct systems. (1) **Projection fibres** connect the hemisphere with the lower parts of the brain and with the medulla spinalis. (2) **Transverse or commissural fibres** unite the two hemispheres. (3) **Association fibres** connect different structures in the same hemisphere; these are, in many

instances, collateral branches of the projection fibres, but others are the axons of independent cells.

1. The **projection fibres** consist of efferent and afferent fibres uniting the cortex with the lower parts of the brain and with the medulla spinalis. The principal efferent strands are: (1) the *motor tract*, occupying the genu and anterior two-thirds of the occipital part of the internal capsule, and consisting of (a) the geniculate fibres, which decussate and end in the motor nuclei of the cerebral nerves of the opposite side; and (b) the cerebrosplinal fibres, which are prolonged through the pyramid of the medulla oblongata into the medulla spinalis: (2) the *corticopontine fibres*, ending in the nuclei pontis. The chief afferent fibres are: (1) those of the lemniscus which are not interrupted in the thalamus; (2) those of the brachia conjunctiva cerebelli which are not interrupted in the red nucleus and thalamus; (3) numerous fibres arising within the thalamus, and passing through its stalks to the different parts of the cortex (page 857); (4) optic and acoustic fibres, the former passing to the occipital, the latter to the temporal lobe.

2. The **transverse or commissural fibres** connect the two hemispheres. They include: (a) the *transverse fibres* of the corpus callosum, (b) the anterior commissure, (c) the posterior commissure, and (d) the lyra or hippocampal commissure; they have already been described.

FIG. 758.—Diagram showing principal systems of association fibres in the cerebrum.

3. The **association fibres** (Fig. 758) unite different parts of the same hemisphere, and are of two kinds: (1) those connecting adjacent gyri, **short association fibres**; (2) those passing between more distant parts, **long association fibres**.

The *short association fibres* lie immediately beneath the gray substance of the cortex of the hemispheres, and connect together adjacent gyri.

The *long association fibres* include the following: (a) the uncinat fasciculus; (b) the cingulum; (c) the superior longitudinal fasciculus; (d) the inferior longitudinal fasciculus; (e) the perpendicular fasciculus; (f) the occipitofrontal fasciculus; and (g) the fornix.

(a) The *uncinate fasciculus* passes across the bottom of the lateral fissure, and unites the gyri of the frontal lobe with the anterior end of the temporal lobe.

(b) The *cingulum* is a band of white matter contained within the cingulate gyrus. Beginning in front at the anterior perforated substance, it passes forward and upward parallel with the rostrum, winds around the genu, runs backward above the corpus callosum, turns around the splenium, and ends in the hippocampal gyrus.

(c) The *superior longitudinal fasciculus* passes backward from the frontal lobe above the lentiform nucleus and insula; some of its fibres end in the occipital lobe, and others curve downward and forward into the temporal lobe.

(d) The *inferior longitudinal fasciculus* connects the temporal and occipital lobes, running along the lateral walls of the inferior and posterior cornua of the lateral ventricle.

(e) The *perpendicular fasciculus* runs vertically through the front part of the occipital lobe, and connects the inferior parietal lobule with the fusiform gyrus.

(f) The *occipitofrontal fasciculus* passes backward from the frontal lobe, along the lateral border of the caudate nucleus, and on the mesial aspect of the corona radiata; its fibres radiate in a fan-like manner and pass into the occipital and temporal lobes lateral to the posterior and inferior cornua. Déjerine regards the fibres of the tapetum as being derived from this fasciculus, and not from the corpus callosum.

(g) The *fornix* connects the hippocampal gyrus with the corpus mamillare and, by means of the thalamomamillary fasciculus, with the thalamus (see page 886). Through the fibres of the hippocampal commissure it probably also unites the opposite hippocampal gyri.

The **gray substance of the hemisphere** is divided into: (1) that of the cerebral cortex, and (2) that of the caudate nucleus, the lentiform nucleus, the claustrum, and the nucleus amygdalæ.

Structure of the Cerebral Cortex (Fig. 759).—The cerebral cortex differs in thickness and structure in different parts of the hemisphere. It is thinner in the occipital region than in the anterior and posterior central gyri, and it is also much thinner at the bottom of the sulci than on the top of the gyri. Again, the minute structure of the anterior central differs from that of the posterior central gyrus, and areas possessing a specialized type of cortex can be mapped out in the occipital lobe.

On examining a section of the cortex with a lens, it is seen to consist of alternating white and gray layers thus disposed from the surface inward: (1) a thin layer of white substance; (2) a layer of gray substance; (3) a second white layer (*outer band of Baillarger* or *band of Gennari*); (4) a second gray layer; (5) a third white layer (*inner band of Baillarger*); (6) a third gray layer, which rests on the medullary substance of the gyrus.

The cortex is made up of nerve cells of varying size and shape, and of nerve fibres which are either medullated or naked axis-cylinders, imbedded in a matrix of neuroglia.

Nerve Cells.—According to Cajal, the nerve cells are arranged in four layers, named from the surface inward as follows: (1) the molecular layer, (2) the layer of small pyramidal cells, (3) the layer of large pyramidal cells, (4) the layer of polymorphous cells.

The Molecular Layer.—In this layer the cells are polygonal, triangular, or fusiform in shape. Each polygonal cell gives off some four or five dendrites, while its axon may arise directly from the cell or from one of its dendrites. Each triangular cell gives off two or three dendrites, from one of which the axon arises. The fusiform cells are placed with their long axes parallel to the surface and are mostly bipolar, each pole being prolonged into a dendrite, which runs horizontally for some distance and furnishes ascending branches. Their axons, two or three in number, arise from the dendrites, and, like them, take a horizontal course, giving off numerous ascending collaterals. The distribution of the axons and dendrites of all three sets of cells is limited to the molecular layer.

The Layer of Small and the Layer of Large Pyramidal Cells.—The cells in these two layers may be studied together, since, with the exception of the difference in size and the more superficial position of the smaller cells, they resemble each other. The average length of the small cells is from 10 to 15 μ ; that of the large cells from 20 to 30 μ . The body of each cell is pyramidal in shape, its base being directed to the deeper parts and its apex toward the surface. It contains granular pigment, and stains deeply with ordinary reagents. The nucleus is of large size, and round or oval in shape. The base of the cell gives off the axis cylinder, and this runs into the central white substance, giving off collaterals in its course, and is distributed as a projection, commissural, or association fibre. The apical and basal parts of the cell give off dendrites; the apical dendrite is directed toward the surface, and ends in the molecular layer by dividing into numerous branches, all of which may be seen, when prepared by the silver or methylene-blue method, to be studded with projecting bristle-like processes. The largest pyramidal cells are found in the upper part of the anterior central gyrus and in the paracentral lobule; they are often arranged in groups or nests of from three to five, and are named the *giant cells of Betz*.

In the former situation they may exceed 50μ in length and 40μ in breadth, while in the paracentral lobule they may attain a length of 65μ .

Layer of Polymorphous Cells.—The cells in this layer, as their name implies, are very irregular in contour; they may be fusiform, oval, triangular, or star-shaped. Their dendrites are directed outward, but do not reach so far as the molecular layer; their axons pass into the subjacent white matter.

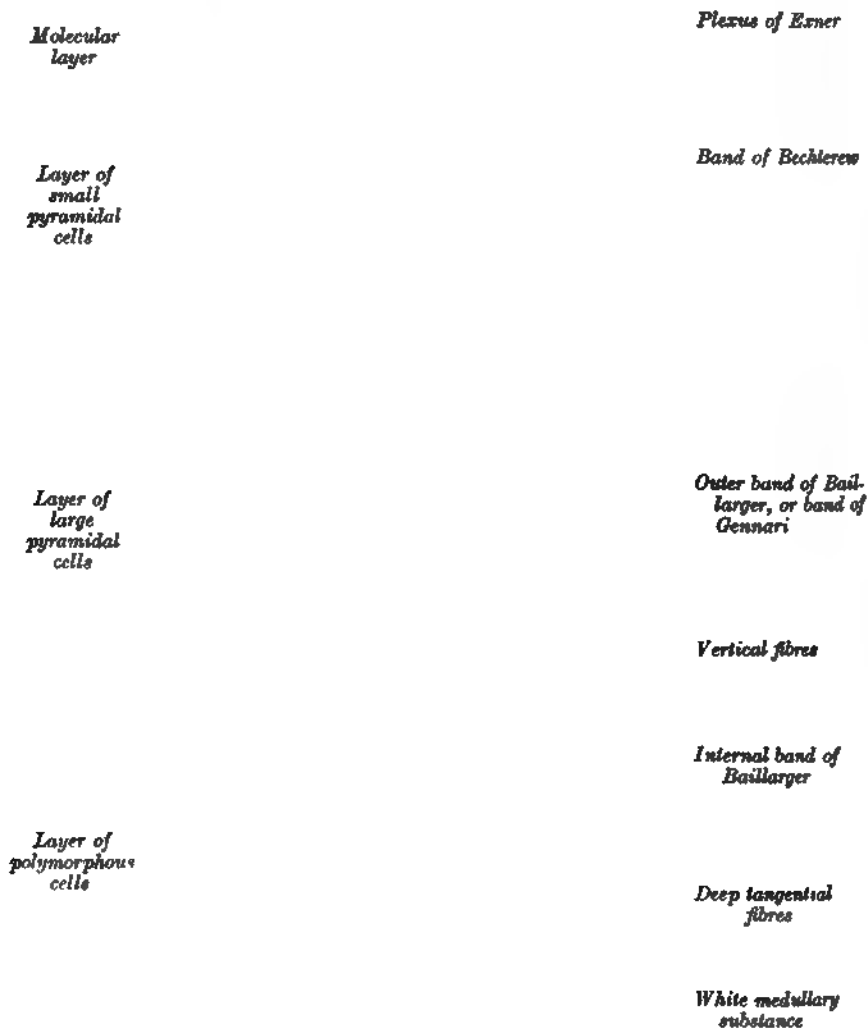

FIG. 759.—Cerebral cortex. (Poirier.) To the left, the groups of cells, to the right, the systems of fibres. Quite to the left of the figure a sensory nerve fibre is shown.

There are two other kinds of cells in the cerebral cortex. They are: (a) the *cells of Golgi*, the axons of which divide immediately after their origins into a large number of branches, which are directed toward the surface of the cortex; (b) the *cells of Martinotti*, which are chiefly found in the polymorphous layer; their dendrites are short, and may have an ascending or descending course, while their axons pass out into the molecular layer and form an extensive horizontal arborization.

Nerve Fibres.—These fill up a large part of the intervals between the cells, and may be medullated or non-medullated—the latter comprising the axons of the smallest pyramidal cells and the cells of Golgi. In their direction the fibres may be either tangential or radial. The *tangential fibres* run parallel to the surface of the hemisphere, intersecting the radial fibres at a right angle.

They constitute several strata, of which the following are the more important: (1) a stratum of white fibres covering the superficial aspect of the molecular layer (*plexus of Exner*); (2) the band of Bechterew, in the outer part of the layer of small pyramidal cells; (3) the band of Gennari or external band of Baillarger, running through the layer of large pyramidal cells; (4) the internal band of Baillarger, between the layer of large pyramidal cells and the polymorphous layer; (5) the deep tangential fibres, in the lower part of the polymorphous layer. The tangential fibres consist of (a) the collaterals of the pyramidal and polymorphous cells and of the cells of Martinotti; (b) the branching axons of Golgi's cells; (c) the collaterals and terminal arborizations of the projection, commissural, or association fibres. *The radial fibres.*—Some of these, viz., the axons of the pyramidal and polymorphous cells, descend into the central white matter, while others, the terminations of the projection, commissural, or association fibres, ascend to end in the cortex. The axons of the cells of Martinotti are also ascending fibres.

Special Types of Cerebral Cortex.—It has been already pointed out that the minute structure of the cortex differs in different regions of the hemisphere; and A. W. Campbell¹ has endeavored to prove, as the result of an exhaustive examination of a series of human and anthropoid brains, "that there exists a direct correlation between physiological function and histological structure." The principal regions where the "typical" structure is departed from will now be referred to.

1. In the calcarine fissure and the gyri bounding it, the internal band of Baillarger is absent, while the band of Gennari is of considerable thickness, and forms a characteristic feature of this region of the cortex. If a section be examined microscopically, an additional layer of cells is seen to be interpolated between the molecular layer and the layer of small pyramidal cells. This extra layer consists of two or three strata of fusiform cells, the long axes of which are at right angles to the surface; each cell gives off two dendrites, external and internal, from the latter of which the axon arises and passes into the white central substance. In the layer of small pyramidal cells, fusiform cells, identical with the above, are seen, as well as ovoid or star-like cells with ascending axons (*cells of Martinotti*). This is the *visual area* of the cortex, and it has been shown by J. S. Bolton² that in old-standing cases of optic atrophy the thickness of Gennari's band is reduced by nearly 50 per cent.

A. W. Campbell says: "Histologically, two distinct types of cortex can be made out in the occipital lobe. The first of these coats the walls and bounding convolutions of the calcarine fissure, and is distinguished by the well-known line of Gennari or *Vicq d'Azyr*; the second area forms an investing zone a centimetre or more broad around the first, and is characterized by a remarkable wealth of fibres, as well as by curious pyriform cells of large size richly stocked with chromophilic elements—cells which seem to have escaped the observation of Ramón y Cajal, Bolton, and others who have worked at this region. As to the functions of these two regions there is abundant evidence, anatomical, embryological, and pathological, to show that the first or calcarine area is that to which visual sensations primarily pass, and we are gradually obtaining proof to the effect that the second investing area is constituted for the interpretation and further elaboration of these sensations. These areas therefore deserve the names *visuo-sensory* and *visuo-psychic*."

2. The anterior central gyrus is characterized by the presence of the giant cells of Betz and by "a wealth of nerve fibres immeasurably superior to that of any other part" (Campbell), and in these respects differs from the posterior central gyrus. These two gyri, together with the paracentral lobule, were long regarded as constituting the "motor areas" of the hemisphere; but Sherrington and Grunbaum have shown³ that in the chimpanzee the motor area never extends on to the free face of the posterior central gyrus, but occupies the entire length of the anterior central gyrus, and in most cases the greater part or the whole of its width. It extends into the depth of the central sulcus, occupying the anterior wall, and in some places the floor, and in some extending even into the deeper part of the posterior wall of the sulcus.

3. In the hippocampus the molecular layer is very thick and contains a large number of Golgi cells. It has been divided into three strata: (a) *s. convolutum* or *s. granulosum*, containing many tangential fibres; (b) *s. lacunosum*, presenting numerous vascular spaces; (c) *s. radiatum*, exhibiting a rich plexus of fibrils. The two layers of pyramidal cells are condensed into one, and the cells are mostly of large size. The axons of the cells in the polymorphous layer may run in an ascending, a descending, or a horizontal direction. Between the polymorphous layer and the ventricular ependyma is the white substance of the alveus.

4. In the fascia dentata hippocampi or dentate gyrus the molecular layer contains some pyramidal cells, while the layer of pyramidal cells is almost entirely represented by small ovoid cells.

5. *The Olfactory Bulb.*—In many of the lower animals this contains a cavity which communicates through the olfactory tract with the lateral ventricle. In man the original cavity is filled up by neuroglia and its wall becomes thickened, but much more so on its ventral than on its dorsal aspect. Its dorsal part contains a small amount of gray and white substance, but it is scanty and ill-defined. A section through the ventral part (Fig. 760) shows it to consist of the following layers from without inward:

¹ Histological Studies on the Localisation of Cerebral Function, Cambridge University Press

² Philosophical Transactions of Royal Society, Series B, xciii, 165.

³ Transactions of the Pathological Society of London, vol. liii.

1. A layer of olfactory nerve fibres, which are the non-medullated axons prolonged from the olfactory cells of the nasal cavity, and reach the bulb by passing through the cribriform plate of the ethmoid bone. At first they cover the bulb, and then penetrate it to end by forming synapses with the dendrites of the mitral cells, presently to be described.

2. *Glomerular Layer*.—This contains numerous spheroidal reticulated enlargements, termed **glomeruli**, produced by the branching and arborization of the processes of the olfactory nerve fibres with the descending dendrites of the mitral cells.

3. *Molecular Layer*.—This is formed of a matrix of neuroglia, imbedded in which are the *mitral cells*. These cells are pyramidal in shape, and the basal part of each gives off a thick dendrite which descends into the glomerular layer, where it arborizes as indicated above, and others which interlace with similar dendrites of neighboring mitral cells. The axons pass through the next layer into the white matter of the bulb, and after becoming bent on themselves at a right angle, are continued into the olfactory tract.

4. *Nerve Fibre Layer*.—This lies next the central core of neuroglia, and its fibres consist of the axons or afferent processes of the mitral cells passing to the brain; some efferent fibres are, however, also present, and end in the molecular layer, but nothing is known as to their exact origin.

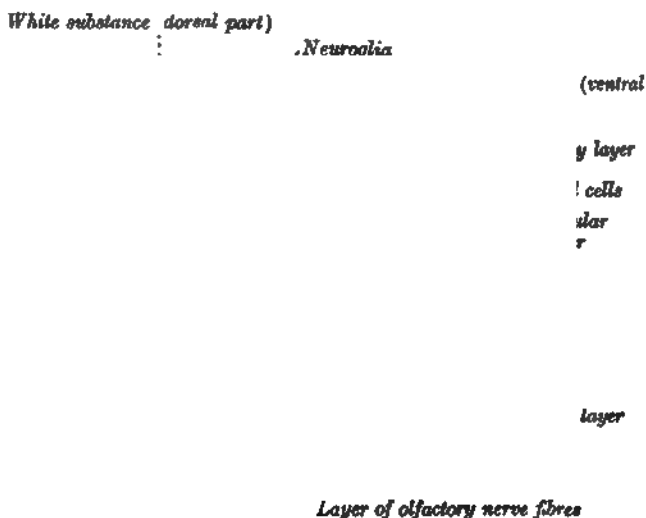

FIG. 760.—Coronal section of olfactory bulb. (Schwalbe.)

Weight of the Encephalon.—The average weight of the brain, in the adult male, is about 1380 gms.; that of the female, about 1250 gms. In the male, the maximum weight out of 278 cases was 1840 gms. and the minimum weight 964 gms. The maximum weight of the adult female brain, out of 191 cases, was 1585 gms. and the minimum weight 879 gms. The brain increases rapidly during the first four years of life, and reaches its maximum weight by about the twentieth year. As age advances, the brain decreases slowly in weight; in old age the decrease takes place more rapidly, to the extent of about 28 gms.

The human brain is heavier than that of any of the lower animals, except the elephant and whale. The brain of the former weighs from 3.5 to 4.5 kilogram., and that of a whale, in a specimen 22.8 metres long, weighed rather more than 225 kilogram.

Cerebral Localization.—Physiological and pathological research have now gone far to prove that a considerable part of the surface of the brain may be mapped out into a series of more or less definite areas, each of which is intimately connected with some well-defined function.

The chief areas are indicated in Figs. 761 and 762.

Motor Areas.—The motor area occupies the anterior central and frontal gyri and the paracentral lobule. The centres for the lower limb are located on the uppermost part of the anterior central gyrus and its continuation on to the paracentral lobule; those for the trunk are on the upper portion, and those for the upper limb on the middle portion of the anterior central gyrus. The facial centres are situated on the lower part of the anterior central gyrus, those for the tongue, larynx, muscles of mastication, and pharynx on the frontal operculum, while those for the head and neck occupy the posterior end of the middle frontal gyrus.

Sensory Areas.—Tactile and temperature senses are located on the posterior central gyrus, while the sense of form and solidity is on the superior parietal lobule and precuneus. With regard to the special senses, the area for the sense of taste is probably related to the uncus and

hippocampal gyrus. The auditory area occupies the middle third of the superior temporal gyrus and the adjacent gyri in the lateral fissure; the visual area, the calcarine fissure and cuneus; the olfactory area, the rhinencephalon. As special centres of much importance may be noted: the emissive centre for speech on the left inferior frontal and anterior central gyri (Broca); the auditory receptive centre on the transverse and superior temporal gyri, and the visual receptive centre on the lingual gyrus and cuneus.

FIG. 761.—Areas of localization on lateral surface of hemisphere. Motor area in red. Area of general sensations in blue. Auditory area in green. Visual area in yellow. The psychic portions are in lighter tints.

Applied Anatomy.—The *internal capsule* is of great interest to the clinician because it is so often the seat of hemorrhage (from the lenticulo-striate and lenticulo-optic arteries, Charcot's "arteries of cerebral hemorrhage"), or of thrombosis, in patients whose vessels are weakened by old age

FIG. 762.—Areas of localisation on medial surface of hemisphere. Motor area in red. Area of general sensations in blue. Visual area in yellow. Olfactory area in purple. The psychic portions are in lighter tints.

or disease. A *stroke* or *apoplexy* is the result; blood is effused from the ruptured vessel and tears up the surrounding brain tissue, and also interferes with the neighboring fibres by the compression set up by its mass. If the hemorrhage is sudden and at all large, rapid and complete loss of consciousness follows, with paralysis of the opposite side of the body and loss of control over

the sphincters. If it is the occipital part of the internal capsule that is involved, the paralysis will be more marked in the leg than in the arm, and will be associated with hemianesthesia, and also with homonymous hemianopsia or blindness of the corresponding halves of the two retinae, the patient being unable to see objects on the opposite side of the body. If the hemorrhage is very extensive blood often makes its way into the ventricles, and death may follow in a few hours or days without recovery of consciousness, and with hyperpyrexia. If the hemorrhage is small, consciousness is soon regained, and a fair degree of recovery from the paralysis follows, particularly in the leg. If the hemorrhage takes place very slowly, the hemiplegia sets in gradually (*ingravescent apoplexy*), with headache and gradual clouding of the faculties. It is the upper motor neuron (see below) that is injured in cerebral hemorrhage; hence the muscles on the affected side of the body become spastic, with increased reflexes, while such muscular atrophy as follows is mainly due to disuse.

THE MOTOR AND SENSORY TRACTS.

The anatomy of the various parts of the central nervous system having been described, a short account will now be given of the motor and sensory nerve tracts connecting the brain and the medulla spinalis. The methods employed in elucidating this complex subject have already been referred to (page 815).

The Motor Tract (Fig. 763).—The constituent fibres of this tract are the axis-cylinder processes of cells situated in the motor area of the cortex. The fibres are at first somewhat widely diffused, but as they descend through the corona radiata they gradually approach each other, and pass between the lentiform nucleus and thalamus, in the genu and anterior two-thirds of the occipital part of the internal capsule; those in the genu are named the **geniculate fibres**, while the remainder constitute the **cerebrospinal fibres**; proceeding downward they enter the middle three-fifths of the base of the cerebral peduncle. The geniculate fibres cross the middle line, and end by arborizing around the cells of the motor nuclei of the cerebral nerves. The cerebrospinal fibres are continued downward into the pyramids of the medulla oblongata, and the transit of the fibres from the medulla oblongata is effected by two paths. The fibres nearest to the anterior median fissure cross the middle line, forming the **decussation of the pyramids**, and descend in the opposite side of the medulla spinalis, as the **lateral cerebrospinal fasciculus** (*crossed pyramidal tract*). Throughout the length of the medulla spinalis fibres from this column pass into the gray substance, to terminate by ramifying around the motor cells of the anterior column. The more laterally placed portion of the tract does not decussate in the medulla oblongata, but descends as the **anterior cerebrospinal fasciculus** (*direct pyramidal tract*); these fibres, however, end in the anterior gray column of the opposite side of the medulla spinalis by passing across in the anterior white commissure. There is considerable variation in the extent to which decussation takes place in the medulla oblongata; about two-thirds or three-fourths of the fibres usually decussate in the medulla oblongata and the remainder in the medulla spinalis.

The axons of the motor cells in the anterior column pass out as the fibres of the anterior roots of the spinal nerves, along which the impulses are conducted to the muscles of the trunk and limbs.

From this it will be seen that all the fibres of the motor tract pass to the nuclei of the motor nerves on the opposite side of the brain or medulla spinalis, a fact which explains why a lesion involving the motor area of one side causes paralysis of the muscles of the opposite side of the body. Further, it will be seen that there is a break in the continuity of the motor chain; in the case of the cerebral nerves this break occurs in the nuclei of these nerves; and in the case of the spinal nerves, in the anterior gray column of the medulla spinalis. For clinical purposes it is convenient to emphasize this break and divide the motor tract into two portions: (1) a series of **upper motor neurons** which comprises the motor cells in the cortex

and their descending fibres down to the nuclei of the motor nerves; (2) a series of **lower motor neurons** which includes the cells of the nuclei of the motor cerebral nerves or the cells of the anterior columns of the medulla spinalis and their axis-cylinder processes to the periphery.¹

FIG. 763.—The motor tract. (Modified from Poirier.)

The Sensory Tract (Fig. 764).—Sensory impulses are conveyed to the medulla spinalis through the posterior roots of the spinal nerves. On entering the medulla spinalis these root fibres divide into descending and ascending branches; the former soon enter the gray substance: some of the latter end in the gray substance after a longer or shorter course, while others are continued directly into the posterior

¹ As already mentioned (footnote, p. 816), a neuron in the posterior column of the medulla spinalis is probably interposed between each upper and lower motor neuron.

funiculi, where they form the fasciculus gracilis and fasciculus cuneatus. From the cells of the posterior column, fibres arise which cross the middle line and ascend in the superficial antero-lateral fasciculus. The fibres of the fasciculus gracilis and fasciculus cuneatus end by arborizing around the cells of the gracile and cuneate nuclei in the medulla oblongata, and from these cells the fibres of the medial

FIG. 764 —The sensory tract. (Modified from Poirier.)

lemniscus take origin and cross to the opposite side in the **sensory decussation**. The medial lemniscus is then joined by the fibres of the superficial antero-lateral fasciculus, which have already crossed in the medulla spinalis, and in its further course receives fibres from the cerebral sensory nuclei of the opposite side, with the exception of the cochlear division of the acoustic nerve. Ascending through the cerebral peduncle, the lemniscus gives off some fibres to the lentiform nucleus

and insula, but the greater part of it is carried into the thalamus, where most of its fibres end—only a small proportion being continued directly into the cerebral cortex. From the gray substance of the thalamus the fibres of the third link in the chain arise and pass to the cerebral cortex. The fibres from the terminal nuclei of the cochlear nerve pass upward in the lateral lemniscus, and are carried through the occipital part of the internal capsule to the temporal lobe. Further, the superficial antero-lateral fasciculus gives off fibres which reach the cerebellum through the brachia conjunctiva. It will be evident, therefore, that in most cases there are three cell-stations interposed in the course of the sensory impulses. For clinical purposes, therefore, three neurons are described: (1) the **lowest sensory neurons** comprise the cells of the posterior root ganglia and their peripheral and central processes; (2) the **intermediate sensory neurons** are the cells of the nuclei cuneati and gracilis and their processes, while (3) the **highest sensory neurons** are the cells of the thalami and the fibres passing from these to the cerebral cortex.

Applied Anatomy.—The chief symptoms of diseases of the brain and medulla spinalis depend upon the particular systems of neurons picked out for attack, and some of them may be briefly summarized as follows: *Motor paralysis* of the *spastic* type, with rigidity of the muscles and increased reflexes, follows destruction of the upper motor neurons; *flaccid paralysis*, with loss of the reflexes and rapid muscular atrophy, follows destruction of the lower motor neurons. *Sensory paralysis* follows injury to any part of the sensory path; in tabes it is due to injury of the lowest sensory neurons, in hemiplegia to destruction of the highest sensory axon as it traverses the occipital part of the internal capsule. *Dissociation of sensations*, or the loss of some forms of sensation while others remain unimpaired, is seen in a number of conditions such as tabes or syringomyelia; it shows that the paths through which various forms of sensation travel to the brain are different. *Abnormalities of reflex actions* are of very great help in the diagnosis of nervous complaints. The numerous *superficial* or *skin reflexes*, e. g., the scapular, irritation of the skin over the scapula produces contraction of the scapular muscles; the abdominal, stroking the abdomen causes its retraction; the cremasteric, stroking the inner side of the thigh causes retraction of the testis on that side; the plantar, tickling the sole of the foot brings on plantar flexion of the toes, if present, show that the reflex arcs on whose integrity their existence depends are intact; but they are often absent in health, and so cannot be trusted to indicate disease. The *deep reflexes* or *tendon reactions*, such as the knee-jerk or the tendo-calcaneus jerk, are increased in chronic degeneration of, or gradually increasing pressure on, the cerebrospinal fibres (upper motor neuron), in nervous or hysterical patients, and when the irritability of the cells of the anterior column (lower motor neuron) is increased, as happens in tetanus or in poisoning by strychnine. They are lost when the lower motor or lower sensory neurons are diseased, and in a few other conditions; absence of the knee-jerk is very rare in health, and suggests disease in some part of its reflex arc, in the third and fourth lumbar segments of the cord, or else, more rarely, grave intracranial or spinal disease cutting off the lower from the higher nervous centres. The *organic reflexes* of the pupil, bladder, and rectum are of the greatest practical importance. The commonest defect in the reflexes of the pupil is reflex iridoplegia, or failure to contract on exposure to light, without failure to contract on convergence or accommodation (*Argyll-Robertson pupil*). The pupil is also contracted (*miosis*), and may or may not dilate when the skin of the neck is pinched (the ciliospinal reflex). Micturition is a spinal reflex much under the control of the brain; if the centre for micturition in the second sacral segment is destroyed the sphincter and the walls of the bladder are paralyzed, the bladder becomes distended with urine, and incontinence from overflow results. If this centre escapes injury but is cut off more or less completely from impulses descending to it from above, there will be more or less interference with micturition. This varies in degree from the "precipitate micturition" of tabetic patients, who must perforce hurry to pass water the moment the impulse seizes them, to the state of "reflex incontinence," when the bladder automatically empties itself from time to time, almost without the patient's knowledge. Defecation is a very similar spinal reflex, and is liable to very similar disorders of function.

The *upper motor neuron* (p. 896) is affected in hemiplegia, the *lower motor neuron* (p. 897) in infantile spinal paralysis; both these systems of neurons are diseased together in the somewhat rare disorders known as *amyotrophic lateral sclerosis* and *progressive muscular atrophy*. The chief symptom here is wasting and weakness in certain groups of muscles; the palsy will be flaccid, with loss of the reflexes, or spastic, with increased reflexes, according as the degeneration mainly involves the lower or the upper motor neuron. The sphincters are affected only in the later stages of these diseases.

Pathological changes in the *lowest sensory neuron* are the cause of *tabes dorsalis* or *locomotor ataxy*, which occurs almost entirely in adults who have had syphilis. In the early or preataxic

stage the patient may exhibit the Argyll-Robertson pupil (page 899), and loss of the knee-jerks, and complain of sharp, stabbing pains ("lightning pains") in the limbs, difficult or precipitate micturition, and sometimes of severe and painful attacks of indigestion (gastric crises). In the second or ataxic stage, coming on perhaps years later, he will complain, in addition, of interference with his powers of getting about and turning, although his muscular strength is well preserved. He is unable to stand steady with his eyes shut or in the dark, his gait becomes exaggerated and stamping in character, he has to use a stout stick to walk with, and he may suffer from painful crises in various parts of the body. Control over the sphincters is further weakened, and on examination there will be found marked incoördination of the limbs, zones of anesthesia about the trunk or down the limbs, and marked analgesia (or insensitiveness to pain) when pressure is applied to the bones, tendons, trachea, tongue, eyeballs, mammae, and testes.¹ The ataxy progresses until the third or bedridden stage is reached; control over the sphincters is still further lost, and the patient is likely to die of intercurrent disease or of general paralysis of the insane.

No nervous disease is recognized as dependent upon degeneration of either the *intermediate* or *highest sensory neuron*.

MENINGES OF THE BRAIN AND MEDULLA SPINALIS.

The brain and medulla spinalis are enclosed within three membranes. These are named from without inward: the *dura mater*, the *arachnoid*, and the *pia mater*.

The Dura Mater.

The *dura mater* is a thick and dense inelastic membrane. The portion which encloses the brain differs in several essential particulars from that which surrounds the medulla spinalis, and therefore it is necessary to describe them separately; but at the same time it must be distinctly understood that the two form one complete membrane, and are continuous with each other at the foramen magnum.

The *cerebral dura mater* (*dura mater encephali*; *dura of the brain*) lines the interior of the skull, and serves the two-fold purpose of an internal periosteum to the bones, and a membrane for the protection of the brain. It is composed of two layers, an inner or meningeal and an outer or endosteal, closely connected together, except in certain situations, where, as already described (page 729), they separate to form sinuses for the passage of venous blood. Its outer surface is rough and fibrillated, and adheres closely to the inner surfaces of the bones, the adhesions being most marked opposite the sutures and at the base of the skull its inner surface is smooth and lined by a layer of endothelium. It sends inward four processes which divide the cavity of the skull into a series of freely communicating compartments, for the lodgement and protection of the different parts of the brain; and it is prolonged to the outer surface of the skull, through the various foramina which exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the spinal dura mater.

Processes.—The processes of the cerebral dura mater, which projects into the cavity of the skull, are formed by reduplications of the inner or meningeal layer of the membrane, and are four in number: the *falx cerebri*, the *tentorium cerebelli*, the *falx cerebelli*, and the *diaphragma sellæ*.

The *falx cerebri* (Fig. 765), so named from its sickle-like form, is a strong, arched process which descends vertically in the longitudinal fissure between the cerebral hemispheres. It is narrow in front, where it is attached to the crista galli of the ethmoid; and broad behind, where it is connected with the upper surface of the tentorium cerebelli. Its upper margin is convex, and attached to the inner surface of the skull in the middle line, as far back as the internal occipital protuberance; it contains the superior sagittal sinus. Its lower margin is free and concave, and contains the inferior sagittal sinus.

¹ J. Grasset, *Le Tabes, Maladie de la Sensibilité profonde*, Montpellier, 1909.

The **tentorium cerebelli** (Fig. 766) is an arched lamina, elevated in the middle, and inclining downward toward the circumference. It covers the superior surface of the cerebellum, and supports the occipital lobes of the brain. Its anterior border is free and concave, and bounds a large oval opening, the **incisura tentorii**, for the transmission of the cerebral peduncles. It is attached, behind, by its convex border, to the transverse ridges upon the inner surface of the occipital bone, and there encloses the transverse sinuses; in front, to the superior angle of the petrous part of the temporal bone on either side, enclosing the superior petrosal sinuses. At the apex of the petrous part of the temporal bone the free and attached borders meet, and, crossing one another, are continued forward to be fixed to the anterior and posterior clinoid processes respectively. To the middle line of its upper surface the posterior border of the **falx cerebri** is attached, the straight sinus being placed at their line of junction.

Facial nerve | *Trochlear nerve*
Abducent nerve | *Trigeminal nerve*

FIG. 765.—Dura mater and its processes exposed by removing part of the right half of the skull and the brain.

The **falx cerebelli** is a small triangular process of dura mater, received into the posterior cerebellar notch. Its base is attached, above, to the under and back part of the tentorium; its posterior margin, to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends, it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

The **diaphragma sellae** is a small circular horizontal fold, which roofs in the sella turcica and almost completely covers the hypophysis; a small central opening transmits the infundibulum.

Structure.—The cranial dura mater consists of white fibrous tissue and elastic fibres arranged in flattened laminae which are imperfectly separated by lacunar spaces and bloodvessels into two layers, **endosteal** and **meningeal**. The **endosteal layer** is the internal periosteum for the cranial bones, and contains the bloodvessels for their supply. At the margin of the foramen magnum it is continuous with the periosteum lining the vertebral canal. The **meningeal** or **supporting layer** is lined on its inner surface by a layer of nucleated endothelium, similar to that found on serous membranes.

Optic nerve Internal carotid artery

75

End of superior sagittal sinus

FIG. 766.—Tentorium cerebelli seen from above.

The **arteries** of the dura mater are very numerous. Those in the anterior fossa are the **anterior meningeal** branches of the anterior and posterior ethmoidal and internal carotid, and a branch from the middle meningeal. Those in the middle fossa are the middle and accessory meningeal of the internal maxillary; a branch from the ascending pharyngeal, which enters the skull through the foramen lacerum; branches from the internal carotid, and a recurrent branch from the lacrimal. Those in the posterior fossa are meningeal branches from the occipital, one entering the skull through the jugular foramen, and another through the mastoid foramen; the posterior meningeal from the vertebral; occasional meningeal branches from the ascending pharyngeal, entering the skull through the jugular foramen and hypoglossal canal; and a branch from the middle meningeal.

The **veins** returning the blood from the cranial dura mater anastomose with the diploic veins and end in the various sinuses. Many of the meningeal veins do not open directly into the sinuses, but indirectly through a series of ampullae, termed **venous lacunae**. These are found on either side of the superior sagittal sinus, especially near its middle portion, and are often invaginated by arachnoid granulations; they also exist near the transverse and straight sinuses. They communicate with the underlying cerebral veins, and also with the diploic and emissary veins.

The **nerves** of the cerebral dura mater are filaments from the semilunar ganglion, from the ophthalmic, maxillary, mandibular, vagus, and hypoglossal nerves, and from the sympathetic.

The **spinal dura mater** (*dura mater spinalis; spinal dura*) (Fig. 767) forms a loose sheath around the medulla spinalis, and represents only the inner or meningeal layer of the cerebral dura mater; the outer or endosteal layer ceases at the foramen magnum, its place being taken by the periosteum lining the vertebral canal. The

spinal dura mater is separated from the arachnoid by a potential cavity, the **subdural cavity**; the two membranes are, in fact, in contact with each other, except where they are separated by a minute quantity of fluid, which serves to moisten the apposed surfaces. It is separated from the wall of the vertebral canal by a space, the **epidural space**, which contains a quantity of loose areolar tissue and a plexus of veins; the situation of these veins between the dura mater and the periosteum of the vertebræ corresponds therefore to that of the cranial sinuses between the meningeal and endosteal layers of the cerebral dura mater. The spinal dura mater is attached to the circumference of the foramen magnum, and to the second and third cervical vertebræ; it is also connected to the posterior longitudinal ligament, especially near the lower end of the vertebral canal, by fibrous slips. The subdural cavity ends at the lower border of the second sacral vertebra; below this level the dura mater closely invests the filum terminale and descends to the back of the coccyx, where it blends with the periosteum. The sheath of dura mater is much larger than is necessary for the accommodation of its contents, and its size is greater in the cervical and lumbar regions than in the thoracic. On each side may be seen the double openings which transmit the two roots of the corresponding spinal nerve, the dura mater being continued in the form of tubular prolongations on them as they pass through the intervertebral foramina. These prolongations are short in the upper part of the vertebral column, but gradually become longer below, forming a number of tubes of fibrous membrane, which enclose the lower spinal nerves and are contained in the vertebral canal.

FIG. 767.—The medulla spinalis and its membranes.

Structure.—The spinal dura mater resembles in structure the meningeal or supporting layer of the cranial dura mater, consisting of white fibrous and elastic tissue arranged in bands or lamellæ which, for the most part, are parallel with one another and have a longitudinal arrangement. Its internal surface is smooth and covered by a layer of endothelium. It is sparingly supplied with bloodvessels, and a few nerves have been traced into it.

The Arachnoid.

The **arachnoid** is a delicate membrane enveloping the brain and medulla spinalis and lying between the pia mater internally and the dura mater externally; it is separated from the pia mater by the subarachnoid cavity, which is filled with cerebrospinal fluid.

The **cerebral part** (*arachnoidea encephali*) of the arachnoid invests the brain loosely, and does not dip into the sulci between the gyri, nor into the fissures, with the exception of the longitudinal. On the upper surface of the brain the arachnoid is thin and transparent; at the base it is thicker, and slightly opaque toward the central part, where it extends across between the two temporal lobes in front of the pons, so as to leave a considerable interval between it and the brain.

The **spinal part** (*arachnoidea spinalis*) of the arachnoid is a thin, delicate, tubular membrane loosely investing the medulla spinalis. *Above*, it is continuous with the cerebral arachnoid; *below*, it widens out and invests the cauda equina and the nerves proceeding from it. It is separated from the dura mater by the **subdural space**, but here and there this space is traversed by isolated connective-tissue trabeculæ, which are most numerous on the posterior surface of the medulla spinalis.

The arachnoid surrounds the cerebral and spinal nerves, and encloses them in loose sheaths as far as their points of exit from the skull and vertebral canal.

Structure.—The arachnoid consists of bundles of white fibrous and elastic tissue intimately blended together. Its outer surface is covered with a layer of endothelium. Vessels of considerable size, but few in number, and, according to Bochdalek, a rich plexus of nerves derived from the motor root of the trigeminal, the facial, and the accessory nerves, are found in the arachnoid.

The **subarachnoid cavity** (*canum subarachnoideale; subarachnoid space*) is the interval between the arachnoid and pia mater. It is occupied by a spongy tissue consisting of trabeculae of delicate connective tissue, and intercommunicating channels in which the subarachnoid fluid is contained. This cavity is small on the surface of the hemispheres of the brain; on the summit of each gyrus the pia mater and the arachnoid are in close contact; but in the sulci between the gyri, triangular spaces are left, in which the subarachnoid trabecular tissue is found, for the pia mater dips into the sulci, whereas the arachnoid bridges across them from gyrus to gyrus. At certain parts of the base of the brain, the arachnoid is separated from the pia mater by wide intervals, which communicate freely with each other and are named **subarachnoid cisternae**; in these the subarachnoid tissue is less abundant.

Opt

Cisterna 1

FIG. 768.—Diagram showing the positions of the three principal subarachnoid cisternae.

Subarachnoid Cisternae (*cisternae subarachnoidales*) (Fig. 768).—The **cisterna cerebellomedullaris** (*cisterna magna*) is triangular on sagittal section, and results from the arachnoid bridging over the interval between the medulla oblongata and the under surfaces of the hemispheres of the cerebellum; it is continuous with the subarachnoid cavity of the medulla spinalis at the level of the foramen magnum. The **cisterna pontis** is a considerable space on the ventral aspect of the pons. It contains the basilar artery, and is continuous behind with the subarachnoid cavity of the medulla spinalis, and with the cisterna cerebellomedullaris; and in front of the pons with the cisterna interpeduncularis. The **cisterna interpeduncularis** (*cisterna basalis*) is a wide cavity where the arachnoid extends across between the two temporal lobes. It encloses the cerebral peduncles and the structures contained in the interpeduncular fossa, and contains the arterial circle of Willis. In front, the cisterna interpeduncularis extends forward across the optic chiasma, forming the **cisterna chiasmatis**, and on to the upper surface of the corpus callosum, for the arachnoid stretches across from one cerebral hemisphere to the other immediately beneath the free border of the falx cerebri, and thus leaves a space in which

the anterior cerebral arteries are contained. The **cisterna fossae cerebri lateralis** is formed in front of either temporal lobe by the arachnoid bridging across the lateral fissure. This cavity contains the middle cerebral artery. The **cisterna venae magnae cerebri** occupies the interval between the splenium of the corpus callosum and the superior surface of the cerebellum; it extends between the layers of the tela chorioidea of the third ventricle and contains the great cerebral vein.

The subarachnoid cavity communicates with the general ventricular cavity of the brain by three openings; one, the **foramen of Majendie**, is in the middle line at the inferior part of the roof of the fourth ventricle; the other two are at the extremities of the lateral recesses of that ventricle, behind the upper roots of the glossopharyngeal nerves. It is stated by Meckel that the lateral ventricles also communicate with the subarachnoid cavity at the apices of their inferior cornua. There is no direct communication between the subdural and subarachnoid cavities.

FIG. 769.—Diagrammatic representation of a section across the top of the skull, showing the membranes of the brain, etc. (Modified from Testut.)

The spinal part of the subarachnoid cavity is a very wide interval, and is the largest at the lower part of the vertebral canal, where the arachnoid encloses the nerves which form the cauda equina. Above, it is continuous with the cranial subarachnoid cavity; below, it ends at the level of the lower border of the second sacral vertebra. It is partially divided by a longitudinal septum, the **subarachnoid septum**, which connects the arachnoid with the pia mater opposite the posterior median sulcus of the medulla spinalis, and forms a partition, incomplete and cribriform above, but more perfect in the thoracic region. The spinal subarachnoid cavity is further subdivided by the **ligamentum denticulatum**, which will be described with the pia mater.

The cerebrospinal fluid is a clear limpid fluid, having a saltish taste, and a slightly alkaline reaction. According to Lassaigne, it consists of 98.5 parts of water, the remaining 1.5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly secreted.

The **arachnoid granulations** (*granulationes arachnoideales*; *glandulae Pacchioni*; *arachnoid villi*; *Pacchionian bodies*) (Fig. 769) are small, fleshy-looking eleva-

tions, usually collected into clusters of variable size, which are present upon the outer surface of the dura mater, in the vicinity of the superior sagittal sinus, and in some other situations. Upon laying open the sagittal sinus and the venous lacunæ on either side of it granulations will be found protruding into its interior. They are not seen in infancy, and very rarely until the third year. They are usually found after the seventh year; and from this period they increase in number and size as age advances. They are not glandular in structure, but are enlarged normal villi of the arachnoid. As they grow they push the thinned dura mater before them, and cause absorption of the bone from pressure, and so produce the pits or depressions on the inner wall of the calvarium.

Structure.—An arachnoidal granulation consists of the following parts: (1) In the interior is a core of subarachnoid tissue, continuous with the mesh-work of the general subarachnoid tissue through a narrow pedicle, by which the granulation is attached to the arachnoid. (2) Around this tissue is a layer of arachnoid membrane, limiting and enclosing the subarachnoid tissue. (3) Outside this is the thinned wall of the lacuna, which is separated from the arachnoid by a space which corresponds to and is continuous with the subdural cavity. (4) And finally, if the granulation projects into the sagittal sinus, it will be covered by the greatly thinned upper walls of the sinus. It will be seen, therefore, that fluid injected into the subarachnoid cavity will find its way into these granulations, and it has been found experimentally that it passes by osmosis from the granulations into the venous sinuses into which they project.

The Pia Mater.

The **pia mater** is a vascular membrane, consisting of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue.

The **cerebral pia mater** (*pia mater encephali*; *pia of the brain*) invests the entire surface of the brain, dips between the cerebral gyri and cerebellar laminæ, and is invaginated to form the tela chorioidea of the third ventricle, and the choroid plexuses of the lateral and third ventricles (pages 887 and 888); as it passes over the roof of the fourth ventricle, it forms the tela chorioidea and the choroid plexuses of this ventricle. Upon the surfaces of the hemispheres, where it covers the gray substance, it gives off from its deep surface a multitude of sheaths, around the minute vessels, that extend perpendicularly for some distance into the cerebral substance. On the cerebellum the membrane is more delicate; the vessels from its deep surface are shorter, and its relations to the cortex are not so intimate.

FIG. 770.—Diagrammatic transverse section of the medulla spinalis and its membranes.

The **spinal pia mater** (*pia mater spinalis*; *pia of the cord*) (Figs. 767, 770) is thicker, firmer, and less vascular than the cerebral pia mater; this is due to the fact that it consists of two layers, the outer or additional one being composed of bundles of connective-tissue fibres, arranged for the most part longitudinally. Between the layers are cleft-like spaces which communicate with the subarachnoid cavity, and a number of bloodvessels which are enclosed in perivascular lymphatic sheaths.

The spinal pia mater covers the entire surface of the medulla spinalis, and is very intimately adherent to it; in front it sends a process backward into the anterior fissure. A longitudinal fibrous band, called the *linea splendens*, extends along the middle line of the anterior surface; and a somewhat similar band, the *ligamentum denticulatum*, is situated on either side. Below the conus medullaris, the pia mater is continued as a long, slender filament (*filum terminale*), which descends through the centre of the mass of nerves forming the cauda equina. It blends with the dura mater at the level of the lower border of the second sacral vertebra, and extends downward as far as the base of the coccyx, where it fuses with the periosteum. It assists in maintaining the medulla spinalis in its position during the movements of the trunk, and is, from this circumstance, called the *central ligament* of the medulla spinalis.

The pia mater forms sheaths for the cerebral and spinal nerves; these sheaths are closely connected with the nerves, and blend with their common membranous investments.

The *ligamentum denticulatum* (*dentate ligament*) (Fig. 767) is a narrow fibrous band situated on either side of the medulla spinalis throughout its entire length, and separating the anterior from the posterior nerve roots. Its medial border is continuous with the pia mater at the side of the medulla spinalis. Its lateral border presents a series of triangular tooth-like processes, the points of which are fixed at intervals to the dura mater. These processes are twenty-one in number, on either side, the first being attached to the dura mater, opposite the margin of the foramen magnum, between the vertebral artery and the hypoglossal nerve; and the last near the lower end of the medulla spinalis.

Applied Anatomy.—Evidence of great value in the diagnosis of meningitis may sometimes be obtained by puncturing the spinal membranes and withdrawing some of the cerebrospinal fluid; moreover, the operation of lumbar puncture is in many cases curative, under the supposition that the draining of some of the cerebrospinal fluid relieves the patient by diminishing the intracranial pressure. The operation is performed by inserting a trocar, of the smallest size, between the laminae of the third and fourth, or of the fourth and fifth lumbar vertebrae, through the *ligamentum flavum*. The medulla spinalis, even of a child at birth, does not reach below the third lumbar vertebra, and therefore the canal may be punctured between the third and fourth lumbar vertebrae without any risk of injuring this structure. The point of puncture is indicated by laying the patient on the side and dropping a perpendicular line from the highest point of the iliac crest; this will cross the upper border of the spinous process of the fourth lumbar vertebra, and will indicate the level at which the trocar should be inserted a little to one side of the middle line. The puncture may require to be repeated more than once, and the greatest precaution must be taken not to allow septic infection of the meninges. If there be any appreciable increase of pressure, the fluid will flow through the trocar with the greatest freedom.

In addition to the constitutional signs and symptoms of fever, *acute spinal meningitis* exhibits certain characteristic features. Pain and tenderness to pressure along the vertebral column are common, and so are pains in the limbs or around the trunk from irritation of the posterior nerve roots by the inflammatory products. Irritation of the anterior nerve roots is shown by the increased tone of the muscles, which may go on to the point where they pass into a state of spasm with much increased reflexes; this is often seen in the retraction of the head and neck. Later in the disease the reflexes are often lost, when, also, the urine and feces may be passed involuntarily.

THE CEREBRAL NERVES (NERVI CEREBRALES; CRANIAL NERVES).

There are twelve pairs of cerebral nerves; they are attached to the brain and are transmitted through foramina in the base of the cranium. The different pairs are named from before backward as follows:

- | | |
|------------------|------------------------|
| 1st. Olfactory. | 7th. Facial. |
| 2d. Optic. | 8th. Acoustic. |
| 3rd. Oculomotor. | 9th. Glossopharyngeal. |
| 4th. Trochlear. | 10th. Vagus. |
| 5th. Trigeminal. | 11th. Accessory. |
| 6th. Abducent. | 12th. Hypoglossal. |

tions, usually collected into clusters of variable size, which are present upon the outer surface of the dura mater, in the vicinity of the superior sagittal sinus, and in some other situations. Upon laying open the sagittal sinus and the venous lacunæ on either side of it granulations will be found protruding into its interior. They are not seen in infancy, and very rarely until the third year. They are usually found after the seventh year; and from this period they increase in number and size as age advances. They are not glandular in structure, but are enlarged normal villi of the arachnoid. As they grow they push the thinned dura mater before them, and cause absorption of the bone from pressure, and so produce the pits or depressions on the inner wall of the calvarium.

Structure.—An arachnoidal granulation consists of the following parts: (1) In the interior is a core of subarachnoid tissue, continuous with the mesh-work of the general subarachnoid tissue through a narrow pedicle, by which the granulation is attached to the arachnoid. (2) Around this tissue is a layer of arachnoid membrane, limiting and enclosing the subarachnoid tissue. (3) Outside this is the thinned wall of the lacuna, which is separated from the arachnoid by a space which corresponds to and is continuous with the subdural cavity. (4) And finally, if the granulation projects into the sagittal sinus, it will be covered by the greatly thinned upper walls of the sinus. It will be seen, therefore, that fluid injected into the subarachnoid cavity will find its way into these granulations, and it has been found experimentally that it passes by osmosis from the granulations into the venous sinuses into which they project.

The Pia Mater.

The **pia mater** is a vascular membrane, consisting of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue.

The **cerebral pia mater** (*pia mater encephali*; *pia of the brain*) invests the entire surface of the brain, dips between the cerebral gyri and cerebellar laminæ, and is invaginated to form the tela chorioidea of the third ventricle, and the choroid plexuses of the lateral and third ventricles (pages 887 and 888); as it passes over the roof of the fourth ventricle, it forms the tela chorioidea and the choroid plexuses of this ventricle. Upon the surfaces of the hemispheres, where it covers the gray substance, it gives off from its deep surface a multitude of sheaths, around the minute vessels, that extend perpendicularly for some distance into the cerebral substance. On the cerebellum the membrane is more delicate; the vessels from its deep surface are shorter, and its relations to the cortex are not so intimate.

FIG. 770.—Diagrammatic transverse section of the medulla spinalis and its membranes.

The **spinal pia mater** (*pia mater spinalis*; *pia of the cord*) (Figs. 767, 770) is thicker, firmer, and less vascular than the cerebral pia mater; this is due to the fact that it consists of two layers, the outer or additional one being composed of bundles of connective-tissue fibres, arranged for the most part longitudinally. Between the layers are cleft-like spaces which communicate with the subarachnoid cavity, and a number of bloodvessels which are enclosed in perivascular lymphatic sheaths.

The spinal pia mater covers the entire surface of the medulla spinalis, and is very intimately adherent to it; in front it sends a process backward into the anterior fissure. A longitudinal fibrous band, called the *linea splendens*, extends along the middle line of the anterior surface; and a somewhat similar band, the *ligamentum denticulatum*, is situated on either side. Below the *conus medullaris*, the pia mater is continued as a long, slender filament (*filum terminale*), which descends through the centre of the mass of nerves forming the *cauda equina*. It blends with the dura mater at the level of the lower border of the second sacral vertebra, and extends downward as far as the base of the coccyx, where it fuses with the periosteum. It assists in maintaining the medulla spinalis in its position during the movements of the trunk, and is, from this circumstance, called the *central ligament* of the medulla spinalis.

The pia mater forms sheaths for the cerebral and spinal nerves; these sheaths are closely connected with the nerves, and blend with their common membranous investments.

The *ligamentum denticulatum* (*dentate ligament*) (Fig. 767) is a narrow fibrous band situated on either side of the medulla spinalis throughout its entire length, and separating the anterior from the posterior nerve roots. Its medial border is continuous with the pia mater at the side of the medulla spinalis. Its lateral border presents a series of triangular tooth-like processes, the points of which are fixed at intervals to the dura mater. These processes are twenty-one in number, on either side, the first being attached to the dura mater, opposite the margin of the foramen magnum, between the vertebral artery and the hypoglossal nerve; and the last near the lower end of the medulla spinalis.

Applied Anatomy.—Evidence of great value in the diagnosis of meningitis may sometimes be obtained by puncturing the spinal membranes and withdrawing some of the cerebrospinal fluid; moreover, the operation of lumbar puncture is in many cases curative, under the supposition that the draining of some of the cerebrospinal fluid relieves the patient by diminishing the intracranial pressure. The operation is performed by inserting a trocar, of the smallest size, between the laminae of the third and fourth, or of the fourth and fifth lumbar vertebrae, through the *ligamentum flavum*. The medulla spinalis, even of a child at birth, does not reach below the third lumbar vertebra, and therefore the canal may be punctured between the third and fourth lumbar vertebrae without any risk of injuring this structure. The point of puncture is indicated by laying the patient on the side and dropping a perpendicular line from the highest point of the iliac crest; this will cross the upper border of the spinous process of the fourth lumbar vertebra, and will indicate the level at which the trocar should be inserted a little to one side of the middle line. The puncture may require to be repeated more than once, and the greatest precaution must be taken not to allow septic infection of the meninges. If there be any appreciable increase of pressure, the fluid will flow through the trocar with the greatest freedom.

In addition to the constitutional signs and symptoms of fever, *acute spinal meningitis* exhibits certain characteristic features. Pain and tenderness to pressure along the vertebral column are common, and so are pains in the limbs or around the trunk from irritation of the posterior nerve roots by the inflammatory products. Irritation of the anterior nerve roots is shown by the increased tone of the muscles, which may go on to the point where they pass into a state of spasm with much increased reflexes; this is often seen in the retraction of the head and neck. Later in the disease the reflexes are often lost, when, also, the urine and feces may be passed involuntarily.

THE CEREBRAL NERVES (NERVI CEREBRALES; CRANIAL NERVES).

There are twelve pairs of cerebral nerves; they are attached to the brain and are transmitted through foramina in the base of the cranium. The different pairs are named from before backward as follows:

- | | |
|------------------|------------------------|
| 1st. Olfactory. | 7th. Facial. |
| 2d. Optic. | 8th. Acoustic. |
| 3rd. Oculomotor. | 9th. Glossopharyngeal. |
| 4th. Trochlear. | 10th. Vagus. |
| 5th. Trigeminal. | 11th. Accessory. |
| 6th. Abducent. | 12th. Hypoglossal. |

The area of attachment of a cerebral nerve to the surface of the brain is termed its **superficial or apparent origin**. The fibres of the nerve can be traced into the substance of the brain to a special *nucleus* of gray substance. The motor or efferent cerebral nerves arise within the brain from groups of nerve cells which constitute their **nuclei of origin**. The sensory or afferent cerebral nerves arise from groups of nerve cells outside the brain; these nerve cells may be grouped to form ganglia on the trunks of the nerves or may be situated in peripheral sensory organs such as the nose and eye. The central processes of these cells run into the brain, and there end by arborizing around nerve cells, which are grouped to form **nuclei of termination**. The nuclei of origin of the motor nerves and the nuclei of termination of the sensory nerves are brought into relationship with the cerebral cortex, the former through the geniculate fibres of the internal capsule, the latter through the lemniscus. The geniculate fibres arise from the cells of the motor area of the cortex, and, after crossing the middle line, end by arborizing around the cells of the nuclei of origin of the motor cerebral nerves. On the other hand, fibres arise from the cells of the nuclei of termination of the sensory nerves, and after crossing to the opposite side, join the lemniscus, and thus connect these nuclei, directly or indirectly, with the cerebral cortex.

THE OLFACTORY NERVES (NN. OLFACTORII; FIRST NERVE) (Fig. 771).

The **olfactory nerves** or nerves of smell are distributed to the mucous membrane of the olfactory region of the nasal cavity: this region comprises the superior nasal concha, and the corresponding part of the nasal septum. The nerves originate from the central or deep processes of the olfactory cells of the nasal mucous membrane. They form a plexiform net-work in the mucous membrane, and are then collected into about twenty branches, which pierce the cribriform plate of the ethmoid bone in two groups, a **lateral** and a **medial group**, and end in the glomeruli

FIG. 771.—Nerves of septum of nose. Right side.

FIG. 772.—Plan of olfactory neurons

of the olfactory bulb (Fig. 772). Each branch receives tubular sheaths from the dura mater and pia mater, the former being lost in the periosteum of the nose, the latter in the neurolemma of the nerve.

The olfactory nerves are non-medullated, and consist of axis-cylinders surrounded by nucleated sheaths, in which, however, there are fewer nuclei than are found in the sheaths of ordinary non-medullated nerve fibres.

The olfactory centre in the cortex is generally associated with the rhinencephalon (page 874).

Applied Anatomy.—In severe injuries to the head involving the anterior fossa of the base of the skull, the olfactory bulb may become separated from the olfactory nerves, or the nerves may be torn, thus producing loss of smell (*anosmia*), and with this there is a considerable loss in the sense of taste, since much of the perfection of the sense of taste is due to the substances being also odorous, and simultaneously exciting the sense of smell.

Anosmia often occurs after influenza or other acute infection of the nose. Parosmia, or a perversion of the sense of smell, may occur in lesions of the cortical olfactory centres, or in insanity.

THE OPTIC NERVE (N. OPTICUS; SECOND NERVE) (Fig. 773).

The optic nerve, or nerve of sight, is distributed exclusively to the bulb of the eye. The nerves of opposite sides are connected together at the optic chiasma, and from the back of the chiasma the nerve fibres may be traced to the brain, in the optic tracts.

The optic tract, at its connection with the brain, is divided into two bands, lateral and medial. The lateral band is larger; it is connected with the lateral geniculate body, the pulvinar of the thalamus and the superior colliculus. The medial band ends in the medial geniculate body; its fibres are merely commissural, forming Gudden's commissure. From these attachments the tract winds obliquely across the under surface of the cerebral peduncle in the form of a flattened band, and is attached to the peduncle by its anterior margin. It then assumes a cylindrical form, and, as it passes forward, is connected with the tuber cinereum and lamina terminalis. It finally joins with the tract of the opposite side to form the optic chiasma.

FIG. 773.—The left optic nerve and the optic tract.

The optic chiasma (*chiasma opticum*), somewhat quadrilateral in form, rests upon the tuberculum sellae and on the anterior part of the diaphragma sellae. It is in relation, *above*, with the lamina terminalis; *behind*, with the tuber cinereum; on *either side*, with the anterior perforated substance. Within the chiasma, the optic nerves undergo a partial decussation. The fibres forming the medial part of each tract and posterior part of the chiasma have no connection with the optic nerves. They simply cross in the chiasma, and connect the medial geniculate bodies of the two sides; they form the **commissure of Gudden**. The remaining and principal part of the chiasma consists of two sets of fibres, crossed and uncrossed. The **crossed fibres** which are the more numerous, occupy the central part of the chiasma, and pass from the optic nerve of one side to the optic tract of the other. decussating in the chiasma with similar fibres of the opposite optic nerve. The **uncrossed fibres** occupy the lateral part of the chiasma, and pass from the nerve of one side into the tract of the same side.¹

The great majority of the fibres of the optic nerve (Fig. 774) consist of the afferent fibres of nerve cells in the retina; a few, however, are efferent fibres, and grow out from cells in the brain. They become medullated about the tenth week after birth. The afferent fibres end in arborizations around the cells in the lateral geniculate body, pulvinar, and superior colliculus, which constitute the **lower visual centres**. From the cells of these centres fibres are prolonged to the **cortical visual centre**, situated in the cuneus and in the neighborhood of the calcarine fissure.

¹ A specimen of congenital absence of the optic chiasma is to be found in the Museum of the Westminster Hospital. See also Henle, *Nervenhiste*, p. 393, ed. 2.

Some fibres are detached from the optic tract, and pass through the cerebral peduncle to the nucleus of the oculomotor nerve. These fibres are small, and may be regarded as afferent branches for the Sphincter pupillae and Ciliaris muscles. Other fibres pass to the cerebellum through the brachia conjunctiva, while others end in the nuclei in the pons.

The **optic nerves** arise from the forepart of the chiasma, and, diverging from one another, each becomes rounded in form and firm in texture, and is enclosed in a sheath derived from the pia mater and arachnoid. The nerve passes beneath the anterior cerebral artery, and enters the optic foramen, receiving as it does so

a sheath from the dura mater. When the nerve reaches the orbit this sheath divides into two layers, one of which becomes continuous with the periosteum of the orbit; the other forms the proper sheath of the nerve, and surrounds it as far as the bulb of the eye. The nerve runs forward and lateralward through the cavity of the orbit, pierces the sclera and choroid at the back part of the bulb of the eye, about 3 to 4 mm. to the nasal side of its centre, and expands to form the **stratum opticum of the retina**. A little behind the bulb of the eye the arteria centralis retinae perforates the optic nerve, and runs along its interior in a tubular canal of fibrous tissue. It supplies the retina, and is accompanied by corresponding veins. The retina is described with the anatomy of the eyeball.

Applied Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affection of the central nervous system, and as a rule the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease. (1) From its mode of development, and from its structure, the optic nerve must be regarded as a prolongation of the brain substance, rather than as an ordinary cerebrospinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes, a perineural sheath from the pia mater, an intermediate sheath from the arachnoid, and an outer sheath from the dura mater, which is also connected with the periosteum as it passes through the optic foramen. These sheaths are separated from each other by cavities which communicate with the subdural and subarachnoid cavities respectively. The innermost or perineural sheath sends a process around the arteria centralis retinae into the interior of the nerve, and enters intimately into its structure. Thus inflammatory affections of the meninges or of the brain may readily extend along these spaces, or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic chiasma has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each optic tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time Charcot believes, and his view has met with general acceptance, that the fibres which do not decussate at the optic chiasma undergo decussation in the corpora quadrigemina, so that the lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed; whereas if one tract, say the right, be destroyed by disease, there will be blindness of the right half of both retine.

An antero-posterior section through the chiasma would divide the decussating fibres, and would therefore produce blindness of the medial half of each eye; while a section at the margin of the side of the optic chiasma would produce blindness of the lateral half of the retina of the same side. An early symptom of tumor growth in the hypophysis is pressure on the chiasma.

The optic nerve may also be affected in injuries or diseases involving the orbit; in fractures of the anterior fossa of the base of the skull; in tumors of the orbit itself, or those invading this cavity from neighboring parts.

THE OCULOMOTOR NERVE (N. OCULOMOTORIUS; THIRD NERVE)

(Figs. 776, 777, 778).

The **oculomotor nerve** supplies all the ocular muscles, except the Obliquus superior and Rectus lateralis; it also supplies through its connections with the ciliary ganglion, the Sphincter pupillae and the Ciliaris muscles.

The fibres of the oculomotor nerve arise from a nucleus which lies in the gray substance of the floor of the cerebral aqueduct and extends in front of the aqueduct a short distance into the floor of the third ventricle. From this nucleus the fibres pass forward through the tegmentum, the red nucleus, and the medial part of the substantia nigra, forming a series of curves with a lateral convexity, and emerge from the oculomotor sulcus on the medial side of the cerebral peduncle.

The nucleus of the oculomotor nerve does not consist of a continuous column of cells, but is broken up into a number of smaller nuclei, which are arranged in two groups, anterior and posterior. Those of the posterior group are six in number, five of which are symmetrical on the two sides of the middle line, while the sixth, centrally placed and is common to the nerves of both sides. The anterior group consists of two nuclei, an antero-medial and an antero-lateral (Fig. 775).

The nucleus of the third nerve is said to give fibres to the facial nerve, which probably supply the Orbicularis oculi, Corrugator, and Frontalis muscles.¹ It is also connected with the nuclei of the trochlear and abducent nerves, with the cerebellum, the superior colliculus, and the cortex of the occipital lobe of the cerebrum.

The nucleus of the oculomotor nerve, considered from a physiological standpoint, can be subdivided into several smaller groups of cells, each group controlling a

¹ See footnote, p. 852.

particular muscle. The nerves to the different muscles appear to take their origin from behind forward, as follows: Obliquus inferior, Rectus inferior, Rectus superior, Levator palpebrae superioris, and Rectus medialis; while from the anterior end of the nucleus the fibres for the Ciliaris and the Sphincter pupillae take their origin.

FIG. 775.—Figure showing the different groups of cells, which constitute, according to Perlia, the nucleus of origin of the oculomotor nerve. (Testut.) 1. Posterior dorsal nucleus. 1'. Posterior ventral nucleus. 2. Anterior dorsal nucleus. 2'. Anterior ventral nucleus. 3. Central nucleus. 4. Nucleus of Edinger and Westphal. 5. Antero-internal nucleus. 6. Antero-external nucleus. 8. Crossed fibres. 9. Trochlear nerve, with 9', its nucleus of origin, and 9'', its decussation. 10. Third ventricle. M, M. Median line.

On emerging from the brain, the nerve is invested with a sheath of pia mater, and enclosed in a prolongation from the arachnoid. It passes between the superior cerebellar and posterior cerebral arteries, and then pierces the dura mater in front of and lateral to the posterior clinoid process, passing between the free and attached borders of the tentorium cerebelli. It runs along the lateral wall of the cavernous sinus, above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic, and a communicating branch from the ophthalmic division of the trigeminal. It then divides into two branches, which enter the orbit through the superior orbital fissure, between the two heads of the Rectus lateralis. Here the nerve is placed below the trochlear nerve and the frontal and lacrimal branches of the ophthalmic nerve, while the nasociliary nerve is placed between its two rami.

The **superior ramus**, the smaller, passes medialward over the optic nerve, and supplies the Rectus superior and Levator palpebrae superioris. The **inferior ramus**, the larger, divides into three branches. One passes beneath the optic nerve to the Rectus medialis; another, to the Rectus inferior; the third and

longest runs forward between the Recti inferior and lateralis to the Obliquus inferior. From the last a short thick branch is given off to the lower part of the

FIG. 776.—Plan of oculomotor nerve.

ciliary ganglion, and forms its **short root**. All these branches enter the muscles on their ocular surfaces, with the exception of the nerve to the Obliquus inferior, which enters the muscle at its posterior border.

Applied Anatomy.—Paralysis of the oculomotor nerve may be the result of many causes, such as cerebral disease; or conditions causing pressure on the cavernous sinus; or periostitis of the bones entering into the formation of the superior orbital fissure. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebrae superioris being paralyzed; (2) external strabismus, on account of the unopposed action of the Rectus lateralis and Obliquus superior, which are not supplied by the oculomotor nerve and are therefore not paralyzed; (3) dilatation of the pupil, because the Sphincter pupillae is paralyzed; (4) loss of power of accommodation and of contraction on exposure to light, as the Sphincter pupillae and the Ciliaris are paralyzed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed; and (6) the patient will complain of the resulting diplopia, or double vision, the false image being higher than the true, and the separation of the two images increasing with medial movements. Occasionally paralysis may affect only a part of the nerve—that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Rectus medialis; accommodation for near objects only, from spasm of the Ciliaris; or miosis (contraction of the pupil) from irritation of the Sphincter pupillae.

The oculomotor nerve is particularly liable to become involved in a syphilitic periarteritis as it leaves the base of the brain, when passing between the posterior cerebral and superior cerebellar arteries; associated with locomotor ataxia various partial or complete paralyses of the nerve are often seen.

THE TROCHLEAR NERVE (N. TROCHLEARIS; FOURTH NERVE) (Fig. 777).

The trochlear nerve, the smallest of the cerebral nerves, supplies the Obliquus superior oculi.

It arises from a nucleus situated in the floor of the cerebral aqueduct, opposite the upper part of the inferior colliculus. From its origin it runs downward through the tegmentum, and then turns backward into the upper part of the anterior medullary velum. Here it decussates with its fellow of the opposite side and emerges from the surface of the velum at the side of the frenulum veli, immediately behind the inferior colliculus.

The nerve is directed across the brachium conjunctiva cerebelli, and then winds forward around the cerebral peduncle, immediately above the pons, pierces the dura mater in the free border of the tentorium cerebelli, just behind, and lateral to, the posterior clinoid process, and passes forward in the lateral wall of the cavernous sinus, between the oculomotor nerve and the ophthalmic division of the trigeminal. It crosses the oculomotor nerve, and enters the orbit through the superior orbital fissure. It now becomes the highest of all the nerves, and lies medial to the frontal nerve. In the orbit it passes medialward, above the origin of the Levator palpebrae superioris, and finally enters the orbital surface of the Obliquus superior.

In the lateral wall of the cavernous sinus the trochlear nerve forms communications with the ophthalmic division of the trigeminal and with the cavernous plexus

*Infra-
trochlear
nerve*

Sensory root *dura mater*

FIG. 777.—Nerves of the orbit. Seen from above.

of the sympathetic. In the superior orbital fissure it occasionally gives off a branch to the lacrimal nerve. It gives off a recurrent branch which passes backward between the layers of the tentorium cerebelli and divides into two or three filaments which may be traced as far as the wall of the transverse sinus.

Applied Anatomy.—When the trochlear nerve is paralyzed there is loss of function in the Obliquus superior, so that the patient is unable to turn his eye downward and outward. Should the patient attempt to do this, the eye of the affected side is rotated inward, producing diplopia or double vision. Single vision exists in the whole of the field so long as the eyes look above the horizontal plane, but diplopia occurs on looking downward. To counteract this the patient holds his head forward, and also inclines it to the sound side.

THE TRIGEMINAL NERVE (N. TRIGEMINUS; FIFTH OR TRIFACIAL NERVE).

The **trigeminal nerve** is the largest cerebral nerve and is the great sensory nerve of the head and face, and the motor nerve of the muscles of mastication.

It emerges from the side of the pons, near its upper border, by a small *motor* and a large *sensory root*—the former being situated in front of and medial to the latter.

Motor Root.—The fibres of the motor root *arise* from two nuclei, a superior and an inferior. The **superior nucleus** consists of a strand of cells occupying the whole length of the lateral portion of the gray substance of the cerebral aqueduct. The **inferior** or **chief nucleus** is situated in the upper part of the pons, close to its dorsal surface, and along the line of the lateral margin of the rhomboid fossa. The fibres from the superior nucleus constitute the **mesencephalic root**: they descend through the mesencephalon, and, entering the pons, join with the fibres from the lower nucleus, and the motor root, thus formed, passes forward through the pons to its point of emergence.

Sensory Root.—The fibres of the sensory root *arise* from the cells of the semilunar ganglion which lies in a cavity of the dura mater near the apex of the petrous part of the temporal bone. They pass backward below the superior petrosal sinus and tentorium cerebelli, and, entering the pons, divide into upper and lower roots. The upper root ends partly in a nucleus which is situated in the pons lateral to the lower motor nucleus, and partly in the locus caeruleus; the lower root descends through the pons and medulla oblongata, and ends in the upper part of the substantia gelatinosa of Rolando. This lower root is sometimes named the **spinal root** of the nerve. Medullation of the fibres of the sensory root begins about the fifth month of fetal life, but the whole of its fibres are not medullated until the third month after birth.

The **semilunar ganglion** (*ganglion semilunare* [Gasser]; *Gasserian ganglion*) occupies a cavity (*cavum Meckelii*) in the dura mater covering the trigeminal impression near the apex of the petrous part of the temporal bone. It is somewhat crescentic in shape, with its convexity directed forward: medially, it is in relation with the internal carotid artery and the posterior part of the cavernous sinus. The motor root runs in front of and medial to the sensory root, and passes beneath the ganglion; it leaves the skull through the foramen ovale, and, immediately below this foramen, joins the mandibular nerve. The greater superficial petrosal nerve lies also underneath the ganglion.

The ganglion receives, on its medial side, filaments from the carotid plexus of the sympathetic. It gives off minute branches to the tentorium cerebelli, and to the dura mater in the middle fossa of the cranium. From its convex border, which is directed forward and lateralward, three large nerves proceed, viz., the **ophthalmic**, **maxillary**, and **mandibular**. The ophthalmic and maxillary consist exclusively of sensory fibres; the mandibular is joined outside the cranium by the motor root.

Associated with the three divisions of the trigeminal nerve are four small ganglia. The **ciliary ganglion** is connected with the ophthalmic nerve; the **sphenopalatine ganglion** with the maxillary nerve; and the **otic** and **submaxillary ganglia** with the mandibular nerve. All four receive sensory filaments from the trigeminal, and motor and sympathetic filaments from various sources; these filaments are called the **roots of the ganglia**.

The **ophthalmic nerve** (*n. ophthalmicus*) (Figs. 777, 778), or **first division** of the trigeminal, is a sensory nerve. It supplies branches to the cornea, ciliary body, and iris; to the lacrimal gland and conjunctiva; to the part of the mucous membrane of the nasal cavity; and to the skin of the eyelids, eyebrow, forehead, and nose. It is the smallest of the three divisions of the trigeminal, and *arises* from the upper part of the semilunar ganglion as a short, flattened band, about 2.5 cm. long, which passes forward along the lateral wall of the cavernous sinus, below the oculomotor and trochlear nerves; just before entering the orbit, through the superior orbital fissure, it divides into three branches, **lacrimal**, **frontal**, and **nasociliary**.

*Sensory
root*
Motor root

FIG. 778.—Nerves of the orbit, and the ciliary ganglion. Side view

The ophthalmic nerve is joined by filaments from the cavernous plexus of the sympathetic, and communicates with the oculomotor, trochlear, and abducent nerves; it gives off a recurrent filament which passes between the layers of the tentorium.

The **Lacrimal Nerve** (*n. lacrimalis*) is the smallest of the three branches of the ophthalmic. It sometimes receives a filament from the trochlear nerve, but this is possibly derived from the branch which goes from the ophthalmic to the trochlear nerve. It passes forward in a separate tube of dura mater, and enters the orbit through the narrowest part of the superior orbital fissure. In the orbit it runs along the upper border of the Rectus lateralis, with the lacrimal artery, and communicates with the zygomatic branch of the maxillary nerve. It enters the lacrimal gland and gives off several filaments, which supply the gland and the conjunctiva. Finally it pierces the orbital septum, and ends in the skin of the upper eyelid, joining with filaments of the facial nerve. The lacrimal nerve is occasionally absent, and its place is then taken by the zygomaticotemporal branch of the maxillary. Sometimes the latter branch is absent, and a continuation of the lacrimal is substituted for it.

The **Frontal Nerve** (*n. frontalis*) is the largest branch of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit through the superior orbital fissure, and runs forward between the Levator palpebrae superioris and the periosteum. Midway between the apex and base of the orbit it divides into two branches, **supratrochlear** and **supraorbital**.

The **supratrochlear nerve** (*n. supratrochlearis*), the smaller of the two, passes above the pulley of the Obliquus superior, and gives off a descending filament, to join the infratrochlear branch of the nasociliary nerve. It then escapes from the orbit between the pulley of the Obliquus superior and the supraorbital foramen, curves up on to the forehead close to the bone, ascends beneath the Corrugator and Frontalis, and dividing into branches which pierce these muscles, it supplies the skin of the lower part of the forehead close to the middle line and sends filaments to the conjunctiva and skin of the upper eyelid.

The **supraorbital nerve** (*n. supraorbitalis*) passes through the supraorbital foramen, and gives off, in this situation, palpebral filaments to the upper eyelid. It then ascends upon the forehead, and ends in two branches, a medial and a lateral, which supply the integument of the scalp, reaching nearly as far back as the lambdoidal suture; they are at first situated beneath the Frontalis, the medial branch perforating the muscle, the lateral branch the galea aponeurotica. Both branches supply small twigs to the pericranium.

The **Nasociliary Nerve** (*n. nasociliaris*; *nasal nerve*) is intermediate in size between the frontal and lacrimal, and is more deeply placed. It enters the orbit between the two heads of the Rectus lateralis, and between the superior and inferior rami of the oculomotor nerve. It passes across the optic nerve and runs obliquely beneath the Rectus superior and Obliquus superior, to the medial wall of the orbital cavity. Here it passes through the anterior ethmoidal foramen, and, entering the cavity of the cranium, traverses a shallow groove on the lateral margin of the front part of the cribriform plate of the ethmoid bone, and runs down, through a slit at the side of the crista galli, into the nasal cavity. It supplies **internal nasal branches** to the mucous membrane of the front part of the septum and lateral wall of the nasal cavity. Finally, it emerges, as the **external nasal branch**, between the lower border of the nasal bone and the lateral nasal cartilage, and, passing down beneath the Nasalis muscle, supplies the skin of the ala and apex of the nose.

The nasociliary nerve gives off the following branches, viz.: the **long root of the ciliary ganglion**, the **long ciliary**, and the **ethmoidal nerves**.

The **long root of the ciliary ganglion** (*radix longa ganglii ciliaris*) usually arises from the nasociliary between the two heads of the Rectus lateralis. It passes forward on the lateral side of the optic nerve, and enters the postero-superior angle of the ciliary ganglion; it is sometimes joined by a filament from the cavernous plexus of the sympathetic, or from the superior ramus of the trochlear nerve.

The **long ciliary nerves** (*nn. ciliares longi*), two or three in number, are given off from the nasociliary, as it crosses the optic nerve. They accompany the short ciliary nerves from the ciliary ganglion, pierce the posterior part of the sclera, and running forward between it and the choroid, are distributed to the Ciliaris muscle, iris, and cornea.

The **infratrochlear nerve** (*n. infratrochlearis*) is given off from the nasociliary just before it enters the anterior ethmoidal foramen. It runs forward along the upper border of the Rectus medialis, and is joined, near the pulley of the Obliquus superior, by a filament from the supratrochlear nerve. It then passes to the medial angle of the eye, and supplies the skin of the eyelids and side of the nose, the conjunctiva, lacrimal sac, and caruncula lacrimalis.

The **ethmoidal branches** (*nn. ethmoidales*) supply the ethmoidal cells; the posterior branch leaves the orbital cavity through the posterior ethmoidal foramen and gives some filaments to the sphenoidal sinus.

The Ciliary Ganglion (*ganglion ciliare; ophthalmic or lenticular ganglion*) (Figs. 776, 778).—The ciliary ganglion is a small, quadrangular, flattened ganglion, of a reddish-gray color, and about the size of a pin's head; it is situated at the back part of the orbit, in some loose fat between the optic nerve and the Rectus lateralis muscle, lying generally on the lateral side of the ophthalmic artery.

Its **roots** are three in number, and enter its posterior border. One, the long or sensory root, is derived from the nasociliary nerve, and joins its postero-superior angle. The second, the short or motor root, is a thick nerve (occasionally divided into two parts) derived from the branch of the oculomotor nerve to the Obliquus inferior, and connected with the postero-inferior angle of the ganglion. The third, the sympathetic root, is a slender filament from the cavernous plexus of the sympathetic; it is frequently blended with the long root. According to Tiedemann, the ciliary ganglion receives a twig of communication from the sphenopalatine ganglion.

Its **branches** are the **short ciliary nerves**. These are delicate filaments, from six to ten in number, which *arise* from the forepart of the ganglion in two bundles connected with its superior and inferior angles; the lower bundle is the larger. They run forward with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are accompanied by the long ciliary nerves from the nasociliary. They pierce the sclera at the back part of the bulb of the eye, pass forward in delicate grooves on the inner surface of the sclera, and are distributed to the Ciliaris muscle, iris, and cornea. Tiedemann has described a small branch as penetrating the optic nerve with the *arteria centralis retinae*.

The **maxillary nerve** (*n. maxillaris; superior maxillary nerve*) (Fig. 779), or **second division** of the trigeminal, is a sensory nerve. It is intermediate, both in position and size, between the ophthalmic and mandibular. It begins at the middle of the semilunar ganglion as a flattened plexiform band, and, passing horizontally forward, it leaves the skull through the foramen rotundum, where it becomes more cylindrical in form, and firmer in texture. It then crosses the pterygopalatine fossa, inclines lateralward on the back of the maxilla, and enters the orbit through the inferior orbital fissure; it traverses the infraorbital groove and canal in the floor of the orbit, and appears upon the face at the infraorbital foramen.¹ At its termination, the nerve lies beneath the Quadratus labii superioris, and divides into a leash of branches which spread out upon the side of the nose, the lower eyelid, and the upper lip, joining with filaments of the facial nerve.

Branches.—Its branches may be divided into four groups, according as they are given off in the **cranium**, in the **pterygopalatine fossa**, in the **infraorbital canal**, or on the **face**.

In the Cranium	Middle meningeal.
In the Pterygopalatine Fossa	{ Zygomatic.
	{ Sphenopalatine.
	{ Posterior superior alveolar.
In the Infraorbital Canal	{ Anterior superior alveolar.
	{ Middle superior alveolar.
	{ Inferior palpebral.
On the Face	{ External nasal.
	{ Superior labial.

The **Middle Meningeal Nerve** (*n. meningeus medius; meningeal or dural branch*) is given off from the maxillary nerve directly after its origin from the semilunar ganglion; it accompanies the middle meningeal artery and supplies the dura mater.

The **Zygomatic Nerve** (*n. zygomaticus; temporomalar nerve; orbital nerve*) arises in the pterygopalatine fossa, enters the orbit by the inferior orbital fissure,

¹ After it enters the infraorbital canal, the nerve is frequently called the *infraorbital*.

and divides at the back of that cavity into two branches, **zygomaticotemporal** and **zygomaticofacial**.

The **zygomaticotemporal branch** (*ramus zygomaticotemporalis; temporal branch*) runs along the lateral wall of the orbit in a groove in the zygomatic bone, receives a branch of communication from the lacrimal, and, passing through a foramen in the zygomatic bone, enters the temporal fossa. It ascends between the bone, and substance of the Temporalis muscle, pierces the temporal fascia about 2.5 cm. above the zygomatic arch, and is distributed to the skin of the side of the forehead, and communicates with the facial nerve and with the auriculotemporal branch of the mandibular nerve. As it pierces the temporal fascia, it gives off a slender twig, which runs between the two layers of the fascia to the lateral angle of the orbit.

FIG. 779.—Distribution of the maxillary and mandibular nerves, and the submaxillary ganglion.

The **zygomaticofacial branch** (*ramus zygomaticofacialis; malar branch*) passes along the infero-lateral angle of the orbit, emerges upon the face through a foramen in the zygomatic bone, and, perforating the Orbicularis oculi, supplies the skin on the prominence of the cheek. It joins with the facial nerve and with the inferior palpebral branches of the maxillary.

The **Sphenopalatine Branches** (*nn. sphenopalatini*), two in number, descend to the sphenopalatine ganglion.

The **Posterior Superior Alveolar Branches** (*rami alveolares superiores posteriores; posterior superior dental branches*) arise from the trunk of the nerve just before it enters the infraorbital groove; they are generally two in number, but sometimes arise by a single trunk. They descend on the tuberosity of the maxilla and give off

several twigs to the gums and neighboring parts of the mucous membrane of the cheek. They then enter the posterior alveolar canals on the infratemporal surface of the maxilla, and, passing from behind forward in the substance of the bone, communicate with the middle superior alveolar nerve, and give off branches to the lining membrane of the maxillary sinus and three twigs to each molar tooth; these twigs enter the foramina at the apices of the roots of the teeth.

The **Middle Superior Alveolar Branch** (*ramus alveolaris superior medius; middle superior dental branch*), is given off from the nerve in the posterior part of the infra-orbital canal, and runs downward and forward in a canal in the lateral wall of the maxillary sinus to supply the two premolar teeth. It forms a superior dental plexus with the anterior and posterior superior alveolar branches.

The **Anterior Superior Alveolar Branch** (*ramus alveolaris superior anteriores; anterior superior dental branch*), of considerable size, is given off from the nerve just before its exit from the infraorbital foramen; it descends in a canal in the anterior wall of the maxillary sinus, and divides into branches which supply the incisor and canine teeth. It communicates with the middle superior alveolar branch, and gives off a **nasal branch**, which passes through a minute canal in the lateral wall of the inferior meatus, and supplies the mucous membrane of the anterior part of the inferior meatus and the floor of the nasal cavity, communicating with the nasal branches from the sphenopalatine ganglion.

The **Inferior Palpebral Branches** (*rami palpebrales; inferiores palpebral branches*) ascend behind the Orbicularis oculi. They supply the skin and conjunctiva of the lower eyelid, joining at the lateral angle of the orbit with the facial and zygomatico-facial nerves.

The **External Nasal Branches** (*rami nasales externi*) supply the skin of the side of the nose and of the septum mobile nasi, and join with the terminal twigs of the nasociliary nerve.

The **Superior Labial Branches** (*rami labiales superiores; labial branches*), the largest and most numerous, descend behind the Quadratus labii superioris, and are distributed to the skin of the upper lip, the mucous membrane of the mouth, and labial glands. They are joined, immediately beneath the orbit, by filaments from the facial nerve, forming with them the **infraorbital plexus**.

Sphenopalatine Ganglion (*ganglion sphenopalatinum; ganglion of Meckel*) (Fig. 780).—The sphenopalatine ganglion, the largest of the ganglia associated with the branches of the trigeminal nerve, is deeply placed in the pterygopalatine fossa, close to the sphenopalatine foramen. It is triangular or heart-shaped, of a reddish-gray color, and is situated just below the maxillary nerve as it crosses the fossa. It receives a sensory, a motor, and a sympathetic root.

Its **sensory root** is derived from two sphenopalatine branches of the maxillary nerve; their fibres, for the most part, pass directly into the palatine nerves; a few, however, enter the ganglion, constituting its sensory root. Its **motor root** is probably derived from the facial nerve through the greater superficial petrosal nerve and its **sympathetic root** from the carotid plexus through the deep petrosal nerve. These two nerves join to form the nerve of the pterygoid canal, before their entrance into the ganglion.

The **greater superficial petrosal nerve** (*n. petrosus superficialis major; large superficial petrosal nerve*) is given off from the genicular ganglion of the facial nerve; it passes through the hiatus of the facial canal, enters the cranial cavity, and runs forward beneath the dura mater in a groove on the anterior surface of the petrous portion of the temporal bone. It then enters the cartilaginous substance which fills the foramen lacerum, and joining with the deep petrosal branch forms the nerve of the pterygoid canal.

The **deep petrosal nerve** (*n. petrosus profundus; large deep petrosal nerve*) is given off from the carotid plexus, and runs through the carotid canal lateral to the internal

carotid artery. It then enters the cartilaginous substance which fills the foramen lacerum, and joins with the greater superficial petrosal nerve to form the nerve of the pterygoid canal.

The **nerve of the pterygoid canal** (*n. canalis pterygoidei* [Vidii]; *Vidian nerve*), formed by the junction of the two preceding nerves in the cartilaginous substance which fills the foramen lacerum, passes forward, through the pterygoid canal, with the corresponding artery, and is joined by a small ascending sphenoidal branch from the otic ganglion. Finally, it enters the pterygopalatine fossa, and joins the posterior angle of the pterygopalatine ganglion.

FIG. 780.—The sphenopalatine ganglion and its branches.

Branches of Distribution.—These are divisible into four groups, viz., orbital, palatine, posterior, superior nasal, and pharyngeal.

The **orbital branches** (*rami orbitales; ascending branches*) are two or three delicate filaments, which enter the orbit by the inferior orbital fissure, and supply the periorbitum. According to Luschka, some filaments pass through foramina in the fronto-ethmoidal suture to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

The **palatine nerves** (*nn. palatini; descending branches*) are distributed to the roof of the mouth, soft palate, tonsil, and lining membrane of the nasal cavity. Most of their fibres are derived from the sphenopalatine branches of the maxillary nerve. They are three in number: **anterior, middle, and posterior.**

The **anterior palatine nerve** (*n. palatinus anterior*) descends through the pterygopalatine canal, emerges upon the hard palate through the greater palatine foramen, and passes forward in a groove in the hard palate, nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the terminal filaments of the nasopalatine nerve. While in the pterygopalatine canal, it gives off **posterior inferior nasal branches**, which enter the nasal cavity through openings in the palatine bone, and ramify

over the inferior nasal concha and middle and inferior meatuses; at its exit from the canal, a palatine branch is distributed to both surfaces of the soft palate.

The **middle palatine nerve** (*n. palatinus medius*) emerges through one of the minor palatine canals and distributes branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The **posterior palatine nerve** (*n. palatinus posterior*) descends through the pterygo-palatine canal, and emerges by a separate opening behind the greater palatine foramen; it supplies the soft palate, tonsil, and uvula. The middle and posterior palatine join with the tonsillar branches of the glossopharyngeal to form a plexus (*circulus tonsillaris*) around the tonsil.

The **posterior superior nasal branches** (*rami nasales posteriores superiores*) are distributed to the septum and lateral wall of the nasal fossa. They enter the posterior part of the nasal cavity by the sphenopalatine foramen and supply the mucous membrane covering the superior and middle nasal conchæ, the lining of the posterior ethmoidal cells, and the posterior part of the septum. One branch, longer and larger than the others, is named the **nasopalatine nerve**. It enters the nasal cavity through the sphenopalatine foramen, passes across the roof of the nasal cavity below the orifice of the sphenoidal sinus to reach the septum, and then runs obliquely downward and forward between the periosteum and mucous membrane of the lower part of the septum. It descends to the roof of the mouth through the incisive canal and communicates with the corresponding nerve of the opposite side and with the anterior palatine nerve. It furnishes a few filaments to the mucous membrane of the nasal septum.

The **pharyngeal nerve** (*pterygopalatine nerve*) is a small branch arising from the posterior part of the ganglion. It passes through the pharyngeal canal with the pharyngeal branch of the internal maxillary artery, and is distributed to the mucous membrane of the nasal part of the pharynx, behind the auditory tube.

The **mandibular nerve** (*n. mandibularis; inferior maxillary nerve*) (Figs. 779, 781) supplies the teeth and gums of the mandible, the skin of the temporal region, the auricula, the lower lip, the lower part of the face, and the muscles of mastication; it also supplies the mucous membrane of the anterior two-thirds of the tongue. It is the largest of the three divisions of the fifth, and is made up of two roots: a large, **sensory root** proceeding from the inferior angle of the semilunar ganglion, and a small **motor root** (the motor part of the trigeminal), which passes beneath the ganglion, and unites with the sensory root, just after its exit through the foramen ovale. Immediately beneath the base of the skull, the nerve gives off from its medial side a recurrent branch (*nervus spinosus*) and the nerve to the Pterygoideus internus, and then divides into two trunks, an anterior and a posterior.

The **Nervus Spinosus** (*recurrent or meningeal branch*) enters the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura mater; the posterior branch also supplies the mucous lining of the mastoid cells; the anterior communicates with the meningeal branch of the maxillary nerve.

The **Internal Pterygoid Nerve** (*n. pterygoideus internus*).—The nerve to the Pterygoideus internus is a slender branch, which enters the deep surface of the muscle; it gives off one or two filaments to the otic ganglion.

The anterior and smaller division of the mandibular nerve receives nearly the whole of the fibres of the motor root of the nerve, and supplies the muscles of mastication and the skin and mucous membrane of the cheek. Its branches are the **masseteric**, **deep temporal**, **buccinator**, and **external pterygoid**.

The **Masseteric Nerve** (*n. massetericus*) passes lateralward, above the Pterygoideus externus, in front of the temporomandibular articulation, and behind the tendon of the Temporalis; it crosses the mandibular notch with the masseteric artery,

to the deep surface of the Masseter, in which it ramifies nearly as far as its anterior border. It gives a filament to the temporomandibular joint.

The **Deep Temporal Nerves** (*nn. temporales profundi*) are two in number, anterior and posterior. They pass above the upper border of the Pterygoideus externus and enter the deep surface of the Temporalis. The **posterior branch**, of small size, is placed at the back of the temporal fossa, and sometimes arises in common with the masseteric nerve. The **anterior branch** is frequently given off from the buccinator nerve, and then turns upward over the upper head of the Pterygoideus externus. Frequently a third or intermediate branch is present.

Auriculotemporal

Deep temporal

A
Sphæ
In
R

FIG. 781.—The Pterygoideus externus and the branches of the mandibular nerve in relation to it.

The **Buccinator Nerve** (*n. buccinatorius*; *long buccal nerve*) passes forward between the two heads of the Pterygoideus externus, and downward beneath or through the lower part of the Temporalis; it emerges from under the anterior border of the Masseter, ramifies on the surface of the Buccinator, and unites with the buccal branches of the facial nerve. It supplies a branch to the Pterygoideus externus during its passage through that muscle, and may give off the anterior deep temporal nerve. The buccinator nerve supplies the skin over the Buccinator, and the mucous membrane lining its inner surface.

External Pterygoid Nerve (*n. pterygoideus externus*).—The nerve to the Pterygoideus externus frequently arises in conjunction with the buccinator nerve, but it may be given off separately from the anterior division of the mandibular nerve. It enters the deep surface of the muscle.

The posterior and larger division of the mandibular nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into **auriculotemporal**, **lingual**, and **inferior alveolar nerves**.

The **Auriculotemporal Nerve** (*n. auriculotemporalis*) generally arises by two roots, between which the middle meningeal artery ascends. It runs backward beneath the Pterygoideus externus to the medial side of the neck of the mandible. It then turns upward with the superficial temporal artery, between the auricula and condyle of the mandible, under cover of the parotid gland; escaping from beneath the gland, it ascends over the zygomatic arch, and divides into superficial temporal branches.

The **branches of communication** of the auriculotemporal nerve are with the facial nerve and with the otic ganglion. The branches to the facial, usually two in number, pass forward from behind the neck of the mandible and join the facial nerve at the posterior border of the Masseter. The filaments to the otic ganglion are derived from the roots of the auriculotemporal nerve close to their origin.

Its **branches of distribution** are:

Anterior auricular.

Branches to the external acoustic meatus.

Superficial temporal.

Articular.

Parotid.

The **anterior auricular branches** (*nn. auriculares anteriores*) are usually two in number; they supply the front of the upper part of the auricula, being distributed principally to the skin covering the front of the helix and tragus.

The **branches to the external acoustic meatus** (*n. meatus auditorii externi*), two in number, enter the meatus between its bony and cartilaginous portions and supply the skin lining it; the upper one sends a filament to the tympanic membrane.

The **articular branches** consist of one or two twigs which enter the posterior part of the temporomandibular joint.

The **parotid branches** (*rami parotidei*) supply the parotid gland.

The **superficial temporal branches** (*rami temporales superficiales*) accompany the superficial temporal artery to the vertex of the skull; they supply the skin of the temporal region and communicate with the facial and zygomaticotemporal nerves.

The **Lingual Nerve** (*n. lingualis*) supplies the mucous membrane of the anterior two-thirds of the tongue. It lies at first beneath the Pterygoideus externus, medial to and in front of the inferior alveolar nerve, and is occasionally joined to this nerve by a branch which may cross the internal maxillary artery. The chorda tympani also joins it at an acute angle in this situation. The nerve then passes between the Pterygoideus internus and the ramus of the mandible, and crosses obliquely to the side of the tongue over the Constrictor pharyngis superior and Styloglossus, and then between the Hyoglossus and deep part of the submaxillary gland; it finally runs across the duct of the submaxillary gland, and along the tongue to its tip, lying immediately beneath the mucous membrane.

Its **branches of communication** are with the facial (through the chorda tympani), the inferior alveolar and hypoglossal nerves, and the submaxillary ganglion. The branches to the submaxillary ganglion are two or three in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyoglossus.

Its **branches of distribution** supply the sublingual gland, the mucous membrane of the mouth, the gums, and the mucous membrane of the anterior two-thirds of the tongue; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve.

The **Inferior Alveolar Nerve** (*n. alveolaris inferior; inferior dental nerve*) is the largest branch of the mandibular nerve. It descends with the inferior alveolar artery, at first beneath the Pterygoideus externus, and then between the sphenomandibular ligament and the ramus of the mandible to the mandibular foramen. It then passes forward in the mandibular canal, beneath the teeth, as far as the mental foramen, where it divides into two terminal branches, incisive and mental.

The branches of the inferior alveolar nerve are the **mylohyoid**, **dental**, **incisive**, and **mental**.

The **mylohyoid nerve** (*n. mylohyoideus*) is derived from the inferior alveolar just before it enters the mandibular foramen. It descends in a groove on the deep surface of the ramus of the mandible, and reaching the under surface of the Mylohyoideus supplies this muscle and the anterior belly of the Digastricus.

The **dental branches** supply the molar and premolar teeth. They correspond in number to the roots of those teeth; each nerve entering the orifice at the point of the root, and supplying the pulp of the tooth; above the alveolar nerve they form an **inferior dental plexus**.

The **incisive branch** is continued onward within the bone, and supplies the canine and incisor teeth.

The **mental nerve** (*n. mentalis*) emerges at the mental foramen, and divides beneath the Triangularis muscle into three branches; one descends to the skin of the chin, and two ascend to the skin and mucous membrane of the lower lip; these branches communicate freely with the facial nerve.

Two small ganglia, the **otic** and the **submaxillary**, are connected with the mandibular nerve.

FIG. 782.—The otic ganglion and its branches.

Otic Ganglion (*ganglion oticum*) (Fig. 782).—The otic ganglion is a small, oval-shaped, flattened ganglion of a reddish-gray color, situated immediately below the foramen ovale; it lies on the medial surface of the mandibular nerve, and surrounds the origin of the nerve to the Pterygoideus internus. It is in relation, *laterally*, with the trunk of the mandibular nerve at the point where the motor and sensory roots join; *medially*, with the cartilaginous part of the auditory tube, and the origin of the Tensor veli palatini; *posteriorly*, with the middle meningeal artery.

Branches of Communication.—It is connected by two or three short filaments with the nerve to the Pterygoideus internus, from which it may obtain a motor, and possibly a sensory root. It communicates with the glossopharyngeal and facial nerves, through the lesser superficial petrosal nerve continued from the tympanic plexus, and through this nerve it probably receives a sensory root from the glossopharyngeal and a motor root from the facial; its sympathetic root consists of a filament from the plexus surrounding the middle meningeal artery. The ganglion

also communicates with the auriculotemporal nerve by a branch which is probably derived from the glossopharyngeal, and which passes to the ganglion, and then through it and auriculotemporal nerve to the parotid gland. A slender filament (*sphenoidal*) ascends from it to the nerve of the Pterygoid canal, and a small branch connects it with the chorda tympani.

Its **branches of distribution** are: a filament to the Tensor tympani, and one to the Tensor veli palatini. The former passes backward, lateral to the auditory tube; the latter arises from the ganglion, near the origin of the nerve to the Pterygoideus internus, and is directed forward. The fibres of these nerves are, however, mainly derived from the nerve to the Pterygoideus internus.

Submaxillary Ganglion (*ganglion submaxillare*) (Fig. 779).—The submaxillary ganglion is of small size and is fusiform in shape. It is situated above the deep portion of the submaxillary gland, on the hyoglossus, near the posterior border of the Mylohyoideus, and is connected by filaments with the lower border of the lingual nerve. It is suspended from the lingual nerve by two filaments which join the anterior and posterior parts of the ganglion. Through the posterior of these it receives a branch from the chorda tympani nerve which runs in the sheath of the lingual; it communicates with the sympathetic by filaments from the sympathetic plexus around the external maxillary artery.

Its **branches of distribution** are five or six in number; they *arise* from the lower part of the ganglion, and supply the mucous membrane of the mouth and the duct of the submaxillary gland, some being lost in the submaxillary gland. The branch of communication from the lingual to the forepart of the ganglion is by some regarded as a branch of distribution, through which filaments pass from the ganglion to the lingual nerve, and by it are conveyed to the sublingual gland and the tongue.

Applied Anatomy.—Paralysis of the trigeminal nerve causes anesthesia of the corresponding anterior half of the scalp, and of the face, excepting over a small area near the angle of the mandible supplied by the cervical nerves, and of the cornea and conjunctiva, and of the mucous membrane of the nose, mouth, and tongue. Taste is lost (*ageusia*) on the affected side. Paralysis and atrophy follow in the Temporalis, Masseter, and Pterygoidei, possibly also in the Tensor tympani; when the mouth is opened the mandible is thrust over toward the paralyzed side. Interference with the secretion of the tears, the nasal mucus, and the saliva, causes dryness of the corresponding mucous membranes. The sense of smell is gradually lost on the affected side from the trophic changes that follow in the nasal mucous membrane. Inflammation of the eyeball, under these circumstances known as *neuroparalytic ophthalmia*, is not rare, and is due to the dryness and insensitiveness of the conjunctiva; it is not a "trophic" phenomenon, but depends on the occurrence and neglect of traumatic inflammation in the anesthetic eye.

Trigeminal Nerve Reflexes.—Pains referred to various branches of the trigeminal nerve are of very frequent occurrence, and should always lead to a careful examination in order to discover a local cause. As a general rule the diffusion of pain over the various branches of the nerve is at first confined to one only of the main divisions, and the search for the causative lesion should always commence with a thorough examination of all those parts which are supplied by that division; although in severe cases pain may radiate over the branches of the other main divisions. The commonest example of this condition is the neuralgia which is so often associated with dental caries—here, although the tooth itself may not appear to be painful, the most distressing referred pains may be experienced, and these are at once relieved by treatment directed to the affected tooth.

Many other examples of trigeminal reflexes could be quoted, but it will be sufficient to mention the more common ones. Dealing with the ophthalmic nerve, severe supraorbital pain is commonly associated with acute glaucoma or with disease of the frontal or ethmoidal air cells. Malignant growths or empyema of the maxillary antrum, or unhealthy conditions about the inferior conchæ or the septum of the nose, are often found giving rise to "second division" neuralgia, and should be always looked for in the absence of dental disease in the maxilla.

It is on the mandibular nerve, however, that some of the most striking reflexes are seen. It is quite common to meet with patients who complain of pain in the ear, in whom there is no sign of aural disease, and the cause is usually to be found in a carious tooth in the mandible. Moreover, with an ulcer or cancer of the tongue, often the first pain to be experienced is one which radiates to the ear and temporal fossa, over the distribution of the auriculotemporal nerve.

The trigeminal nerve is often the seat of severe neuralgia for which no local cause can be discovered; each of the three divisions has been divided, or a portion of the nerve excised, for this affection, usually, however, with only temporary relief. The supraorbital nerve may be exposed by making an incision 4 cm. in length along the supraorbital margin, below the eyebrow which is to be drawn upward, the centre of the incision corresponding to the supraorbital notch. The skin and Orbicularis oculi having been divided, the nerve can be easily found emerging from the notch, and lying in some loose cellular tissue. It should be drawn up by a blunt hook and 1.25 cm. of it resected, or the nerve can be injected with absolute alcohol.

The infraorbital nerve has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infraorbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with sphenopalatine ganglion as far back as the foramen rotundum may be removed, but even then a return of the neuralgia in some other branches of the trigeminal nerve is the rule rather than the exception. The operation is performed as follows: the maxilla is first exposed by a T-shaped incision, one limb passing along the lower margin of the orbit, the other from the centre of this vertically down the cheek to the angle of the mouth. The nerve is to be found, divided, and a piece of silk tied to it as a guide. A small trephine (half-inch) is applied to the bone, below, but including the infraorbital foramen, and the maxillary sinus opened. The trephine is then applied to the posterior wall of the sinus, and the pterygo-palatine fossa exposed. The infraorbital canal is opened up from below, and the nerve drawn down into the trephine hole, and held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided.

FIG. 783.—Diagram showing cutaneous areas of face and scalp.

The inferior alveolar nerve can be reached by a transverse incision over the ramus of the mandible placed so as to avoid injury to the facial nerve; the Masseter having been divided, a small trephine is applied to the ramus immediately beneath the mandibular notch, and, when the bone has been removed, the nerve is found lying on the Pterygoideus internus just as it enters the mandibular foramen, and it can here be resected. The lingual nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line be drawn from the middle of the crown of the last molar tooth to the angle of the mandible it will cross the nerve, which lies about 1.25 cm. behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. The tongue should be pulled forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue, and after division of the mucous membrane can be easily seized with a hook and a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when the division is required, the operation is not practicable.

In severe cases of neuralgia of the trigeminal nerve, the semilunar ganglion has been removed in whole or in part with a considerable measure of success. Rose was the first to perform this operation; and he reached the ganglion by trephining the base of the skull in the position of the foramen ovale, after dividing the zygomatic arch, in front and behind, and turning it and the Masseter downward, and cutting through the coronoid process of the mandible, and turning it and the Temporalis upward. A more efficient method appears to be that known as the Krause-Hartley method. The bone forming the temporal fossa having been removed to a sufficient extent, the dura mater beneath the temporal lobe of the brain is gradually raised from the middle fossa, until the foramen spinosum, with the middle meningeal artery passing through it, is exposed. This vessel is to be ligatured in two places, and divided between the ligatures; and then by further raising the dura mater, the foramina ovale and rotundum will be exposed, with the mandibular and maxillary nerves passing through them. These nerves are to be clearly defined and divided. The dura mater is then to be raised from the ganglion, when the ophthalmic nerve will be exposed and must be divided, and the ganglion, by means of a little careful dissection, raised from its bed and removed. In some cases where the neuralgia has been limited to the maxillary nerve an intracranial resection of that nerve alone has been performed with great success. In other cases where the disease has not affected the ophthalmic division, resection of the lateral half of the ganglion only, with the maxillary and mandibular nerves, has been performed, thus leaving the sensory nerve supply to the cornea intact. The motor root is usually resected with the mandibular nerve, leading to complete paralysis of the muscles of mastication on that side.

THE ABDUCENT NERVE (N. ABDUCENS; SIXTH NERVE) (Fig. 778).

The abducent nerve supplies the Rectus lateralis oculi.

Its fibres arise from a small nucleus situated in the upper part of the rhomboid fossa, close to the middle line and beneath the colliculus facialis. They pass downward and forward through the pons, and emerge in the furrow between the lower border of the pons and the upper end of the pyramid of the medulla oblongata.

From the nucleus of the sixth nerve, fibres pass through the medial longitudinal fasciculus to the oculomotor nerve of the opposite side, along which they are carried to the Rectus medialis. The Rectus lateralis of one eye and the Rectus medialis of the other may therefore be said to receive their nerves from the same nucleus (Fig. 784).

The nerve pierces the dura mater on the dorsum sellae of the sphenoid, runs through a notch in the bone below the posterior clinoid process, and passes forward through the cavernous sinus, on the lateral side of the internal carotid artery. It enters the orbit through the superior orbital fissure, above the ophthalmic vein, from which it is separated by a lamina of dura mater. It then passes between the two heads of the Rectus lateralis, and enters the ocular surface of that muscle. The abducent nerve is joined by several filaments from the carotid and cavernous plexuses, and by one from the ophthalmic nerve. The oculomotor, trochlear, ophthalmic, and abducent nerves bear certain relations to each other in the cavernous sinus, at the superior orbital fissure, and in the cavity of the orbit, as follows:

FIG. 784.—Figure showing the mode of innervation of the Recti medialis and lateralis of the eye (after Duval and Laborde). (Testut.) a. Left eyeball. b. Right eyeball. 1. Rectus lateralis. 2. Rectus medialis. 3. Rhomboid fossa. 4. Nucleus of abducent nerve. 5. Nucleus of oculomotor nerve. 6. Abducent nerve. 7. Nerve to Rectus medialis arising from the nucleus of the oculomotor of the same side. 7'. Nerve to Rectus medialis arising from the nucleus of the abducent of the opposite side. 8. Decussation of the fibres of the abducent nerve to the Rectus medialis.

In the **cavernous sinus** (Fig. 785), the oculomotor, trochlear, and ophthalmic nerves are placed in the lateral wall of the sinus, in the order given, from above downward. The abducent nerve lies at the lateral side of the internal carotid artery. As these nerves pass forward to the superior orbital fissure, the oculo-

	<i>Internal carotid artery</i>	
<i>Oculomotor</i>		motor and ophthalmic divide into
<i>Trochlear</i>		branches, and the abducent nerve
		approaches the others; so that their
<i>Ophthalmic</i>		relative positions are considerably
<i>Abducent</i>		changed.
<i>Maxillary</i>		

In the **superior orbital fissure** (Fig. 786), the trochlear nerve and the frontal and lacrimal divisions of the ophthalmic lie in this order from the medial to the lateral side upon the same plane; they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the Rectus lateralis. The superior division of

FIG. 785.—Oblique section through the right cavernous sinus.

the oculomotor is the highest of these; beneath this lies the nasociliary branch of the ophthalmic; then the inferior division of the oculomotor; and the abducent lowest of all.

<i>Inf. ramus of oculomotor nerve</i>	<i>Inf. orbital fissure</i>	<i>Optic foramen</i>
---------------------------------------	-----------------------------	----------------------

FIG. 786.—Dissection showing origins of right ocular muscles, and nerves entering by the superior orbital fissure.

In the **orbit**, the trochlear, frontal, and lacrimal nerves lie immediately beneath the periosteum, the trochlear nerve resting on the Obliquus superior, the frontal on the Levator palpebrae superioris, and the lacrimal on the Rectus lateralis. The superior division of the oculomotor nerve lies immediately beneath the Rectus superior, while the nasociliary nerve crosses the optic nerve to reach the medial wall of the orbit. Beneath these is the optic nerve, surrounded in front by the ciliary nerves, and having the ciliary ganglion on its lateral side, between it and the Rectus lateralis. Below the optic nerve are the inferior division of the oculomotor, and the abducent, the latter lying on the medial surface of the Rectus lateralis.

Applied Anatomy.—The abducent nerve is frequently involved in fractures of the base of the skull. The result of paralysis of this nerve is medial or convergent squint. Diplopia is also present. When injured so that its function is destroyed there is, in addition to the paralysis of the Rectus lateralis oculi, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the Dilator pupillae muscle are conveyed through this nerve.

THE FACIAL NERVE (N. FACIALIS; SEVENTH NERVE) (Figs. 787, 789).

The facial nerve consists of a motor and a sensory part, the latter being frequently described under the name of the *nervus intermedius* (*pars intermedii* of *Wrisberg*) (Fig. 787). The two parts emerge at the lower border of the pons in the recess between the olive and the restiform body, the motor part being the more medial; immediately to the lateral side of the sensory part is the acoustic nerve.

FIG. 787.—Plan of the facial nerve. The course of the sensory fibres is represented by the blue lines.

The motor part supplies the muscles of the face, scalp, and auricular, the Buccinator and Platysma, the Stapedius, the Stylohyoideus, and posterior belly of the Digastricus; it also contains some fibres which constitute the vasodilator nerves of the submaxillary and sublingual glands, and are conveyed to these glands through the chorda tympani nerve. The sensory part contains the fibres of taste for the anterior two-thirds of the tongue.

The motor root arises from a nucleus which lies deeply in the reticular formation of the lower part of the pons. This nucleus is situated above the nucleus ambiguus, behind the superior olivary nucleus, and medial to the spinal tract of the trigeminal nerve. From this origin the fibres pursue a curved course in the substance

of the pons. They first pass backward and medialward toward the rhomboid fossa, and, reaching the posterior end of the nucleus of the abducent nerve, run upward close to the middle line beneath the colliculus fascialis. At the anterior end of the nucleus of the abducent nerve they make a second bend, and run downward and forward through the pons to their point of emergence between the olive and the restiform body.

Some fibres from the nucleus of the oculomotor nerve are said to descend in the medial longitudinal fasciculus and join the motor root of the facial nerve before it leaves the pons. These fibres are believed to supply the *Orbicularis oculi*, *Corrugator*, and *Frontalis*, since these muscles have been observed to escape paralysis in lesions of the motor nucleus of the facial nerve.¹

The **sensory root** arises from the genicular ganglion, which is situated on the geniculum of the facial nerve in the facial canal, behind the hiatus of the canal. The cells of this ganglion are unipolar, and the single process divides in a T-shaped manner into central and peripheral branches. The central branches leave the trunk of the facial nerve in the internal acoustic meatus, and form the sensory root; the peripheral branches are continued into the chorda tympani and greater superficial petrosal nerves. Entering the brain at the lower border of the pons between the motor root and the acoustic nerve, the fibres of the sensory root pass into the substance of the medulla oblongata and end in the upper part of the terminal nucleus of the glossopharyngeal nerve and in the fasciculus solitarius.

From their superficial attachments to the brain, the two roots of the facial nerve pass lateralward and forward with the acoustic nerve to the internal acoustic meatus. In the meatus the motor root lies in a groove on the upper and anterior surface of the acoustic nerve, the sensory root being placed between them.

At the bottom of the meatus, the facial nerve enters the facial canal, which it traverses to its termination at the stylomastoid foramen. It is at first directed lateralward between the cochlea and vestibule toward the medial wall of the tympanic cavity; it then bends suddenly backward and arches downward behind the tympanic cavity to the stylomastoid foramen. The point where it changes its direction is named the **geniculum**; it presents a reddish gangliform swelling, the **genicular ganglion** (*ganglion geniculi*; *geniculate ganglion*; *nucleus of the sensory root*

Branch to join lesser superficial petrosal
Greater superficial petrosal
Genicular ganglion

FIG. 788.—The course and connections of the facial nerve in the temporal bone.

of the nerve) (Fig. 788). On emerging from the stylomastoid foramen, the facial nerve runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the mandible into branches, from which numerous offsets are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. The branches and their offsets unite to form the **parotid plexus**.

Branches of Communication.—The branches of communication of the facial nerve may be arranged as follows:

¹ See footnote, p. 852.

In the internal acoustic meatus	With the acoustic nerve.
At the genicular ganglion	{ With the sphenopalatine ganglion by the greater superficial petrosal nerve. { With the otic ganglion by a branch which joins the lesser superficial petrosal nerve. { With the sympathetic on the middle meningeal artery.
In the facial canal	With the auricular branch of the vagus.
At its exit from the stylomastoid foramen	{ With the glossopharyngeal. { With the vagus. { With the great auricular. { With the auriculotemporal.
Behind the ear	With the lesser occipital.
On the face	With the trigeminal.
In the neck	With the cutaneous cervical.

In the internal acoustic meatus some minute filaments pass from the facial to the acoustic nerve.

The **greater superficial petrosal nerve** (*large superficial petrosal nerve*) arises from the genicular ganglion, and consists chiefly of sensory branches which are distributed to the mucous membrane of the soft palate; but it probably contains a few motor fibres which form the motor root of the sphenopalatine ganglion. It passes forward through the hiatus of the facial canal, and runs in a sulcus on the anterior surface of the petrous portion of the temporal bone beneath the semilunar ganglion, to the foramen lacerum. It receives a twig from the tympanic plexus, and in the foramen is joined by the deep petrosal, from the sympathetic plexus on the internal carotid artery, to form the nerve of the pterygoid canal which passes forward through the pterygoid canal and ends in the sphenopalatine ganglion. The genicular ganglion is connected with the otic ganglion by a branch which joins the lesser superficial petrosal nerve, and also with the sympathetic filaments accompanying the middle meningeal artery. According to Arnold, a twig passes back from the ganglion to the acoustic nerve. Just before the facial nerve emerges from the stylomastoid foramen, it generally receives a twig from the auricular branch of the vagus.

After its exit from the stylomastoid foramen, the facial nerve sends a twig to the glossopharyngeal, and communicates with the auricular branch of the vagus, with the great auricular nerve of the cervical plexus, with the auriculotemporal nerve in the parotid gland, and with the lesser occipital behind the ear; on the face with the terminal branches of the trigeminal, and in the neck with the cutaneous cervical nerve.

Branches of Distribution.—The branches of distribution (Fig. 787) of the facial nerve may be thus arranged:

With the facial canal	{ Nerve to the Stapedius muscle. { Chorda tympani.
At its exit from the stylomastoid foramen	{ Posterior auricular. { Digastric. { Stylohyoid.
On the face	{ Temporal. { Zygomatic. { Buccal. { Mandibular. { Cervical.

The **Nerve to the Stapedius** (*n. stapedius; tympanic branch*) arises opposite the pyramidal eminence (page 1052); it passes through a small canal in this eminence to reach the muscle.

The **Chorda Tympani Nerve** is given off from the facial as it passes downward behind the tympanic cavity, about 6 mm. from the stylomastoid foramen. It runs upward and forward in a canal, and enters the tympanic cavity, through an aperture (*iter chordae posterius*) on its posterior wall, close to the medial surface of the posterior border of the tympanic membrane and on a level with the upper

FIG. 789.—The nerves of the scalp, face, and side of neck.

end of the manubrium of the malleus. It traverses the tympanic cavity, between the fibrous and mucous layers of the tympanic membrane, crosses the manubrium of the malleus, and emerges from the cavity through a foramen situated at the inner end of the petrotympanic fissure, and named the *iter chordae anterior* (*canal of Huguier*). It then descends between the Pterygoideus externus and internus on the medial surface of the spina angularis of the sphenoid, which it sometimes grooves, and joins, at an acute angle, the posterior border of the lingual nerve. It receives a few efferent fibres from the motor root; these enter the submaxillary ganglion, and through it are distributed to the submaxillary and sublingual glands;

the majority of its fibres are efferent, and are continued onward through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds; they constitute the nerve of taste for this portion of the tongue. Before uniting with the lingual nerve the chorda tympani is joined by a small branch from the otic ganglion.

The **Posterior Auricular Nerve** (*n. auricularis posterior*) arises close to the stylo-mastoid foramen, and runs upward in front of the mastoid process; here it is joined by a filament from the auricular branch of the vagus, and communicates with the posterior branch of the great auricular, and with the lesser occipital. As it ascends between the external acoustic meatus and mastoid process it divides into auricular and occipital branches. The **auricular branch** supplies the Auricularis posterior and the intrinsic muscles on the cranial surface of the auricula. The **occipital branch**, the larger, passes backward along the superior nuchal line of the occipital bone, and supplies the Occipitalis.

The **Digastric Branch** (*ramus digastricus*) arises close to the stylomastoid foramen, and divides into several filaments, which supply the posterior belly of the Digastricus; one of these filaments joins the glossopharyngeal nerve.

The **Stylohyoid Branch** (*ramus stylohyoideus*) frequently arises in conjunction with the digastric branch; it is long and slender, and enters the Stylohyoideus about its middle.

The **Temporal Branches** (*rami temporales*) cross the zygomatic arch to the temporal region, supplying the Auriculares anterior and superior, and joining with the zygomaticotemporal branch of the maxillary, and with the auriculotemporal branch of the mandibular. The more anterior branches supply the Frontalis, the Orbicularis oculi, and the Corrugator, and join the supraorbital and lacrimal branches of the ophthalmic.

The **Zygomatic Branches** (*rami zygomatici; malar branches*) run across the zygomatic bone to the lateral angle of the orbit, where they supply the Orbicularis oculi, and join with filaments from the lacrimal nerve and the zygomaticofacial branch of the maxillary nerve.

The **Buccal Branches** (*rami buccales; infraorbital branches*), of larger size than the rest, pass horizontally forward to be distributed below the orbit and around the mouth. The **superficial branches** run beneath the skin and above the superficial muscles of the face, which they supply: some are distributed to the Procerus, joining at the medial angle of the orbit with the infratrochlear and nasociliary branches of the ophthalmic. The **deep branches** pass beneath the Zygomaticus and the Quadratus labii superioris, supplying them and forming an **infraorbital plexus** with the infraorbital branch of the maxillary nerve. These branches also supply the small muscles of the nose. The lower deep branches supply the Buccinator and Orbicularis oris, and join with filaments of the buccinator branch of the mandibular nerve.

The **Mandibular Branch** (*ramus marginalis mandibulae*) passes forward beneath the Platysma and Triangularis, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior alveolar nerve.

The **Cervical Branch** (*ramus colli*) runs forward beneath the Platysma, and forms a series of arches across the side of the neck over the suprahyoid region. One branch descends to join the cervical cutaneous nerve from the cervical plexus; others supply the Platysma.

Applied Anatomy.—Facial palsy is commonly unilateral, and may be either: (1) *peripheral*, from lesion of the facial nerve; (2) *nuclear*, from destruction of the facial nucleus; or (3) *central, cerebral, or supranuclear*, from injury in the brain to the fibres passing from the cortex through the internal capsule to the facial nucleus, or from injury to the face area of the motor cortex itself. In supranuclear facial paralysis, which is usually part of a hemiplegia, it is the lower part of the face that is chiefly affected, while the forehead can be freely wrinkled on the palsied side, the eye can be closed fairly well, and the eyeball is not rolled up under the upper lid; emotional

movements of the face are much better executed than voluntary; and the electrical reactions of the muscles on the affected side are not altered. If the paralysis is due to lesion of the facial nucleus, the Orbicularis oris escapes, as the nuclear origin of the nerve to this muscle seems to be connected with that of the tongue nerves; otherwise the symptoms are identical with those of the common peripheral facial palsy, of which several types may be distinguished according to the point in its course at which the facial nerve is injured. If the lesion occurs (a) in the pons, facial paralysis is produced as in (d) below; taste and hearing are not affected, but the abducent nerve also will be paralyzed because the fibres of the facial nerve loop around its nucleus in the pons. When the nerve is paralyzed (b) in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is unable to recognize the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting; and the sense of hearing is affected from paralysis of the Stapedius. When the cause of the paralysis is (c) fracture of the base of the skull, the acoustic and petrosal nerves are usually involved. But by far the commonest cause of facial palsy is (d) exposure of the nerve to cold or injury at or after its exit from the stylomastoid foramen (*Bell's paralysis*). In these cases the face looks asymmetrical even when at rest, and more so in the old than in the young. The affected side of the face and forehead remains motionless when voluntary or emotional movement is attempted. The lines on the forehead are smoothed out, the eye can be shut only by hand, tears fail to enter the lacrimal puncta because they are no longer in contact with the conjunctiva, the conjunctival reflex is absent, and efforts to close the eye merely cause the eyeball to roll upward until the cornea lies under the upper lid. The tip of the nose is drawn over toward the sound side; the nasolabial fold is partially obliterated on the affected side, and the ala nasi does not move properly on respiration. The lips remain in contact on the paralyzed side, and cannot be put together for whistling; when a smile is attempted the angle of the mouth is drawn up on the unaffected side; on the affected side the lips remain nearly closed, and the mouth assumes a characteristic triangular form. During mastication food accumulates in the cheek, from paralysis of the Buccinator, and dribbles or is pushed out from between the paralyzed lips. On protrusion the tongue seems to be thrust over toward the palsied side, but verification of its position by reference to the incisor teeth will show that this is not really so. The Platysma and the muscles of the auricula are paralyzed; in severe cases the articulation of labials is impaired. The electrical reactions of the affected muscles are altered (reaction of degeneration), and the degree to which this alteration has taken place after a week or ten days gives a valuable guide to the prognosis. Most cases of Bell's palsy recover completely.

The facial nerve is at fault in cases of so-called *histrionic spasm*, which consists in an almost constant and uncontrollable twitching of some or all of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient, and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear, from the root of the mastoid process to the angle of the mandible. The parotid is turned forward and the dissection carried along the anterior border of the Sternocleidomastoideus and mastoid process, until the upper border of the posterior belly of the Digastricus is found. The nerve is parallel to this on about the level of the middle of the mastoid process. When found, the nerve must be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve.

THE ACOUSTIC NERVE (N. ACUSTICUS; EIGHTH OR AUDITORY NERVE).

The **acoustic nerve**, or **nerve of hearing**, is distributed exclusively to the internal ear. It consists of two sets of fibres, which, although differing in their central connections, are both concerned in the transmission of afferent impulses from the internal ear to the medulla oblongata and pons, and from there, by means of fibres which arise from collections of gray substance in these structures, to the cerebrum and cerebellum. One set of fibres forms the vestibular root of the nerve, and *arises* from the cells in the vestibular ganglion situated in the internal acoustic meatus; the other set constitutes the cochlear root, and takes *origin* from the cells in the ganglion spirale, which occupies the spiral canal of the cochlea. Both of these ganglia consist of bipolar nerve cells; from each of the cells a central fibre passes to the brain, a peripheral fibre to the internal ear. At its connection with the brain the eighth nerve occupies the groove between the pons and medulla, lying behind the facial nerve and in front of the restiform body.

Vestibular Root (*radix vestibularis; vestibular nerve*) (Fig. 790).—The fibres of this root enter the medulla oblongata on the medial side of those of the cochlear root, and pass between the restiform body and the spinal tract of the trigeminal. They then divide into ascending and descending fibres. The latter end by arborizing around the cells of the **medial nucleus**, which is situated in the **area acustica** of the rhomboïd fossa. The ascending fibres either end in the same manner or in the **lateral nucleus**, which is situated lateral to the area acustica and farther from the ventricular floor; the lateral nucleus consists of two parts, a medial, the **nucleus of Deiters**, and a lateral, the **nucleus of Bechterew**. Some of the axons of the cells of the lateral nucleus, and possibly also of the medial nucleus, are continued upward through the restiform body to the roof nuclei of the opposite side of the cerebellum, to which also other fibres of the vestibular root are prolonged without interruption in the nuclei of the medulla oblongata. A second set of fibres from the medial and lateral nuclei end partly in the tegmentum, while the remainder ascend in the medial longitudinal fasciculus to arborize around the cells of the nuclei of the oculomotor nerve.

Cochlear Root (*radix cochlearis; cochlear nerve*) (Fig. 791).—The cochlear root is placed lateral to the vestibular root. Its fibres end in two nuclei: one, the **accessory nucleus**, lies immediately in front of the restiform body; the other, the **tuberculum acusticum**, somewhat lateral to it.

The **striae medullares** (*striae acusticae*) are the axons of the cells of the tuberculum acusticum. They pass over the restiform body, and across the rhomboid fossa to the median sulcus. Here they dip into the substance of the pons, to end around the cells of the superior olivary nuclei of both sides. There are, however, other fibres, and these are both direct and crossed, which pass into the lateral lemniscus. The cells of the accessory nucleus give origin to fibres which run transversely in the pons and constitute the trapezium. Of the trapezoid fibres some end around the cells of the superior olivary nucleus or of the trapezoid nucleus of the same or opposite side, while others, crossed or uncrossed, pass directly into the lateral lemniscus.

If the further connections of the cochlear nerve of one side, say the left, be considered, it is found that they lie lateral to the main sensory tract, the lemniscus, and are therefore termed the **lateral lemniscus**. The fibres comprising the left lateral lemniscus arise in the superior olivary and trapezoid nuclei of the same or opposite side, while others are the uninterrupted fibres already alluded to, and these are either crossed or uncrossed, the former being the axons of the cells of the right accessory nucleus or of the cells of the right tuberculum acusticum, while the latter are derived from the cells of the left nuclei. In the upper part of the lateral lemniscus there is a collection of nerve cells, the **nucleus of the lateral lemniscus**, around the cells of which some of the fibres arborize and from the cells of which axons originate to continue upward the tract of the lateral lemniscus. The ultimate

remembered that all these tests are liable to anomalies and exceptions, and are not applicable to old people. If, however, concordant results are yielded by the tests of Weber, Rin  , and Gell  , Bezold's "triad of symptoms," nerve deafness rather than deafness due to disease of the conducting structures is rendered highly probable.

Tinnitus aurium, or the hearing of sounds in the ear that have no objective cause outside the body, is said to be present in as many as 60 per cent. of cases of ear disease of all sorts, and is commonest in disease of the labyrinth or of the nerve. It is very variable in intensity; the worst forms are purely subjective and due to irritation of the nerve itself. The sounds heard are of the most varied nature—buzzing, hissing, whistling, rushing, bell ringing, and so forth—and may occupy the patient's attention so completely that he is no longer able to attend to his business; he may even commit suicide in order to escape from them. In the insane, tinnitus is associated with delusions and hallucinations of hearing; cases of insanity have even been recorded in which cure was effected by the removal of cerumen impacted in the meatus and giving rise to persistent tinnitus.

THE GLOSSOPHARYNGEAL NERVE (N. GLOSSOPHARYNGEUS; NINTH NERVE) (Figs. 792, 793, 794).

The **glossopharyngeal nerve** contains both motor and sensory fibres, and is distributed, as its name implies, to the tongue and pharynx. It is the nerve of ordinary sensation to the mucous membrane of the pharynx, fauces, and palatine tonsil, and the nerve of taste to the posterior part of the tongue. It is attached by three or four filaments to the upper part of the medulla oblongata, in the groove between the olive and the restiform body.

The **sensory fibres** arise from the cells of the superior and petrous ganglia, which are situated on the trunk of the nerve, and will be presently described. When traced into the medulla, some of the sensory fibres end by arborizing around the cells of the upper part of a nucleus which lies beneath the ala cinerea in the lower part of the rhomboid fossa. Many of the fibres, however, contribute to form a strand, named the **fasciculus solitarius**, which descends in the medulla oblongata. Associated with this strand are numerous nerve cells, and around these the fibres of the fasciculus end.

The **motor fibres** spring from the cells of the **nucleus ambiguus**, which lies some distance from the surface of the rhomboid fossa in the lateral part of the medulla and is continuous below with the anterior gray column of the medulla spinalis. From this nucleus the fibres are first directed backward, and then they bend forward and lateralward to join the fibres of the sensory root. The nucleus ambiguus gives origin to the motor branches of the glossopharyngeal and vagus nerves, and to the cerebral part of the accessory nerve.

FIG. 792.—Plan of upper portions of glossopharyngeal, vagus, and accessory nerves.

From the medulla oblongata, the glossopharyngeal nerve passes lateralward across the flocculus, and leaves the skull through the central part of the jugular foramen, in a separate sheath of the dura mater, lateral to and in front of the vagus and accessory nerves (Fig. 793). In its passage through the jugular foramen, it grooves the lower border of the petrous part of the temporal bone; and, at its exit from the skull, passes forward between the internal jugular vein and internal carotid artery; it descends in front of the latter vessel, and beneath the styloid process and the muscles connected with it, to the lower border of the Stylopharyngeus. It then curves forward, forming an arch on the side of the neck and lying upon the Stylopharyngeus and Constrictor pharyngis medius. Thence it passes under cover of the Hyoglossus, and is finally distributed to the palatine tonsil, the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth.

FIG. 793.—Upper part of medulla spinalis and hind- and mid-brains; posterior aspect, exposed *in situ*.

In passing through the jugular foramen, the nerve presents two ganglia, the superior and the petrous (Fig. 792).

The **superior ganglion** (*ganglion superius; jugular ganglion*) is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is very small, and is usually regarded as a detached portion of the petrous ganglion.

The **petrous ganglion** (*ganglion petrosum; inferior ganglion*) is larger than the superior and is situated in a depression in the lower border of the petrous portion of the temporal bone.

Branches of Communication.—

Glossopharyngeal

The glossopharyngeal nerve communicates with the **vagus**, **sympathetic**, and **facial**.

The branches to the vagus are two filaments which arise from the petrous ganglion, one passing to the auricular branch, and the other to the jugular ganglion, of the vagus. The petrous ganglion is connected by a filament with the superior cervical ganglion of the sympathetic. The branch of communication with the facial perforates the posterior belly of the Digastricus. It arises from the trunk of the glossopharyngeal below the petrous ganglion, and joins the facial just after the exit of that nerve from the stylomastoid foramen.

Branches of Distribution.—The branches of distribution of the glossopharyngeal are: the **tympanic**, **carotid**, **pharyngeal**, **muscular**, **tonsillar**, and **lingual**.

The **Tympanic Nerve** (*n. tympanicus; nerve of Jacobson*) arises from the petrous ganglion, and ascends to the tympanic cavity through a small canal on the under surface of the petrous portion of the temporal bone on the ridge which separates the carotid canal from the jugular fossa. In the tympanic cavity it divides into branches which form the **tympanic plexus** and are contained in grooves upon the surface of the promontory. This plexus gives off: (1) the lesser superficial petrosal nerve; (2) a branch to join the greater superficial petrosal nerve; and (3) branches to the tympanic cavity, all of which will be described in connection with the anatomy of the middle ear.

FIG. 794.—Course and distribution of the glossopharyngeal, vagus, and accessory nerves.

The **Carotid Branches** (*n. caroticotympanicus superior* and *n. caroticotympanicus inferior*) descend along the trunk of the internal carotid artery as far as its origin, communicating with the pharyngeal branch of the vagus, and with branches of the sympathetic.

The **Pharyngeal Branches** (*rami pharyngei*) are three or four filaments which unite, opposite the Constrictor pharyngis medius, with the pharyngeal branches of the vagus and sympathetic, to form the **pharyngeal plexus**; branches from this plexus perforate the muscular coat of the pharynx and supply its muscles and mucous membrane.

The **Muscular Branch** (*ramus stylopharyngeus*) is distributed to the Stylopharyngeus.

The **Tonsillar Branches** (*rami tonsillares*) supply the palatine tonsil, forming around it a plexus from which filaments are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

The **Lingual Branches** (*rami linguales*) are two in number; one supplies the papillae vallatae and the mucous membrane covering the base of the tongue; the other supplies the mucous membrane and follicular glands of the posterior part of the tongue, and communicates with the lingual nerve.

THE VAGUS NERVE (N. VAGUS; TENTH NERVE; PNEUMOGASTRIC NERVE) (Figs. 792, 793, 794).

The **vagus nerve** is composed of both motor and sensory fibres, and has a more extensive course and distribution than any of the other cerebral nerves, since it passes through the neck and thorax to the abdomen.

The vagus is attached by eight or ten filaments to the medulla oblongata in the groove between the olive and the restiform body, below the glossopharyngeal. The **sensory fibres arise** from the cells of the jugular ganglion and ganglion nodosum of the nerve, and; when traced into the medulla oblongata mostly end by arborizing around the cells of the inferior part of a nucleus which lie beneath the *ala cinerea* in the lower part of the rhomboid fossa. Some of the sensory fibres of the glossopharyngeal nerve have been seen to end in the upper part of this nucleus. A few of the sensory fibres of the vagus descend in the fasciculus solitarius and end around its cells. The **motor fibres arise** from the cells of the nucleus ambiguus, already referred to in connection with the motor root of the glossopharyngeal nerve (page 937).

The filaments of the nerve unite, and form a flat cord, which passes beneath the flocculus to the jugular foramen, through which it leaves the cranium. In emerging through this opening, the vagus is accompanied by and contained in the same sheath of dura mater with the accessory nerve, a septum separating them from the glossopharyngeal which lies in front (Fig. 793). In this situation the vagus presents a well-marked ganglionic enlargement, which is called the **jugular ganglion** (*ganglion of the root*); to it the accessory nerve is connected by one or two filaments. After its exit from the jugular foramen the vagus is joined by the cerebral portion of the accessory nerve, and enlarges into a second gangliform swelling, called the **ganglion nodosum** (*ganglion of the trunk*); through this the fibres of the cerebral portion of the accessory pass without interruption, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus, but some of its fibres descend in the trunk of the vagus, to be distributed with the recurrent nerve and probably also with the cardiac nerves.

The vagus nerve passes vertically down the neck within the carotid sheath, lying between the internal jugular vein and internal carotid artery as far as the upper border of the thyroid cartilage, and then between the same vein and the common carotid artery to the root of the neck. The further course of the nerve differs on the two sides of the body.

On the *right side*, the nerve passes across the subclavian artery between it and the right innominate vein, and descends by the side of the trachea to the back of

the root of the lung, where it spreads out in the **posterior pulmonary plexus**. From the lower part of this plexus two cords descend on the œsophagus, and divide to form, with branches from the opposite nerve, the **œsophageal plexus**. Below, these branches are collected into a single cord, which runs along the back of the œsophagus enters the abdomen, and is distributed to the postero-inferior surface of the stomach, joining the left side of the cœliac plexus, and sending filaments to the lienal plexus.

On the *left side*, the vagus enters the thorax between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the left side of the arch of the aorta, and descends behind the root of the left lung, forming there the **posterior pulmonary plexus**. From this it runs along the anterior surface of the œsophagus, where it unites with the nerve of the right side in the **œsophageal plexus**, and is continued to the stomach, distributing branches over its antero-superior surface; some of these extend over the fundus, and others along the lesser curvature. Filaments from these branches enter the lesser omentum, and join the hepatic plexus.

The **jugular ganglion** (*ganglion jugulare; ganglion of the root*) is of a grayish color, spherical in form, about 4 mm. in diameter.

Branches of Communication.—This ganglion is connected by several delicate filaments to the cerebral portion of the accessory nerve; it also communicates by a twig with the petrous ganglion of the glossopharyngeal, with the facial nerve by means of its auricular branch, and with the sympathetic by means of an ascending filament from the superior cervical ganglion.

The **ganglion nodosum** (*ganglion of the trunk; inferior ganglion*) is cylindrical in form, of a reddish color, and 2.5 cm. in length. Passing through it is the cerebral portion of the accessory nerve, which blends with the vagus below the ganglion.

Branches of Communication.—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.

Branches of Distribution.—The branches of distribution of the vagus are:

In the Jugular Fossa	{ Meningeal.
	{ Auricular.
	{ Pharyngeal.
In the Neck	{ Superior laryngeal.
	{ Recurrent.
	{ Superior cardiac.
In the Thorax	{ Inferior cardiac.
	{ Anterior bronchial.
	{ Posterior bronchial.
	{ Œsophageal.
In the Abdomen	{ Gastric.
	{ Cœliac.
	{ Hepatic.

The **Meningeal Branch** (*ramus meningeus; dural branch*) is a recurrent filament given off from the jugular ganglion; it is distributed to the dura mater in the posterior fossa of the base of the skull.

The **Auricular Branch** (*ramus auricularis; nerve of Arnold*) arises from the jugular ganglion, and is joined soon after its origin by a filament from the petrous ganglion of the glossopharyngeal; it passes behind the internal jugular vein, and enters the mastoid canaliculus on the lateral wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the facial canal about 4 mm. above the stylo-mastoid foramen, and here it gives off an ascending branch which joins the facial nerve. The nerve reaches the surface by passing through the tympanomastoid fissure between the mastoid process and the tympanic part of the temporal bone,

and divides into two branches: one joins the posterior auricular nerve, the other is distributed to the skin of the back of the auricula and to the posterior part of the external acoustic meatus.

The **Pharyngeal Branch** (*ramus pharyngeus*), the principal motor nerve of the pharynx, *arises* from the upper part of the ganglion nodosum, and consists principally of filaments from the cerebral portion of the accessory nerve. It passes across the internal carotid artery to the upper border of the Constrictor pharyngis medius, where it divides into numerous filaments, which join with branches from the glossopharyngeal, sympathetic, and external laryngeal to form the **pharyngeal plexus**. From the plexus, branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate, except the Tensor veli palatini. A minute filament descends and joins the hypoglossal nerve as it winds around the occipital artery.

The **Superior Laryngeal Nerve** (*n. laryngeus superior*) larger than the preceding, *arises* from the middle of the ganglion nodosum and in its course receives a branch from the superior cervical ganglion of the sympathetic. It descends, by the side of the pharynx, behind the internal carotid artery, and divides into two branches, **external** and **internal**.

The **external branch** (*ramus externus*), the smaller, descends on the larynx, beneath the Sternothyroideus, to supply the Cricothyroideus. It gives branches to the pharyngeal plexus and the Constrictor pharyngis inferior, and communicates with the superior cardiac nerve, behind the common carotid artery.

The **internal branch** (*ramus internus*) descends to the hyothyroid membrane, pierces it in company with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. Of these branches some are distributed to the epiglottis, the base of the tongue, and the epiglottic glands; others pass backward, in the aryepiglottic fold, to supply the mucous membrane surrounding the entrance of the larynx, and that lining the cavity of the larynx as low down as the vocal folds. A filament descends beneath the mucous membrane on the inner surface of the thyroid cartilage and joins the recurrent nerve.

The **Recurrent Nerve** (*n. recurrens; inferior or recurrent laryngeal nerve*) *arises*, on the *right side*, in front of the subclavian artery; winds from before backward around that vessel, and ascends obliquely to the side of the trachea behind the common carotid artery, and either in front of or behind the inferior thyroid artery. On the *left side*, it *arises* on the left of the arch of the aorta, and winds below the aorta at the point where the ligamentum arteriosum is attached, and then ascends to the side of the trachea. The nerve on either side ascends in the groove between the trachea and œsophagus, passes under the lower border of the Constrictor pharyngis inferior, and enters the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid; it is distributed to all the muscles of the larynx, excepting the Cricothyroideus. It communicates with the internal branch of the superior laryngeal nerve, and gives off a few filaments to the mucous membrane of the lower part of the larynx.

As the recurrent nerve hooks around the subclavian artery or aorta, it gives off several cardiac filaments to the deep part of the cardiac plexus. As it ascends in the neck it gives off branches, more numerous on the left than on the right side, to the mucous membrane and muscular coat of the œsophagus; branches to the mucous membrane and muscular fibres of the trachea; and some pharyngeal filaments to the Constrictor pharyngis inferior.

The **Superior Cardiac Branches** (*rami cardiaci superiores; cervical cardiac branches*), two or three in number, *arise* from the vagus, at the upper and lower parts of the neck.

The **upper branches** are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the deep part of the cardiac plexus.

The **lower branch** arises at the root of the neck, just above the first rib. That from the right vagus passes in front or by the side of the innominate artery, and proceeds to the deep part of the cardiac plexus; that from the left runs down across the left side of the arch of the aorta, and joins the superficial part of the cardiac plexus.

The **Inferior Cardiac Branches** (*rami cardiaci inferiores; thoracic cardiac branches*), on the right side, arise from the trunk of the vagus as it lies by the side of the trachea, and from its recurrent nerve; on the left side from the recurrent nerve only; passing inward, they end in the deep part of the cardiac plexus.

The **Anterior Bronchial Branches** (*rami bronchiales anteriores; anterior or ventral pulmonary branches*), two or three in number, and of small size, are distributed on the anterior surface of the root of the lung. They join with filaments from the sympathetic, and form the **anterior pulmonary plexus**.

The **Posterior Bronchial Branches** (*rami bronchiales posteriores; posterior or dorsal pulmonary branches*), more numerous and larger than the anterior, are distributed on the posterior surface of the root of the lung; they are joined by filaments from the third and fourth (sometimes also from the first and second) thoracic ganglia of the sympathetic trunk, and form the **posterior pulmonary plexus**. Branches from this plexus accompany the ramifications of the bronchi through the substance of the lung.

The **Œsophageal Branches** (*rami oesophagei*) are given off both above and below the bronchial branches; the lower are numerous and larger than the upper. They form, together with the branches from the opposite nerve, the **œsophageal plexus**. From this plexus filaments are distributed to the back of the pericardium.

The **Gastric Branches** (*rami gastrici*) are distributed to the stomach. The right vagus forms the **posterior gastric plexus** on the postero-inferior surface of the stomach and the left the **anterior gastric plexus** on the antero-superior surface.

The **Celiac Branches** (*rami coeliaci*) are mainly derived from the right vagus: they join the celiac plexus and through it supply branches to the pancreas, spleen, kidneys, suprarenal bodies, and intestine.

The **Hepatic Branches** (*rami hepatici*) arise from the left vagus: they join the hepatic plexus and through it are conveyed to the liver.

Applied Anatomy.—The trunk of the vagus is rarely injured, but the functions of the nerve may be interfered with by damage to its nucleus of origin in the medulla; by thickening or growth from the meninges or bones, or aneurism of the basilar artery, before its exit from the skull; injuries such as gunshot or punctured wounds in the neck, or injuries during such operations as ligation of the carotid artery, removal of tuberculous glands or other deep-seated tumors. The vagus may also be compressed by aneurisms of the carotid artery, and its deep origin becomes affected in bulbar paralysis. The symptoms produced by paralysis of the nerve are palpitation, with increased frequency of the pulse, constant vomiting, slowing of the respiration, and a sensation of suffocation.

"Reflexes" on the branches of the vagus are not at all uncommonly met with. The "ear cough" is perhaps one of the commonest, where a plug of wax in the acoustic meatus may by irritating the filaments of the auricular (Arnold's) nerve be responsible for a persistent cough. Syringing the external acoustic meatus frequently produces cough, and, in children, vomiting is not uncommon as the result of such a procedure; moreover, in people with weak hearts, syringing the ear has been responsible for a sudden fatal syncope, by reflex irritation of the cardiac branches. Another very common example is the persistent cough which is frequently due to enlarged bronchial glands in children, the irritation of which is referred to the superior laryngeal filaments.

The anatomy of the laryngeal nerves is of importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When its trunk is pressed upon by, for instance, a goitre or an aneurism of the upper part of the carotid, there is a peculiar dry, brassy cough. When the nerve is paralyzed, there is anesthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, as the nerve also supplies the Cricothyreoideus muscle, the vocal folds cannot be made tense, and the voice is deep and hoarse. Paralysis may be the result of bulbar paralysis; may be a sequel to diphtheria, when both nerves are usually involved; or it may, though less commonly, be caused

by the pressure of tumors or aneurisms, when the paralysis is generally unilateral. Irritation of the recurrent nerves produces spasm of the muscles of the larynx. When both recurrent nerves are paralyzed, the vocal folds are motionless, in the so-called "cadaveric position" that is to say, in the position in which they are found in ordinary tranquil respiration; neither closed as in phonation, nor open as in deep inspiratory efforts. When one recurrent nerve is paralyzed, the vocal fold of the same side is motionless, while the opposite one crosses the middle line to accommodate itself to the affected one; hence phonation is possible, but the voice is altered and weak in timbre. The nerves may be paralyzed in bulbar paralysis or after diphtheria, when the paralysis usually affects both sides; or they may be affected by the pressure of aneurisms of the aorta, innominate, or subclavian arteries; by mediastinal tumors; by gummata; or by cancer of the upper part of the oesophagus, when the paralysis is often unilateral. Paralysis of the adductor muscles of the larynx on both sides is quite common, and is usually functional in nature. The voice is reduced to a whisper, but the power of coughing is preserved.

FIG. 795.—Hypoglossal nerve, cervical plexus, and their branches.

THE ACCESSORY NERVE (N. ACCESSORIUS; ELEVENTH NERVE; SPINAL ACCESSORY NERVE) (Figs. 793, 794, 795).

The accessory nerve consists of two parts: a cerebral and a spinal.

The cerebral part (*ramus internus; accessory portion*) is the smaller of the two. Its fibres arise from the cells of the *nucleus ambiguus* and emerge as four or five delicate rootlets from the side of the medulla oblongata, below the roots of the vagus. It runs lateralward to the jugular foramen, where it interchanges fibres with the spinal portion or becomes united to it for a short distance; here it is also connected by one or two filaments with the jugular ganglion of the vagus. It

then passes through the jugular foramen, separates from the spinal portion and is continued over the surface of the ganglion nodosum of the vagus, to the surface of which it is adherent, and is distributed principally to the pharyngeal and superior laryngeal branches of the vagus. Through the pharyngeal branch it probably supplies the *Musculus uvulae* and *Levator veli palatini*. Some few filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent nerve and probably also with the cardiac nerves.

The **spinal part** (*ramus externus; spinal portion*) is firm in texture, and its fibres arise from the motor cells in the lateral part of the anterior column of the gray substance of the medulla spinalis as low as the fifth cervical nerve. Passing through the lateral funiculus of the medulla spinalis, they emerge on its surface and unite to form a single trunk, which ascends between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed to the jugular foramen, through which it passes, lying in the same sheath of dura mater as the vagus, but separated from it by a fold of the arachnoid. In the jugular foramen, it receives one or two filaments from the cerebral part of the nerve, or else joins it for a short distance and then separates from it again. At its exit from the jugular foramen, it runs backward in front of the internal jugular vein in 66.6 per cent. of cases, and behind in it 33.3 per cent. (Tandler). The nerve then descends obliquely behind the *Digastricus* and *Stylohyoideus* to the upper part of the *Sternocleidomastoideus*; it pierces this muscle, and courses obliquely across the posterior triangle of the neck, to end in the deep surface of the *Trapezius*. As it traverses the *Sternocleidomastoideus* it gives several filaments to the muscle, and joins with branches from the second cervical nerve. In the posterior triangle it unites with the second and third cervical nerves, while beneath the *Trapezius* it forms a plexus with the third and fourth cervical nerves, and from this plexus fibres are distributed to the muscle.

Applied Anatomy.—The functions of the accessory nerve may be interfered with either by central changes; or at its exit from the skull, by fractures running across the jugular foramen; or in the neck, by inflamed lymph glands, etc. The acute wry-neck in children is most commonly due to inflamed or suppurating glands, and rapidly subsides with appropriate treatment. Central irritation causes clonic spasm of the *Sternocleidomastoideus* and *Trapezius* muscles, or, as it is termed, spasmodic torticollis. In cases of this affection in which all previous palliative treatment has failed, and the spasms are so severe as to undermine the patient's health, division or excision of a portion of the accessory nerve has been resorted to. This must be done from the anterior border of the *Sternocleidomastoideus*. The operation consists in making an incision, 8 cm. in length, from the apex of the mastoid process along the anterior border of the muscle, which is defined and pulled backward, so as to stretch the nerve, which is then to be sought for beneath the *Digastricus*, about 5 cm. below the apex of the mastoid process. Unfortunately, the operation does not yield a satisfactory or permanent cure, as the spasms tend to recur after an interval, either in the same muscles or in other groups of neck muscles.

In cases where extensive dissections are undertaken for enlarged glands in the neck, it is essential that this nerve should be at once sought for and isolated from the mass of inflamed glands so as to maintain its continuity.

THE HYPOGLOSSAL NERVE (N. HYPOGLOSSUS; TWELFTH NERVE) (Figs. 795, 796).

The **hypoglossal nerve** is the motor nerve of the tongue.

Its fibres arise from the cells of the **hypoglossal nucleus**, which is an upward prolongation of the base of the anterior column of gray substance of the medulla spinalis. This nucleus is about 2 cm. in length, and its upper part corresponds with the **trigonum hypoglossi**, or lower portion of the medial eminence of the rhomboid fossa (page 848). The lower part of the nucleus extends downward into the closed part of the medulla oblongata, and there lies in relation to the ventro-lateral aspect of the central canal. The fibres run forward through the medulla oblongata, and emerge in the antero-lateral sulcus between the pyramid and the olive.

The rootlets of this nerve are collected into two bundles, which perforate the dura mater separately, opposite the hypoglossal canal in the occipital bone, and unite together after their passage through it; in some cases the canal is divided into two by a small bony spicule. The nerve descends almost vertically to a point corresponding with the angle of the mandible. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and intimately connected with the vagus nerve; it then passes forward between the vein and artery, and lower down in the neck becomes superficial below the Digastricus. The nerve then loops

FIG. 796.—Plan of hypoglossal nerve.

around the occipital artery, and crosses the external carotid and lingual arteries below the tendon of the Digastricus. It passes beneath the tendon of the Digastricus, the Stylohyoides, and the Mylohyoides, lying between the last-named muscle and the Hyoglossus, and communicates at the anterior border of the Hyoglossus with the lingual nerve; it is then continued forward in the fibres of the Genioglossus as far as the tip of the tongue, distributing branches to its muscular substance.

Branches of Communication.—Its branches of communication are, with the

Vagus.

Sympathetic.

First and second cervical nerves.

Lingual.

The communications with the vagus take place close to the skull, numerous filaments passing between the hypoglossal and the ganglion nodosum of the vagus

through the mass of connective tissue which unites the two nerves. As the nerve winds around the occipital artery it gives off a filament to the pharyngeal plexus.

The communication with the sympathetic takes place opposite the atlas by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by a filament derived from the loop connecting the first and second cervical nerves.

The communications with the lingual take place near the anterior border of the Hyoglossus by numerous filaments which ascend upon the muscle.

Branches of Distribution.—The branches of distribution of the hypoglossal nerve are.

Meningeal.
Descending.

Thyroid.
Muscular.

Of these branches, the meningeal, descending, thyroid, and the muscular twig to the Geniohyoideus, are probably derived mainly from the branch which passes from the loop between the first and second cervical to join the hypoglossal (Fig. 746).

Meningeal Branches (dural branches).—As the hypoglossal nerve passes through the hypoglossal canal it gives off, according to Luschka, several filaments to the dura mater in the posterior fossa of the skull.

The **Descending Ramus** (*ramus descendens; descendens hypoglossi*), long and slender, quits the hypoglossal where it turns around the occipital artery and descends in front of or in the sheath of the carotid vessels; it gives a branch to the superior belly of the Omohyoideus, and then joins the communicantes cervicales from the second and third cervical nerves; just below the middle of the neck, to form a loop, the **ansa hypoglossi**. From the convexity of this loop branches pass to supply the Sternohyoideus, the Sternothyreoideus, and the inferior belly of the Omohyoideus. According to Arnold, another filament descends in front of the vessels into the thorax, and joins the cardiac and phrenic nerves.

The **Thyroid Branch** (*ramus thyrohyoideus*) arises from the hypoglossal near the posterior border of the hyoglossus; it runs obliquely across the greater cornu of the hyoid bone, and supplies the Thyrohyoideus muscle.

The **Muscular Branches** are distributed to the Styloglossus, Hyoglossus, Geniohyoideus, and Genioglossus. At the under surface of the tongue numerous slender branches pass upward into the substance of the organ to supply its intrinsic muscles.

Applied Anatomy.—The hypoglossal nerve is an important guide in the operation of ligature of the lingual artery (see p. 632). It runs forward on the Hyoglossus just above the greater cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for by cutting through the fibres of the Hyoglossus. In cases where the nerve is involved by gumma or new growth of the base of the skull, or where it has been injured on one side of the neck, or in some cases of bulbar paralysis, unilateral paralysis, together with hemiatrophy of the tongue, results; the tongue, when protruded, being directed to the paralyzed side owing to the unopposed action of the Genioglossus of the opposite side. On retraction, the wasted and paralyzed side of the tongue rises up higher than the other. The larynx may deviate toward the sound side on swallowing, from the unilateral paralysis of the depressors of the hyoid bone. If the paralysis is bilateral, the tongue lies motionless in the mouth, while articulation and mastication are much interfered with.

THE SPINAL NERVES (NERVI SPINALES).

The **spinal nerves** spring from the medulla spinalis, and are transmitted through the intervertebral foramina. They number thirty-one pairs, which are grouped as follows: Cervical, 8; Thoracic, 12; Lumbar, 5; Sacral, 5; Coccygeal, 1.

The **first cervical nerve** emerges from the vertebral canal between the occipital bone and the atlas, and is therefore called the **suboccipital nerve**; the eighth issues between the seventh cervical and first thoracic vertebræ.

Nerve Roots.—Each nerve is attached to the medulla spinalis by two roots, an **anterior** or **ventral**, and a **posterior** or **dorsal**, the latter being characterized by the presence of a ganglion, the **spinal ganglion**.

The **Anterior Root** (*radix anterior; ventral root*) emerges from the anterior surface of the medulla spinalis as a number of rootlets or filaments (*fila radicularia*), which coalesce to form two bundles near the intervertebral foramen.

The **Posterior Root** (*radix posterior; dorsal root*) is larger than the anterior owing to the greater size and number of its rootlets; these are attached along the posterolateral furrow of the medulla spinalis and unite to form two bundles which join the spinal ganglion. The posterior root of the first cervical nerve is exceptional in that it is smaller than the anterior; it is occasionally wanting.

Ventral aspect

Dorsal aspect

FIG. 797.—Distribution of cutaneous nerves.

The **Spinal Ganglia** (*ganglion spinale*) are collections of nerve cells on the posterior roots of the spinal nerves. Each ganglion is oval in shape, reddish in color, and its size bears a proportion to that of the nerve root on which it is situated; it is bifid medially where it is joined by the two bundles of the posterior nerve root.

The ganglia are usually placed in the intervertebral foramina, immediately outside the points where the nerve roots perforate the dura mater, but there are exceptions to this rule; thus the ganglia of the first and second cervical nerves lie on the vertebral arches of the atlas and axis respectively, those of the sacral nerves are inside the vertebral canal, while that on the posterior root of the coccygeal nerve is placed within the sheath of dura mater.

Structure (Fig. 679).—The ganglia consist chiefly of unipolar nerve cells, and from these the fibres of the posterior root take origin—the single process of each cell dividing after a short course into a central fibre which enters the medulla spinalis and a peripheral fibre which runs into the spinal nerve. Two other forms of cells are, however, present, viz.: (a) the cells of Dogiel, whose axons ramify close to the cell (type II, of Golgi), and are distributed entirely within the ganglion; and (b) multipolar cells similar to those found in the sympathetic ganglia.

The ganglia of the first cervical nerve may be absent, while small *aberrant ganglia* consisting of groups of nerve cells are sometimes found on the posterior roots between the spinal ganglia and the medulla spinalis.

Each nerve root receives a covering from the pia mater, and is loosely invested by the arachnoid, the latter being prolonged as far as the points where the roots pierce the dura mater. The two roots pierce the dura mater separately, each receiving a sheath from this membrane; where the roots join to form the spinal nerve this sheath is continuous with the epineurium of the nerve.

Size and Direction.—The roots of the upper four *cervical* nerves are small, those of the lower four are large. The posterior roots of the cervical nerves bear a proportion to the anterior of three to one, which is greater than in the other regions; their individual filaments are also larger than those of the anterior roots. The posterior root of the first cervical is an exception to this rule, being smaller than the anterior root; in eight per cent. of cases it is wanting. The roots of the first and second cervical nerves are short, and run nearly horizontally to their points of exit from the vertebral canal. From the second to the eighth cervical they are directed obliquely downward, the obliquity and length of the roots successively increasing; the distance, however, between the level of attachment of any of these roots to the medulla spinalis and the points of exit of the corresponding nerves never exceeds the depth of one vertebra.

The roots of the *thoracic* nerves, with the exception of the first, are of small size, and the posterior only slightly exceed the anterior in thickness. They increase successively in length, from above downward, and in the lower part of the thoracic region descend in contact with the medulla spinalis for a distance equal to the height of at least two vertebræ before they emerge from the vertebral canal.

The roots of the lower *lumbar* and upper *sacral* nerves are the largest, and their individual filaments the most numerous of all the spinal nerves, while the roots of the *coccygeal* nerve are the smallest.

The roots of the lumbar, sacral, and coccygeal nerves run vertically downward to their respective exits, and as the medulla spinalis ends near the lower border of the first lumbar vertebra it follows that the length of the successive roots must rapidly increase. As already mentioned (page 806), the term *cauda equina* is applied to this collection of nerve roots.

From the description given it will be seen that the largest nerve roots, and consequently the largest spinal nerves, are attached to the cervical and lumbar swellings of the medulla spinalis; these nerves are distributed to the upper and lower limbs.

Connections with Sympathetic.—Immediately beyond the spinal ganglion, the anterior and posterior nerve roots unite to form the *spinal nerve* which emerges through the intervertebral foramen. Each spinal nerve receives a branch (*gray ramus communicans*) from the adjacent ganglion of the sympathetic trunk, while the thoracic, and the first and second lumbar nerves each contribute a branch

(white ramus communicans) to the adjoining sympathetic ganglion. The second, third, and fourth sacral nerves also supply white rami; these, however, are not connected with the ganglia of the sympathetic trunk, but run directly into the pelvic plexuses of the sympathetic.

Structure.—Each typical spinal nerve contains fibres belonging to two systems, viz., the **somatic**, and the **sympathetic** or **splanchnic**, as well as fibres connecting these systems with each other (Fig. 798).

1. The **somatic fibres** are efferent and afferent. The *efferent fibres* originate in the cells of the anterior column of the medulla spinalis, and run outward through the anterior nerve roots to the spinal nerve. They convey impulses to the voluntary muscles, and are continuous from their origin to their peripheral distribution. The *afferent fibres* convey impressions inward from the skin, etc., and originate in the unipolar nerve cells of the spinal ganglia. The single processes of these cells divide into peripheral and central fibres, and the latter enter the medulla spinalis through the posterior nerve roots.

FIG. 798.—Scheme showing structure of a typical spinal nerve. 1. Somatic efferent. 2. Somatic afferent. 3, 4, 5. Splanchnic efferent. 6, 7. Splanchnic afferent.

2. The **sympathetic fibres** are also efferent and afferent. The *efferent fibres* originate in the lateral column of the medulla spinalis, and are conveyed through the anterior nerve root and the white ramus communicans to the corresponding ganglion of the sympathetic trunk; here they may end by forming synapses around its cells, or may run through the ganglion to end in another of the ganglia of the sympathetic trunk, or in a more distally placed ganglion in one of the sympathetic plexuses. In all cases they end by forming synapses around other nerve cells. From the cells of the ganglia of the sympathetic trunk other fibres take origin; some of these run through the gray rami communicantes to join the spinal nerves, along which they are carried to the blood-vessels of the trunk and limbs, while others pass to the viscera, either directly or after interruption in one of the distal ganglia. The *afferent fibres* are derived partly from the unipolar cells and partly from the multipolar cells of the spinal ganglia. Their peripheral processes are carried through the white rami communicantes, and after passing through one or more sympathetic ganglia (but always without interruption in them) finally end in the tissues of the viscera. The central processes of the unipolar cells enter the medulla spinalis through the posterior nerve root and form synapses around either somatic or sympathetic efferent neurones, thus completing reflex arcs. The dendrites of the multipolar nerve cells form synapses around the cells of type II (cells of Dogiel) in the spinal ganglia, and by this path the original impulse is transferred from the sympathetic to the somatic system, through which it is conveyed to the sensorium.

Divisions.—After emerging from the intervertebral foramen, each spinal nerve gives off a small **meningeal branch** which reënters the vertebral canal through the intervertebral foramen and supplies the vertebræ and their ligaments, and the bloodvessels of the medulla spinalis and its membranes. The spinal nerve then splits into a **posterior or dorsal**, and an **anterior or ventral division**, each receiving fibres from both nerve roots.

POSTERIOR DIVISIONS OF THE SPINAL NERVES (RAMI POSTERIORES).

The **posterior divisions** are as a rule smaller than the anterior. They are directed backward, and, with the exceptions of those of the first cervical, the fourth and fifth sacral, and the coccygeal, divide into medial and lateral branches for the supply of the muscles and skin (Figs. 799, 800) of the posterior part of the trunk.

The Cervical Nerves (Nn. Cervicales).

The **posterior division of the first cervical or suboccipital nerve** is larger than the anterior division, and emerges above the posterior arch of the atlas and beneath the vertebral artery. It enters the suboccipital triangle and supplies the muscles which bound this triangle, viz., the Rectus capitis posterior major, and the Obliquus superior and inferior; it gives branches also to the Rectus capitis posterior minor and the Semispinalis capitis. A filament from the branch to the Obliquus inferior joins the posterior division of the second cervical nerve.

The nerve occasionally gives off a cutaneous branch which accompanies the occipital artery to the scalp, and communicates with the greater and lesser occipital nerves.

The **posterior division of the second cervical nerve** is much larger than the anterior division, and is the greatest of all the cervical posterior divisions. It emerges between the posterior arch of the atlas and the lamina of the axis, below the Obliquus inferior. It supplies a twig to this muscle, receives a communicating filament from the posterior division of the first cervical, and then divides into a large medial and a small lateral branch.

The **medial branch** (*ramus medialis; internal branch*), called from its size and distribution the **greater occipital nerve** (*n. occipitalis major; great occipital nerve*), ascends obliquely between the Obliquus inferior and the Semispinalis capitis, and pierces the latter muscle and the Trapezius near their attachments to the occipital bone (Fig. 799). It is then joined by a filament from the medial branch of the posterior division of the third cervical, and, ascending on the back of the head with the occipital artery, divides into branches which communicate with the lesser occipital nerve and supply the skin of the scalp as far forward as the vertex of the skull. It gives off muscular branches to the Semispinalis capitis, and occasionally a twig to the back of the auricula. The **lateral branch** (*ramus lateralis; external branch*) supplies filaments to the Splenius, Longus capitis, and Semispinalis capitis, and is often joined by the corresponding branch of the third cervical.

The **posterior division of the third cervical** is intermediate in size between those of the second and fourth. Its **medial branch** runs between the Semispinalis capitis and cervicis, and, piercing the Splenius and Trapezius, ends in the skin. While under the Trapezius it gives off a branch called the **third occipital nerve**, which pierces the Trapezius and ends in the skin of the lower part of the back of the head (Fig. 799). It lies medial to the greater occipital and communicates with it. The **lateral branch** often joins that of the second cervical.

The posterior division of the suboccipital, and the medial branches of the posterior division of the second and third cervical nerves are sometimes joined by communicating loops to form the **posterior cervical plexus** (Cruveilhier).

The **posterior divisions of the lower five cervical nerves** divide into medial and lateral branches. The **medial branches** of the fourth and fifth run between the

Semispinales cervicis and capitis, and, having reached the spinous processes, pierce the Splenius and Trapezius to end in the skin (Fig. 799). Sometimes the branch of the fifth fails to reach the skin. Those of the lower three nerves are small, and end in the Semispinales cervicis and capitis, Multifidus, and Interspinales. The lateral branches of the lower five nerves supply the Iliocostalis cervicis, Longissimus cervicis, and Longissimus capitis.

FIG. 799.—Diagram of the distribution of the cutaneous branches of the posterior divisions of the spinal nerves.

FIG. 800.—Areas of distribution of the cutaneous branches of the posterior divisions of the spinal nerves. (H. M. Johnston.) The areas of the medial branches are in black, those of the lateral in red.

The Thoracic Nerves (Nn. Thoracales).

The medial branches (*ramus medialis; internal branch*) of the posterior divisions of the upper six thoracic nerves run between the Semispinalis dorsi and Multifidus, which they supply; they then pierce the Rhomboidei and Trapezius, and reach the skin by the sides of the spinous processes (Fig. 799). The medial branches

of the lower six are distributed chiefly to the Multifidus and Longissimus dorsi; occasionally they give off filaments to the skin near the middle line.

The lateral branches (*ramus lateralis; external branch*) increase in size from above downward. They run through or beneath the Longissimus dorsi to the interval between it and the Iliocostales, and supply these muscles; the lower five or six also give off cutaneous branches which pierce the Serratus posterior inferior and Latissimus dorsi in a line with the angles of the ribs (Fig. 799). The lateral branches of a variable number of the upper thoracic nerves also give filaments to the skin. The lateral branch of the twelfth thoracic, after sending a filament medialward along the iliac crest, passes downward to the skin of the buttock.

The medial cutaneous branches of the posterior divisions of the thoracic nerves descend for some distance close to the spinous processes before reaching the skin, while the lateral branches travel downward for a considerable distance—it may be as much as the breadth of four ribs—before they become superficial; the branch from the twelfth thoracic, for instance, reaches the skin only a little way above the iliac crest.¹

The Lumbar Nerves (Nn. Lumbales).

The medial branches of the posterior divisions of the lumbar nerves run close to the articular processes of the vertebræ and end in the Multifidus.

The lateral branches supply the Sacrospinalis. The upper three give off cutaneous nerves which pierce the aponeurosis of the Latissimus dorsi at the lateral border of the Sacrospinalis and descend across the posterior part of the iliac crest to the skin of the buttock (Fig. 799), some of their twigs running as far as the level of the greater trochanter.

FIG. 801.—The posterior divisions of the sacral nerves.

The Sacral Nerves (Nn. Sacrales).

The posterior divisions of the sacral nerves (*rami posteriores*) (Fig. 801) are small, and diminish in size from above downward; they emerge, except the last,

¹ See article by H. M. Johnston, *Journal of Anatomy and Physiology*, vol. xliii.

The rootlets of this nerve are collected into two bundles, which perforate the dura mater separately, opposite the hypoglossal canal in the occipital bone, and unite together after their passage through it; in some cases the canal is divided into two by a small bony spicule. The nerve descends almost vertically to a point corresponding with the angle of the mandible. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and intimately connected with the vagus nerve; it then passes forward between the vein and artery, and lower down in the neck becomes superficial below the Digastricus. The nerve then loops

FIG. 796.—Plan of hypoglossal nerve.

around the occipital artery, and crosses the external carotid and lingual arteries below the tendon of the Digastricus. It passes beneath the tendon of the Digastricus, the Stylohyoideus, and the Mylohyoideus, lying between the last-named muscle and the Hyoglossus, and communicates at the anterior border of the Hyoglossus with the lingual nerve; it is then continued forward in the fibres of the Genioglossus as far as the tip of the tongue, distributing branches to its muscular substance.

Branches of Communication.—Its branches of communication are, with the

Vagus.

Sympathetic.

First and second cervical nerves.

Lingual.

The communications with the vagus take place close to the skull, numerous filaments passing between the hypoglossal and the ganglion nodosum of the vagus

through the mass of connective tissue which unites the two nerves. As the nerve winds around the occipital artery it gives off a filament to the pharyngeal plexus.

The communication with the sympathetic takes place opposite the atlas by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by a filament derived from the loop connecting the first and second cervical nerves.

The communications with the lingual take place near the anterior border of the Hyoglossus by numerous filaments which ascend upon the muscle.

Branches of Distribution.—The branches of distribution of the hypoglossal nerve are:

Meningeal.
Descending.

Thyrohyoid.
Muscular.

Of these branches, the meningeal, descending, thyrohyoid, and the muscular twig to the Geniohyoideus, are probably derived mainly from the branch which passes from the loop between the first and second cervical to join the hypoglossal (Fig. 796).

Meningeal Branches (dural branches).—As the hypoglossal nerve passes through the hypoglossal canal it gives off, according to Luschka, several filaments to the dura mater in the posterior fossa of the skull.

The **Descending Ramus** (*ramus descendens; descendens hypoglossi*), long and slender, quits the hypoglossal where it turns around the occipital artery and descends in front of or in the sheath of the carotid vessels; it gives a branch to the superior belly of the Omohyoideus, and then joins the communicantes cervicales from the second and third cervical nerves; just below the middle of the neck, to form a loop, the **ansa hypoglossi**. From the convexity of this loop branches pass to supply the Sternohyoideus, the Sternothyreoideus, and the inferior belly of the Omohyoideus. According to Arnold, another filament descends in front of the vessels into the thorax, and joins the cardiac and phrenic nerves.

The **Thyrohyoid Branch** (*ramus thyreochoideus*) arises from the hypoglossal near the posterior border of the hyoglossus; it runs obliquely across the greater cornu of the hyoid bone, and supplies the Thyreochoideus muscle.

The **Muscular Branches** are distributed to the Styloglossus, Hyoglossus, Geniohyoideus, and Genioglossus. At the under surface of the tongue numerous slender branches pass upward into the substance of the organ to supply its intrinsic muscles.

Applied Anatomy.—The hypoglossal nerve is an important guide in the operation of ligature of the lingual artery (see p. 632). It runs forward on the Hyoglossus just above the greater cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought for by cutting through the fibres of the Hyoglossus. In cases where the nerve is involved by gumma or new growth of the base of the skull, or where it has been injured on one side of the neck, or in some cases of bulbar paralysis, unilateral paralysis, together with hemiatrophy of the tongue, results; the tongue, when protruded, being directed to the paralyzed side owing to the unopposed action of the Genioglossus of the opposite side. On retraction, the wasted and paralyzed side of the tongue rises up higher than the other. The larynx may deviate toward the sound side on swallowing, from the unilateral paralysis of the depressors of the hyoid bone. If the paralysis is bilateral, the tongue lies motionless in the mouth, while articulation and mastication are much interfered with.

THE SPINAL NERVES (NERVI SPINALES).

The **spinal nerves** spring from the medulla spinalis, and are transmitted through the intervertebral foramina. They number thirty-one pairs, which are grouped as follows: Cervical, 8; Thoracic, 12; Lumbar, 5; Sacral, 5; Coccygeal, 1.

The **first cervical nerve** emerges from the vertebral canal between the occipital bone and the atlas, and is therefore called the **suboccipital nerve**; the eighth issues between the seventh cervical and first thoracic vertebrae.

Nerve Roots.—Each nerve is attached to the medulla spinalis by two roots, an **anterior** or **ventral**, and a **posterior** or **dorsal**, the latter being characterized by the presence of a ganglion, the **spinal ganglion**.

The **Anterior Root** (*radix anterior; ventral root*) emerges from the anterior surface of the medulla spinalis as a number of rootlets or filaments (*fila radicularia*), which coalesce to form two bundles near the intervertebral foramen.

The **Posterior Root** (*radix posterior; dorsal root*) is larger than the anterior owing to the greater size and number of its rootlets; these are attached along the posterolateral furrow of the medulla spinalis and unite to form two bundles which join the spinal ganglion. The posterior root of the first cervical nerve is exceptional in that it is smaller than the anterior; it is occasionally wanting.

Ventral aspect

Dorsal aspect

FIG. 797.—Distribution of cutaneous nerves.

The **Spinal Ganglia** (*ganglion spinale*) are collections of nerve cells on the posterior roots of the spinal nerves. Each ganglion is oval in shape, reddish in color, and its size bears a proportion to that of the nerve root on which it is situated; it is bifid medially where it is joined by the two bundles of the posterior nerve root.

The ganglia are usually placed in the intervertebral foramina, immediately outside the points where the nerve roots perforate the dura mater, but there are exceptions to this rule; thus the ganglia of the first and second cervical nerves lie on the vertebral arches of the atlas and axis respectively, those of the sacral nerves are inside the vertebral canal, while that on the posterior root of the coccygeal nerve is placed within the sheath of dura mater.

Structure (Fig. 679).—The ganglia consist chiefly of unipolar nerve cells, and from these the fibres of the posterior root take origin—the single process of each cell dividing after a short course into a central fibre which enters the medulla spinalis and a peripheral fibre which runs into the spinal nerve. Two other forms of cells are, however, present, viz.: (a) the cells of Dogiel, whose axons ramify close to the cell (type II, of Golgi), and are distributed entirely within the ganglion; and (b) multipolar cells similar to those found in the sympathetic ganglia.

The ganglia of the first cervical nerve may be absent, while small *aberrant ganglia* consisting of groups of nerve cells are sometimes found on the posterior roots between the spinal ganglia and the medulla spinalis.

Each nerve root receives a covering from the pia mater, and is loosely invested by the arachnoid, the latter being prolonged as far as the points where the roots pierce the dura mater. The two roots pierce the dura mater separately, each receiving a sheath from this membrane; where the roots join to form the spinal nerve this sheath is continuous with the epineurium of the nerve.

Size and Direction.—The roots of the upper four *cervical* nerves are small, those of the lower four are large. The posterior roots of the cervical nerves bear a proportion to the anterior of three to one, which is greater than in the other regions; their individual filaments are also larger than those of the anterior roots. The posterior root of the first cervical is an exception to this rule, being smaller than the anterior root; in eight per cent. of cases it is wanting. The roots of the first and second cervical nerves are short, and run nearly horizontally to their points of exit from the vertebral canal. From the second to the eighth cervical they are directed obliquely downward, the obliquity and length of the roots successively increasing; the distance, however, between the level of attachment of any of these roots to the medulla spinalis and the points of exit of the corresponding nerves never exceeds the depth of one vertebra.

The roots of the *thoracic* nerves, with the exception of the first, are of small size, and the posterior only slightly exceed the anterior in thickness. They increase successively in length, from above downward, and in the lower part of the thoracic region descend in contact with the medulla spinalis for a distance equal to the height of at least two vertebræ before they emerge from the vertebral canal.

The roots of the lower *lumbar* and upper *sacral* nerves are the largest, and their individual filaments the most numerous of all the spinal nerves, while the roots of the *coccygeal* nerve are the smallest.

The roots of the lumbar, sacral, and coccygeal nerves run vertically downward to their respective exits, and as the medulla spinalis ends near the lower border of the first lumbar vertebra it follows that the length of the successive roots must rapidly increase. As already mentioned (page 806), the term *cauda equina* is applied to this collection of nerve roots.

From the description given it will be seen that the largest nerve roots, and consequently the largest spinal nerves, are attached to the cervical and lumbar swellings of the medulla spinalis; these nerves are distributed to the upper and lower limbs.

Connections with Sympathetic.—Immediately beyond the spinal ganglion, the anterior and posterior nerve roots unite to form the *spinal nerve* which emerges through the intervertebral foramen. Each spinal nerve receives a branch (*gray ramus communicans*) from the adjacent ganglion of the sympathetic trunk, while the thoracic, and the first and second lumbar nerves each contribute a branch

(white ramus communicans) to the adjoining sympathetic ganglion. The second, third, and fourth sacral nerves also supply white rami; these, however, are not connected with the ganglia of the sympathetic trunk, but run directly into the pelvic plexuses of the sympathetic.

Structure.—Each typical spinal nerve contains fibres belonging to two systems, viz., the **somatic**, and the **sympathetic** or **splanchnic**, as well as fibres connecting these systems with each other (Fig. 798).

1. The **somatic fibres** are efferent and afferent. The *efferent fibres* originate in the cells of the anterior column of the medulla spinalis, and run outward through the anterior nerve roots to the spinal nerve. They convey impulses to the voluntary muscles, and are continuous from their origin to their peripheral distribution. The *afferent fibres* convey impressions inward from the skin, etc., and originate in the unipolar nerve cells of the spinal ganglia. The single processes of these cells divide into peripheral and central fibres, and the latter enter the medulla spinalis through the posterior nerve roots.

FIG. 798.—Scheme showing structure of a typical spinal nerve. 1. Somatic efferent. 2. Somatic afferent. 3, 4, 5. Splanchnic efferent. 6, 7. Splanchnic afferent.

2. The **sympathetic fibres** are also efferent and afferent. The *efferent fibres* originate in the lateral column of the medulla spinalis, and are conveyed through the anterior nerve root and the white ramus communicans to the corresponding ganglion of the sympathetic trunk; here they may end by forming synapses around its cells, or may run through the ganglion to end in another of the ganglia of the sympathetic trunk, or in a more distally placed ganglion in one of the sympathetic plexuses. In all cases they end by forming synapses around other nerve cells. From the cells of the ganglia of the sympathetic trunk other fibres take origin; some of these run through the gray rami communicantes to join the spinal nerves, along which they are carried to the blood-vessels of the trunk and limbs, while others pass to the viscera, either directly or after interruption in one of the distal ganglia. The *afferent fibres* are derived partly from the unipolar cells and partly from the multipolar cells of the spinal ganglia. Their peripheral processes are carried through the white rami communicantes, and after passing through one or more sympathetic ganglia (but always without interruption in them) finally end in the tissues of the viscera. The central processes of the unipolar cells enter the medulla spinalis through the posterior nerve root and form synapses around either somatic or sympathetic efferent neurons, thus completing reflex arcs. The dendrites of the multipolar nerve cells form synapses around the cells of type II (cells of Dogiel) in the spinal ganglia, and by this path the original impulse is transferred from the sympathetic to the somatic system, through which it is conveyed to the sensorium.

Divisions.—After emerging from the intervertebral foramen, each spinal nerve gives off a small **meningeal branch** which reënters the vertebral canal through the intervertebral foramen and supplies the vertebræ and their ligaments, and the bloodvessels of the medulla spinalis and its membranes. The spinal nerve then splits into a **posterior or dorsal**, and an **anterior or ventral division**, each receiving fibres from both nerve roots.

POSTERIOR DIVISIONS OF THE SPINAL NERVES (RAMI POSTERIORES).

The **posterior divisions** are as a rule smaller than the anterior. They are directed backward, and, with the exceptions of those of the first cervical, the fourth and fifth sacral, and the coccygeal, divide into medial and lateral branches for the supply of the muscles and skin (Figs. 799, 800) of the posterior part of the trunk.

The Cervical Nerves (Nn. Cervicales).

The **posterior division of the first cervical or suboccipital nerve** is larger than the anterior division, and emerges above the posterior arch of the atlas and beneath the vertebral artery. It enters the suboccipital triangle and supplies the muscles which bound this triangle, viz., the Rectus capitis posterior major, and the Obliquus superior and inferior; it gives branches also to the Rectus capitis posterior minor and the Semispinalis capitis. A filament from the branch to the Obliquus inferior joins the posterior division of the second cervical nerve.

The nerve occasionally gives off a cutaneous branch which accompanies the occipital artery to the scalp, and communicates with the greater and lesser occipital nerves.

The **posterior division of the second cervical nerve** is much larger than the anterior division, and is the greatest of all the cervical posterior divisions. It emerges between the posterior arch of the atlas and the lamina of the axis, below the Obliquus inferior. It supplies a twig to this muscle, receives a communicating filament from the posterior division of the first cervical, and then divides into a large medial and a small lateral branch.

The **medial branch** (*ramus medialis; internal branch*), called from its size and distribution the **greater occipital nerve** (*n. occipitalis major; great occipital nerve*), ascends obliquely between the Obliquus inferior and the Semispinalis capitis, and pierces the latter muscle and the Trapezius near their attachments to the occipital bone (Fig. 799). It is then joined by a filament from the medial branch of the posterior division of the third cervical, and, ascending on the back of the head with the occipital artery, divides into branches which communicate with the lesser occipital nerve and supply the skin of the scalp as far forward as the vertex of the skull. It gives off muscular branches to the Semispinalis capitis, and occasionally a twig to the back of the auricula. The **lateral branch** (*ramus lateralis; external branch*) supplies filaments to the Splenius, Longus capitis, and Semispinalis capitis, and is often joined by the corresponding branch of the third cervical.

The **posterior division of the third cervical** is intermediate in size between those of the second and fourth. Its **medial branch** runs between the Semispinalis capitis and cervicis, and, piercing the Splenius and Trapezius, ends in the skin. While under the Trapezius it gives off a branch called the **third occipital nerve**, which pierces the Trapezius and ends in the skin of the lower part of the back of the head (Fig. 799). It lies medial to the greater occipital and communicates with it. The **lateral branch** often joins that of the second cervical.

The posterior division of the suboccipital, and the medial branches of the posterior division of the second and third cervical nerves are sometimes joined by communicating loops to form the **posterior cervical plexus** (Cruveilhier).

The **posterior divisions of the lower five cervical nerves** divide into medial and lateral branches. The **medial branches** of the fourth and fifth run between the

Semispinales cervicis and capitis, and, having reached the spinous processes, pierce the Splenius and Trapezius to end in the skin (Fig. 799). Sometimes the branch of the fifth fails to reach the skin. Those of the lower three nerves are small, and end in the Semispinales cervicis and capitis, Multifidus, and Interspinales. The lateral branches of the lower five nerves supply the Iliocostalis cervicis, Longissimus cervicis, and Longissimus capitis.

FIG. 799. —Diagram of the distribution of the cutaneous branches of the posterior divisions of the spinal nerves.

FIG. 800. —Areas of distribution of the cutaneous branches of the posterior divisions of the spinal nerves. (H. M. Johnston.) The areas of the medial branches are in black, those of the lateral in red.

The Thoracic Nerves (Nn. Thoracales).

The medial branches (*ramus medialis; internal branch*) of the posterior divisions of the upper six thoracic nerves run between the Semispinalis dorsi and Multifidus, which they supply; they then pierce the Rhomboidei and Trapezius, and reach the skin by the sides of the spinous processes (Fig. 799). The medial branches

of the lower six are distributed chiefly to the Multifidus and Longissimus dorsi; occasionally they give off filaments to the skin near the middle line.

The lateral branches (*ramus lateralis; external branch*) increase in size from above downward. They run through or beneath the Longissimus dorsi to the interval between it and the Iliocostales, and supply these muscles; the lower five or six also give off cutaneous branches which pierce the Serratus posterior inferior and Latissimus dorsi in a line with the angles of the ribs (Fig. 799). The lateral branches of a variable number of the upper thoracic nerves also give filaments to the skin. The lateral branch of the twelfth thoracic, after sending a filament medialward along the iliac crest, passes downward to the skin of the buttock.

The medial cutaneous branches of the posterior divisions of the thoracic nerves descend for some distance close to the spinous processes before reaching the skin, while the lateral branches travel downward for a considerable distance—it may be as much as the breadth of four ribs—before they become superficial; the branch from the twelfth thoracic, for instance, reaches the skin only a little way above the iliac crest.¹

The Lumbar Nerves (Nn. Lumbales).

The medial branches of the posterior divisions of the lumbar nerves run close to the articular processes of the vertebræ and end in the Multifidus.

The lateral branches supply the Sacrospinalis. The upper three give off cutaneous nerves which pierce the aponeurosis of the Latissimus dorsi at the lateral border of the Sacrospinalis and descend across the posterior part of the iliac crest to the skin of the buttock (Fig. 799), some of their twigs running as far as the level of the greater trochanter.

FIG. 801.—The posterior divisions of the sacral nerves.

The Sacral Nerves (Nn. Sacrales).

The posterior divisions of the sacral nerves (*rami posteriores*) (Fig. 801) are small, and diminish in size from above downward; they emerge, except the last,

¹ See article by H. M. Johnston, *Journal of Anatomy and Physiology*, vol. xliii.

through the posterior sacral foramina. The *upper three* are covered at their points of exit by the Multifidus, and divide into medial and lateral branches.

The **medial branches** are small, and end in the Multifidus.

The **lateral branches** join with one another and with the lateral branches of the posterior divisions of the last lumbar and fourth sacral to form loops on the dorsal surface of the sacrum. From these loops branches run to the dorsal surface of the sacrotuberous ligament and form a second series of loops under the Glutæus maximus. From this second series cutaneous branches, two or three in number, pierce the Glutæus maximus along a line drawn from the posterior superior iliac spine to the tip of the coccyx; they supply the skin over the posterior part of the buttock.

The posterior divisions of the *lower two* sacral nerves are small and lie below the Multifidus. They do not divide into medial and lateral branches, but unite with each other and with the posterior division of the coccygeal nerve to form loops on the back of the sacrum; filaments from these loops supply the skin over the coccyx.

The Coccygeal Nerve (N. Coccygeus).

The **posterior division of the coccygeal nerve** (*ramus posterior*) does not divide into a medial and a lateral branch, but receives, as already stated, a communicating branch from the last sacral; it is distributed to the skin over the back of the coccyx.

ANTERIOR DIVISIONS OF THE SPINAL NERVES (RAMI ANTERIORES).

The **anterior divisions of the spinal nerves** supply the antero-lateral parts of the trunk, and the limbs; they are for the most part larger than the posterior divisions. In the thoracic region they run independently of one another, but in the cervical, lumbar, and sacral regions they unite near their origins to form plexuses.

The Cervical Nerves (Nn. Cervicales).

The anterior divisions of the cervical nerves (*rami anteriores*), with the exception of the first, pass outward between the Intertransversarii anterior and posterior, lying on the grooved upper surfaces of the transverse processes of the vertebræ. The **anterior division of the first or suboccipital nerve** issues from the vertebral canal above the posterior arch of the atlas and runs forward around the lateral aspect of its superior articular process, medial to the vertebral artery. In most cases it descends medial to and in front of the Rectus capitis lateralis, but occasionally it pierces the muscle.

The anterior divisions of the **upper four cervical nerves** unite to form the **cervical plexus**, and each receives a gray ramus communicans from the superior cervical ganglion of the sympathetic trunk. Those of the **lower four cervical**, together with the greater part of the first thoracic, form the **brachial plexus**. They each receive a gray ramus communicans, those for the fifth and sixth being derived from the middle, and those for the seventh and eighth from the lowest, cervical ganglion of the sympathetic trunk.

The Cervical Plexus (*plexus cervicalis*) (Fig. 802).—The cervical plexus is formed by the anterior divisions of the upper four cervical nerves; each nerve, except the first, divides into an upper and a lower branch, and the branches unite to form three loops. The plexus is situated opposite the upper four cervical vertebræ, in front of the Levator scapulae and Scalenus medius, and covered by the Sternocleidomastoideus.

Its branches are divided into two groups, **superficial and deep**, and are here given in tabular form; the figures following the names indicate the nerves from which the different branches take origin:

<i>Superficial</i>	{	Smaller occipital	2, C.				
		Great auricular	2, 3, C.				
		Cutaneous cervical	2, 3, C.				
		Supraclavicular	3, 4, C.				
<i>Deep</i>	{	<i>Internal</i>	{	Communicating	{	With hypoglossal	1, 2, C.
				“ vagus	1, 2, C.		
				“ sympathetic	1, 2, 3, 4, C.		
				Rectus capitis lateralis	1, C.		
				Rectus capitis anterior	1, 2, C.		
		<i>Muscular</i>	Longus capitis	1, 2, 3, C.			
			Communicantes cervicales	2, 3, C.			
			Phrenic	3, 4, 5, C.			
			{	<i>External</i>	Communicating with accessory	2, 3, 4, C.	
					Sternocleidomastoideus	2, C.	
	Trapezius	3, 4, C.					
	Levator scapulæ	3, 4, C.					
	Scalenus medius	3, 4, C.					

FIG. 802.—Plan of cervical plexus.

Superficial Branches of the Cervical Plexus (Fig. 803).—The **Smaller Occipital Nerve** (*n. occipitalis minor*; *small occipital nerve*) arises from the second cervical nerve, sometimes also from the third; it curves around and ascends along the posterior border of the Sternocleidomastoideus. Near the cranium it perforates the deep fascia, and is continued upward along the side of the head behind the auricula, supplying the skin and communicating with the greater occipital, the great auricular, and the posterior auricular branch of the facial. The smaller occipital varies in size, and is sometimes duplicated.

Termination
f supratrochlear
f infratrochlear
f nasociliary

FIG. 803.—The nerves of the scalp, face, and side of neck.

It gives off an **auricular branch**, which supplies the skin of the upper and back part of the auricula, communicating with the mastoid branch of the great auricular. This branch is occasionally derived from the greater occipital nerve.

The **Great Auricular Nerve** (*n. auricularis magnus*) is the largest of the ascending branches. It arises from the second and third cervical nerves, winds around the posterior border of the Sternocleidomastoideus, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into an anterior and a posterior branch.

The **anterior branch** (*ramus anterior*; *facial branch*) is distributed to the skin of the face over the parotid gland, and communicates in the substance of the gland with the facial nerve.

The **posterior branch** (*ramus posterior; mastoid branch*) supplies the skin over the mastoid process and on the back of the auricula, except at its upper part; a filament pierces the auricula to reach its lateral surface, where it is distributed to the lobule and lower part of the concha. The posterior branch communicates with the smaller occipital, the auricular branch of the vagus, and the posterior auricular branch of the facial.

The **Cutaneous Cervical** (*n. cutaneus colli; superficial or transverse cervical nerve*) arises from the second and third cervical nerves, turns around the posterior border of the Sternocleidomastoideus about its middle, and, passing obliquely forward beneath the external jugular vein to the anterior border of the muscle, it perforates the deep cervical fascia, and divides beneath the Platysma into ascending and descending branches, which are distributed to the antero-lateral parts of the neck.

The **ascending branches** (*rami superiores*) pass upward to the submaxillary region, and form a plexus with the cervical branch of the facial nerve beneath the Platysma; others pierce that muscle, and are distributed to the skin of the upper and front part of the neck.

The **descending branches** (*rami inferiores*) pierce the Platysma, and are distributed to the skin of the side and front of the neck, as low as the sternum.

The **Supraclavicular Nerves** (*nn. supraclaviculares; descending branches*) arise from the third and fourth cervical nerves; they emerge beneath the posterior border of the Sternocleidomastoideus, and descend in the posterior triangle of the neck beneath the Platysma and deep cervical fascia. Near the clavicle they perforate the fascia and Platysma to become cutaneous, and are arranged, according to their position, into three groups—**anterior, middle and posterior**.

The **anterior supraclavicular nerves** (*nn. supraclaviculares anteriores; suprasternal nerves*) cross obliquely over the external jugular vein and the clavicular and sternal heads of the Sternocleidomastoideus, and supply the skin as far as the middle line. They furnish one or two filaments to the sternoclavicular joint.

The **middle supraclavicular nerves** (*nn. supraclaviculares medii; supraclavicular nerves*) cross the clavicle, and supply the skin over the Pectoralis major and Deltoideus, communicating with the cutaneous branches of the upper intercostal nerves.

The **posterior supraclavicular nerves** (*nn. supraclaviculares posteriores; supra-acromial nerves*) pass obliquely across the outer surface of the Trapezius and the acromion, and supply the skin of the upper and posterior parts of the shoulder.

Deep Branches of the Cervicle Plexus. INTERNAL SERIES.—The **Communicating Branches** consist of several filaments, which pass from the loop between the first and second cervical nerves to the vagus, hypoglossal, and sympathetic. The branch to the hypoglossal ultimately leaves that nerve as a series of branches, viz., the descending ramus, the nerve to the Thyreohyoideus and the nerve, to the Geniohyoideus (see page 947). A communicating branch also passes from the fourth to the fifth cervical, while each of the first four cervical nerves receives a gray ramus communicans from the superior cervical ganglion of the sympathetic.

Muscular Branches supply the Longus capitis, Rectus capitis anterior, and Rectus capitis lateralis.

The **Communicantes Cervicales** (*communicantes hypoglossi*) (Fig. 802) consist usually of two filaments, one derived from the second, and the other from the third cervical. These filaments join to form the **descendens cervicalis**, which passes downward on the lateral side of the internal jugular vein, crosses in front of the vein a little below the middle of the neck, and forms a loop (*ansa hypoglossi*) with the descending ramus of the hypoglossal in front of the sheath of the carotid vessels (see page 947). Occasionally, the loop is formed within the sheath.

The **Phrenic Nerve** (*n. phrenicus; internal respiratory nerve of Bell*) contains motor and sensory fibres in the proportion of about two to one. It arises chiefly from the

fourth cervical nerve, but receives a branch from the third and another from the fifth; the fibres from the fifth occasionally come through the nerve to the Subclavius. It descends to the root of the neck, running obliquely across the front of the Scalenus anterior, and beneath the Sternocleidomastoideus, the inferior belly of the Omohyoideus, and the transverse cervical and transverse scapular vessels. It next passes in front of the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the thorax, crosses the internal mammary artery near its origin. Within the thorax, it descends nearly vertically in front of the root of the lung, and then between the pericardium and the mediastinal pleura, to the Diaphragma, where it divides into branches, which pierce that muscle, and are distributed to its under surface. In the thorax it is accompanied by the pericardiophrenic branch of the internal mammary artery.

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The **right nerve** is situated more deeply, and is shorter and more vertical in direction than the left; it lies lateral to the right innominate vein and superior vena cava.

The **left nerve** is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragma being lower on this than on the right side. At the root of the neck it is crossed by the thoracic duct; in the superior mediastinal cavity it lies between the left common carotid and left subclavian arteries, and crosses superficial to the vagus on the left side of the arch of the aorta.

Each nerve supplies filaments to the pericardium and pleura, and at the root of the neck is joined by a filament from the sympathetic, and, occasionally, by one from the ansa hypoglossi. Branches have been described as passing to the peritoneum.

From the *right nerve*, one or two filaments pass to join in a small **phrenic ganglion** with phrenic branches of the coeliac plexus; and branches from this ganglion are distributed to the falciform and coronary ligaments of the liver, the suprarenal gland, inferior vena cava, and right atrium. From the *left nerve*, filaments pass to join the phrenic branches of the coeliac plexus, but without any ganglionic enlargement; and a twig is distributed to the left suprarenal gland.

Deep Branches of the Cervical Plexus. EXTERNAL SERIES.—**Communicating Branches.**—The external series of deep branches of the cervical plexus communicates with the accessory nerve, in the substance of the Sternocleidomastoideus, in the posterior triangle, and beneath the Trapezius.

Muscular Branches are distributed to the Sternocleidomastoideus, Trapezius, Levator scapulae, and Scalenus medius.

The branch for the Sternocleidomastoideus is derived from the second cervical; the Trapezius and Levator scapulae receive branches from the third and fourth. The Scalenus medius receives twigs either from the third or fourth, or occasionally from both.

Applied Anatomy.—Pains referred to the terminal branches of the cervical plexus are not uncommon in caries of the cervical vertebræ, where pain may be felt radiating over the occipital bone, if the disease is situated high up in the vertebral column.

The Brachial Plexus (*plexus brachialis*) (Fig. 804).—The brachial plexus is formed by the union of the anterior divisions of the lower four cervical nerves and the greater part of the anterior division of the first thoracic nerve; the fourth cervical usually gives a branch to the fifth cervical, and the first thoracic frequently receives one from the second thoracic. The plexus extends from the lower part of the side of the neck to the axilla. The nerves which form it are nearly equal in size, but their mode of communication is subject to some variation. The following

is, however, the most constant arrangement. The fifth and sixth cervical unite soon after their exit from the intervertebral foramina to form a trunk. The eighth cervical and first thoracic also unite to form one trunk, while the seventh cervical runs out alone. Three trunks—upper, middle, and lower—are thus formed, and, as they pass beneath the clavicle, each splits into an **anterior** and a **posterior division**.¹ The anterior divisions of the upper and middle trunks unite to form a cord, which is situated on the lateral side of the second part of the axillary artery, and is called the **lateral cord or fasciculus of the plexus**. The anterior division of the lower trunk passes down on the medial side of the axillary artery, and forms the **medial cord or fasciculus of the brachial plexus**. The posterior divisions of all three trunks unite to form the **posterior cord or fasciculus of the plexus**, which is situated behind the second portion of the axillary artery.

FIG. 804.—Plan of brachial plexus.

Relations.—*In the neck*, the brachial plexus lies in the posterior triangle, being covered by the skin, Platysma, and deep fascia; it is crossed by the supraclavicular nerves, the inferior belly of the Omohyoideus, the external jugular vein, and the transverse cervical artery. It emerges between the Scaleni anterior and medius; its upper part lies above the third part of the subclavian artery, while the trunk formed by the union of the eighth cervical and first thoracic is placed behind the artery; the plexus next passes behind the clavicle, the Subclavius, and the transverse scapular vessels, and lies upon the first digitation of the Serratus anterior, and the Subscapularis. *In the axilla* it is placed lateral to the first portion of the axillary artery; it surrounds the second part of the artery, one cord lying medial to it, one lateral to it, and one behind it; at the lower part of the axilla it gives off its terminal branches to the upper limb.

¹ The posterior division of the lower trunk is very much smaller than the others, and is frequently derived entirely from the eighth cervical nerve.

Branches of Communication.—Close to their exit from the intervertebral foramina the fifth and sixth cervical nerves each receive a gray ramus communicans from the middle cervical ganglion of the sympathetic trunk, and the seventh and eighth cervical similar twigs from the inferior ganglion. The first thoracic nerve receives a gray ramus from, and contributes a white ramus to, the first thoracic ganglion. On the Scalenus anterior the phrenic nerve is joined by a branch from the fifth cervical.

Branches of Distribution.—The branches of distribution of the brachial plexus may be arranged into two groups, viz., those given off above and those below the clavicle.

SUPRACLAVICULAR BRANCHES.

Dorsal scapular	5 C.
Suprascapular	5, 6 C.
Nerve to Subclavius	5, 6 C.
Long thoracic	5, 6, 7 C.
To Longus colli and Scaleni	5, 6, 7, 8 C.

The **Dorsal Scapular Nerve** (*n. dorsalis scapulae*; *nerve to the Rhomboidei*; *posterior scapular nerve*) arises from the fifth cervical, pierces the Scalenus medius, passes beneath the Levator scapulae, to which it occasionally gives a twig, and ends in the Rhomboidei.

The **Suprascapular** (*n. suprascapularis*) (Fig. 810) arises from the trunk formed by the union of the fifth and sixth cervical nerves. It runs lateralward beneath the Trapezius and the Omohyoideus, and enters the supraspinatous fossa through the suprascapular notch, below, the superior transverse scapular ligament; it then passes beneath the Supraspinatus, and curves around the lateral border of the spine of the scapula to the infraspinatous fossa. In the supraspinatous fossa it gives off two branches to the Supraspinatus muscle, and an articular filament to the shoulder-joint; and in the infraspinatous fossa it gives off two branches to the Infraspinatus muscle, besides some filaments to the shoulder-joint and scapula.

The **Nerve to the Subclavius** (*n. subclavius*) is a small filament, which arises from the point of junction of the fifth and sixth cervical nerves; it descends to the muscle in front of the third part of the subclavian artery and the lower trunk of the plexus, and is usually connected by a filament with the phrenic nerve.

The **Long Thoracic Nerve** (*n. thoracalis longus*; *external respiratory nerve of Bell*; *posterior thoracic nerve*) (Fig. 809) supplies the Serratus anterior. It usually arises by three roots from the fifth, sixth, and seventh cervical nerves; but the root from the seventh nerve may be absent. The roots from the fifth and sixth nerves pierce the Scalenus medius, while that from the seventh passes in front of the muscle. The nerve descends behind the brachial plexus and the axillary vessels, resting on the outer surface of the Serratus anterior. It extends along the side of the thorax to the lower border of that muscle, supplying filaments to each of its digitations.

The branches for the Longus colli and Scaleni arise from the lower four cervical nerves at their exit from the intervertebral foramina.

INFRACLAVICULAR BRANCHES.

The infraclavicular branches are derived from the three cords of the brachial plexus, but the fasciculi of the nerves may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

Lateral cord .	{ Musculocutaneous	5, 6, 7 C.
	{ Lateral anterior thoracic	5, 6, 7 C.
	{ Lateral head of median	6, 7 C.
Medial cord .	{ Medial anterior thoracic	} 8 C, 1 T.
	{ Medial antibrachial cutaneous	
	{ Medial brachial cutaneous	
	{ Ulnar	
Posterior cord .	{ Medial head of median	} 8 C, 1 T.
	{ Upper subscapular	
	{ Lower subscapular	
	{ Thoracodorsal	
	{ Axillary	
	{ Radial	

The **Anterior Thoracic Nerves** (*nn. thoracales anteriores*) (Fig. 809) supply the Pectorales major and minor.

The **lateral anterior thoracic** (*fasciculus lateralis*) the larger of the two, *arises* from the lateral cord of the brachial plexus, and through it from the fifth, sixth, and seventh cervical nerves. It passes across the axillary artery and vein, pierces the coracoclavicular fascia, and is distributed to the deep surface of the Pectoralis major. It sends a filament to join the medial anterior thoracic and form with it a loop in front of the first part of the axillary artery.

The **medial anterior thoracic** (*fasciculus medialis*) *arises* from the medial cord of the plexus and through it from the eighth cervical and first thoracic. It passes behind the first part of the axillary artery, curves forward between the axillary artery and vein, and unites in front of the artery with a filament from the lateral nerve. It then enters the deep surface of the Pectoralis minor, where it divides into a number of branches, which supply the muscle. Two or three branches pierce the muscle and end in the Pectoralis major.

The **Subscapular Nerves** (*nn. subscapulares*), two in number, spring from the posterior cord of the plexus and through it from the fifth and sixth cervical nerves.

The **upper subscapular** (*short subscapular*), the smaller enters the upper part of the Subscapularis, and is frequently represented by two branches.

The **lower subscapular** supplies the lower part of the Subscapularis, and ends in the Teres major; the latter muscle is sometimes supplied by a separate branch.

The **Thoracodorsal Nerve** (*n. thoracodorsalis*; *middle or long subscapular nerve*), a branch of the posterior cord of the plexus, derives its fibres from the fifth, sixth, and seventh cervical nerves; it follows the course of the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi, in which it may be traced as far as the lower border of the muscle.

The **Axillary Nerve** (*n. axillaris*; *circumflex nerve*) (Fig. 810) *arises* from the posterior cord of the brachial plexus, and its fibres are derived from the fifth and sixth cervical nerves. It lies at first behind the axillary artery, and in front of the Subscapularis, and passes downward to the lower border of that muscle. It then winds backward, in company with the posterior humeral circumflex artery, through a quadrilateral space bounded above by the Subscapularis, below by the Teres major, medially by the long head of the Triceps brachii, and laterally by the surgical neck of the humerus, and divides into an anterior and a posterior branch.

The **anterior branch** (*upper branch*) winds around the surgical neck of the humerus, beneath the Deltoides, with the posterior humeral circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off a few small cutaneous branches, which pierce the muscle and ramify in the skin covering its lower part.

The **posterior branch** (*lower branch*) supplies the Teres minor and the posterior part of the Deltoides; upon the branch to the Teres minor an oval enlargement

(pseudoganglion) usually exists. The posterior branch then pierces the deep fascia and is continued as the **lateral brachial cutaneous nerve**, which sweeps around the posterior border of the Deltoides and supplies the skin over the lower two-thirds of the posterior part of this muscle, as well as that covering the long head of the Triceps brachii (Figs 805, 807).

FIG. 806.—Cutaneous nerves of right upper extremity. Anterior view.

FIG. 806.—Diagram of segmental distribution of the cutaneous nerves of the right upper extremity. Anterior view.

The trunk of the axillary nerve gives off an articular filament which enters the shoulder-joint below the Subscapularis.

The **Musculocutaneous Nerve** (*n. musculocutaneus*) (Fig. 809) arises from the lateral cord of the brachial plexus, opposite the lower border of the Pectoralis minor, its fibres being derived from the fifth, sixth, and seventh cervical nerves.

It pierces the Coracobrachialis muscle and passes obliquely between the Biceps brachii and the Brachialis, to the lateral side of the arm; a little above the elbow it pierces the deep fascia lateral to the tendon of the Biceps brachii and is continued into the forearm as the **lateral antibrachial cutaneous nerve**. In its course through the arm it supplies the Coracobrachialis, Biceps brachii, and the greater part of the

FIG. 808.—Diagram of segmental distribution of the cutaneous nerves of the right upper extremity. Posterior view.

Brachialis. The branch to the Coracobrachialis is given off from the nerve close to its origin, and in some instances as a separate filament from the lateral cord of the plexus; it is derived from the seventh cervical nerve. The branches to the Biceps brachii and Brachialis are given off after the musculocutaneous has pierced the Coracobrachialis; that supplying the Brachialis gives a filament to the elbow-

joint. The nerve also sends a small branch to the bone, which enters the nutrient foramen with the accompanying artery.

The **lateral antibrachial cutaneous nerve** (*n. cutaneus antibrachii cutaneus lateralis; branch of musculocutaneous nerve*) passes behind the cephalic vein, and divides, opposite the elbow-joint, into a volar and a dorsal branch (Figs. 805, 807).

The **volar branch** (*ramus volaris; anterior branch*) descends along the radial border of the forearm to the wrist, and supplies the skin over the lateral half of its volar surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the dorsal surface of the carpus. The nerve then passes downward to the ball of the thumb, where it ends in cutaneous filaments. It communicates with the superficial branch of the radial nerve, and with the palmar cutaneous branch of the median nerve.

The **dorsal branch** (*ramus dorsalis; posterior branch*) descends, along the dorsal surface of the radial side of the forearm to the wrist. It supplies the skin of the lower two-thirds of the dorso-lateral surface of the forearm, communicating with the superficial branch of the radial nerve and the dorsal antibrachial cutaneous branch of the radial.

The musculocutaneous nerve presents frequent irregularities. It may adhere for some distance to the median and then pass outward, beneath the Biceps brachii, instead of through the Coracobrachialis. Some of the fibres of the median may run for some distance in the musculo-cutaneous and then leave it to join their proper trunk; less frequently the reverse is the case, and the median sends a branch to join the musculocutaneous. The nerve may pass under the Coracobrachialis or through the Biceps brachii. Occasionally it gives a filament to the Pronator teres, and it supplies the dorsal surface of the thumb when the superficial branch of the radial nerve is absent.

The **Medial Antibrachial Cutaneous Nerve** (*n. cutaneus antibrachii medialis; internal cutaneous nerve*) (Fig. 809) arises from the medial cord of the brachial plexus. It derives its fibres from the eighth cervical and first thoracic nerves, and at its commencement is placed medial to the axillary artery. It gives off, near the axilla, a filament, which pierces the fascia and supplies the integument covering the Biceps brachii, nearly as far as the elbow. The nerve then runs down the ulnar side of the arm medial to the brachial artery, pierces the deep fascia with the basilic vein, about the middle of the arm, and divides into a volar and an ulnar branch.

The **volar branch** (*ramus volaris; anterior branch*), the larger, passes usually in front of, but occasionally behind, the vena mediana cubiti (*median basilic vein*). It then descends on the front of the ulnar side of the forearm, distributing filaments to the skin as far as the wrist, and communicating with the palmar cutaneous branch of the ulnar nerve (Fig. 805).

The **ulnar branch** (*ramus ulnaris; posterior branch*) passes obliquely downward on the medial side of the basilic vein, in front of the medial epicondyle of the humerus, to the back of the forearm, and descends on its ulnar side as far as the wrist, distributing filaments to the skin. It communicates with the medial brachial cutaneous, the dorsal antibrachial cutaneous branch of the radial, and the dorsal branch of the ulnar (Fig. 807).

The **Medial Brachial Cutaneous Nerve** (*n. cutaneus brachii medialis; lesser internal cutaneous nerve; nerve of Wrisberg*) is distributed to the skin on the ulnar side of the arm (Figs. 805, 807). It is the smallest branch of the brachial plexus, and arising from the medial cord receives its fibres from the eighth cervical and first thoracic nerves. It passes through the axilla, at first lying behind, and then medial to the axillary vein, and communicates with the intercostobrachial nerve. It descends along the medial side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the skin of the back of the lower third of the arm, extending as far as the elbow, where some filaments are lost in the skin in

front of the medial epicondyle, and others over the olecranon. It communicates with the ulnar branch of the medial antibrachial cutaneous nerve.

In some cases the medial brachial cutaneous and intercostobrachial are connected by two or three filaments, which form a plexus in the axilla. In other cases the intercostobrachial is of large size, and takes the place of the medial brachial cutaneous, receiving merely a filament of communication from the brachial plexus, which represents the latter nerve; in a few cases, this filament is wanting.

The Median Nerve (*n. medianus*) (Fig. 809) extends along the middle of the arm and forearm to the hand. It *arises* by two roots, one from the lateral and one from the medial cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front of or lateral to that vessel. Its fibres are derived from the sixth, seventh, and eighth cervical and first thoracic nerves. As it descends through the arm, it lies at first lateral to the brachial artery; about the level of the insertion of the Coracobrachialis it crosses the artery, usually in front of, but occasionally behind it, and lies on its medial side at the bend of the elbow, where it is situated behind the lacertus fibrosus (*bicipital fascia*), and is separated from the elbow-joint by the Brachialis. **In the forearm** it passes between the two heads of the Pronator teres and crosses the ulnar artery, but is separated from this vessel by the deep head of the Pronator teres. It descends beneath the Flexor digitorum sublimis, lying on the Flexor digitorum profundus, to within 5 cm. of the transverse carpal ligament; here it becomes more superficial, and is situated between the tendons of the Flexor digitorum sublimis and Flexor carpi radialis. In this situation it lies behind, and rather to the radial side of, the tendon of the Palmaris longus, and is covered by the skin and fascia. It then passes behind the transverse carpal ligament into the palm of the hand. In its course through the forearm it is accompanied by the median artery, a branch of the volar interosseous artery.

Branches.—With the exception of the nerve to the Pronator teres, which sometimes arises above the elbow-joint, the median nerve gives off no branches in the arm. As it passes in front of the elbow, it supplies one or two twigs to the joint.

In the forearm its branches are: **muscular**, **volar interosseous**, and **palmar**.

The **muscular branches** (*rami musculares*) are derived from the nerve near the elbow and supply all the superficial muscles on the front of the forearm, except the Flexor carpi ulnaris.

The **volar interosseous nerve** (*n. interosseus [antibrachii] volaris; anterior interosseous nerve*) supplies the deep muscles on the front of the forearm, except the ulnar half of the Flexor digitorum profundus. It accompanies the volar interosseous artery along the front of the interosseous membrane, in the interval between the Flexor pollicis longus and Flexor digitorum profundus, supplying the whole of the former and the radial half of the latter, and ending below in the Pronator quadratus and wrist-joint.

The **palmar branch** (*ramus cutaneus palmaris n. mediani*) of the median nerve *arises* at the lower part of the forearm. It pierces the volar carpal ligament, and divides into a lateral and a medial branch; the lateral branch supplies the skin over the ball of the thumb, and communicates with the volar branch of the lateral antibrachial cutaneous nerve; the medial branch supplies the skin of the palm and communicates with the palmar cutaneous branch of the ulnar.

In the palm of the hand the median nerve is covered by the skin and the palmar aponeurosis, and rests on the tendons of the Flexor muscles. Immediately after emerging from under the transverse carpal ligament the nerve becomes enlarged and flattened and splits into a smaller, lateral, and a larger, medial portion. The **lateral portion** supplies a short, stout branch to certain of the muscles of the ball of the thumb, viz., the Abductor brevis, the Opponens, and the superficial head of the Flexor brevis, and then divides into three **proper volar digital nerves**; two of these supply the sides of the thumb, while the third gives a twig to the first Lumbricalis

and is distributed to the radial side of the index finger. The medial portion of the nerve divides into two **common volar digital nerves**. The first of these gives a twig
rad

rad
radial
ner

FIG. 800.—Nerves of the left upper extremity.

to the second Lumbricalis and runs toward the cleft between the index and middle fingers, where it divides into two proper digital nerves for the adjoining sides of these digits; the second runs toward the cleft between the middle and ring fingers, and splits into two proper digital nerves for the adjoining sides of these digits; it communicates with a branch from the ulnar nerve and sometimes sends a twig to the third Lumbricalis.

Each proper digital nerve, opposite the base of the first phalanx, gives off a dorsal branch which joins the dorsal digital nerve from the superficial branch of the radial nerve, and supplies the integument on the dorsal aspect of the last phalanx. At the end of the digit, the proper digital nerve divides into two branches, one of which supplies the pulp of the finger, the other ramifies around and beneath the nail. The proper digital nerves, as they run along the fingers, are placed superficial to the corresponding arteries.

The **Ulnar Nerve** (*n. ulnaris*) (Fig. 809) is placed along the medial side of the limb, and is distributed to the muscles and skin of the forearm and hand. It *arises* from the medial cord of the brachial plexus, and derives its fibres from the eighth cervical and first thoracic nerves. It is smaller than the median, and lies at first behind it, but diverges from it in its course down the arm. At its origin it lies medial to the axillary artery, and bears the same relation to the brachial artery as far as the middle of the arm. Here it pierces the medial intermuscular septum, runs obliquely across the medial head of the Triceps brachii, and descends to the groove between the medial epicondyle and the olecranon, accompanied by the superior ulnar collateral artery. **At the elbow**, it rests upon the back of the medial epicondyle, and enters the forearm between the two heads of the Flexor carpi ulnaris. **In the forearm**, it descends along the ulnar side, lying upon the Flexor digitorum profundus; its upper half is covered by the Flexor carpi ulnaris, its lower half lies on the lateral side of the muscle, covered by the integument and fascia. In the upper third of the forearm, it is separated from the ulnar artery by a considerable interval, but in the rest of its extent lies close to the medial side of the artery. About 5 cm. above the wrist it ends by dividing into a dorsal and a volar branch.

The branches of the ulnar nerve are: **articular** to the elbow-joint, **muscular**, **palmar cutaneous**, **dorsal**, and **volar**.

The **articular branches** to the elbow-joint are several small filaments which *arise* from the nerve as it lies in the groove between the medial epicondyle and olecranon.

The **muscular branches** (*rami musculares*) two in number, *arise* near the elbow: one supplies the Flexor carpi ulnaris; the other, the ulnar half of the Flexor digitorum profundus.

The **palmar cutaneous branch** (*ramus cutaneus palmaris*) *arises* about the middle of the forearm, and descends on the ulnar artery, giving off some filaments to the vessel. It perforates the volar carpal ligament and ends in the skin of the palm, communicating with the palmar branch of the median nerve.

The **dorsal branch** (*ramus dorsalis manus*) *arises* about 5 cm. above the wrist; it passes backward beneath the Flexor carpi ulnaris, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, divides into two dorsal digital branches; one supplies the ulnar side of the little finger; the other, the adjacent sides of the little and ring fingers. It also sends a twig to join that given by the superficial branch of the radial nerve for the adjoining sides of the middle and ring fingers, and assists in supplying them. A branch is distributed to the metacarpal region of the hand, communicating with a twig of the superficial branch of the radial nerve (Fig. 807).

On the little finger the dorsal digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the proper volar digital branches of the ulnar nerve.

The **volar branch** (*ramus volaris manus*) crosses the transverse carpal ligament on the lateral side of the pisiform bone, medial to and a little behind the ulnar

Supra

artery. It ends by dividing into a superficial and a deep branch.

The **superficial branch** (*ramus superficialis* [*n. ulnaris*]) supplies the Palmaris brevis, and the skin on the ulnar side of the hand, and divides into a proper volar digital branch for the ulnar side of the little finger, and a common volar digital branch which gives a communicating twig to the median nerve and divides into two proper digital nerves for the adjoining sides of the little and ring fingers (Fig. 805). The proper digital branches are distributed to the fingers in the same manner as those of the median.

The **deep branch** (*ramus profundus*) accompanied by the deep branch of the ulnar artery, passes between the Abductor digiti quinti and Flexor digiti quinti brevis; it then perforates the Opponens digiti quinti and follows the course of the deep volar arch beneath the Flexor tendons. At its origin it supplies the three short muscles of the little finger. As it crosses the deep part of the hand, it supplies all the Interossei and the third and fourth Lumbricalis; it ends by supplying the Adductores pollicis and the medial head of the Flexor pollicis brevis. It also sends articular filaments to the wrist-joint.

It has been pointed out that the ulnar part of the Flexor digitorum profundus is supplied by the ulnar nerve; the third and fourth Lumbricales, which are connected with the tendons

FIG. 810.—The supraescapular, axillary, and radial nerves.

of this part of the muscle, are supplied by the same nerve. In like manner the lateral part of the Flexor digitorum profundus and the first and second Lumbricales are supplied by the median nerve; the third Lumbricalis frequently receives an additional twig from the median nerve.

The **Radial Nerve** (*n. radialis*; *musculospiral nerve*) (Fig. 810), the largest branch of the brachial plexus, is the continuation of the posterior cord of the plexus. Its fibres are derived from the fifth, sixth, seventh, and eighth cervical and first thoracic

nerves. It descends behind the first part of the axillary artery and the upper part of the brachial artery, and in front of the tendons of the Latissimus dorsi and Teres major. It then winds around from the medial to the lateral side of the humerus in a groove with the a. profunda brachii, between the medial and lateral heads of the Triceps brachii. It pierces the lateral intermuscular septum, and passes between the Brachialis and Brachioradialis to the front of the lateral epicondyle, where it divides into a superficial and a deep branch.

The **branches** of the musculospiral nerve are:

Muscular.
Cutaneous.

Superficial.
Deep.

The **muscular branches** (*rami musculares*) supply the Triceps brachii, Anconaeus, Brachioradialis, Extensor carpi radialis longus, and Brachialis, and are grouped as medial, posterior, and lateral.

The medial muscular branches supply the medial and long heads of the Triceps brachii. That to the medial head is a long, slender filament, which lies close to the ulnar nerve as far as the lower third of the arm, and is therefore frequently spoken of as the **ulnar collateral nerve**.

The posterior muscular branch, of large size, *arises* from the nerve in the groove between the Triceps brachii and the humerus. It divides into filaments, which supply the medial and lateral heads of the Triceps brachii and the Anconaeus muscles. The branch for the latter muscle is a long, slender filament, which descends in the substance of the medial head of the Triceps brachii.

The lateral muscular branches supply the Brachioradialis, Extensor carpi radialis longus, and the lateral part of the Brachialis.

The **cutaneous branches** are two in number, the posterior brachial cutaneous and the dorsal antibrachial cutaneous.

The **posterior brachial cutaneous nerve** (*n. cutaneus brachii posterior; internal cutaneous branch of musculospiral*) *arises* in the axilla, with the medial muscular branch. It is of small size, and passes through the axilla to the medial side of the area supplying the skin on its dorsal surface nearly as far as the olecranon. In its course it crosses behind, and communicates with, the intercostobrachial.

The **dorsal antibrachial cutaneous nerve** (*n. cutaneus antibrachii dorsalis; external cutaneous branch of musculospiral*) *perforates* the lateral head of the Triceps brachii at its attachment to the humerus. The **upper** and smaller branch of the nerve passes to the front of the elbow, lying close to the cephalic vein, and supplies the skin of the lower half of the arm (Fig. 805). The **lower** branch pierces the deep fascia below the insertion of the Deltoideus, and descends along the lateral side of the arm and elbow, and then along the back of the forearm to the wrist, supplying the skin in its course, and joining, near its termination, with the dorsal branch of the lateral antibrachial cutaneous nerve (Fig. 807).

The **Superficial Branch of the Radial Nerve** (*ramus superficialis radial nerve*) passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first slightly lateral to the radial artery, concealed beneath the Brachioradialis. In the middle third of the forearm, it lies behind the same muscle, close to the lateral side of the artery. It quits the artery about 7 cm. above the wrist, passes beneath the tendon of the Brachioradialis, and, piercing the deep fascia, divides into two branches (Fig. 807).

The lateral branch, the smaller, supplies the skin of the radial side and ball of the thumb, joining with the volar branch of the lateral antibrachial cutaneous nerve.

The medial branch communicates, above the wrist, with the dorsal branch of the lateral antibrachial cutaneous, and, on the back of the hand, with the dorsal branch of the ulnar nerve. It then divides into four digital nerves, which are

distributed as follows: the first supplies the ulnar side of the thumb; the second, the radial side of the index finger; the third, the adjoining sides of the index and middle fingers; the fourth communicates with a filament from the dorsal branch of the ulnar nerve, and supplies the adjacent sides of the middle and ring fingers.¹

The **Deep Branch of the Radial Nerve** (*n. interosseus dorsalis; dorsal or posterior interosseous nerve*) winds to the back of the forearm around the lateral side of the radius between the two planes of fibres of the Supinator, and is prolonged downward between the superficial and deep layers of muscles, to the middle of the forearm. Considerably diminished in size, it descends, as the **dorsal interosseous nerve**, on the interosseous membrane, in front of the Extensor pollicis longus, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the ligaments and articulations of the carpus. It supplies all the muscles on the radial side and dorsal surface of the forearm, excepting the Anconaeus, Brachioradialis, and Extensor carpi radialis longus.

Applied Anatomy.—The brachial plexus may be injured by falls from a height on to the side of the head and shoulder, whereby the nerves of the plexus are violently stretched; the fifth cervical nerve sustains the greatest amount of injury, and the subsequent paralysis may be confined to the muscles supplied by this nerve, viz., the Deltoides, Biceps brachii, Brachialis, and Brachioradialis, with sometimes the Supra- and Infraspinatus and the Supinator. The position of the limb, under such conditions, is characteristic; the arm hangs by the side and is rotated inward; the forearm is extended and pronated. The arm cannot be raised from the side; all power of flexion of the elbow is lost, as is also supination of the forearm. This is known as *Erb's paralysis*, and a very similar condition is occasionally met with in newborn children, either from injury to the fifth nerve from the pressure of forceps used in affecting delivery, or from traction of the head in breech presentations. A second variety of partial palsy of the brachial plexus is known as *Klumpke's paralysis*. In this it is the eighth cervical and first thoracic nerves that are injured, either before or after they have joined to form the lower trunk. Atrophy follows in the intrinsic muscles of the hand, and in the Flexors of the fingers and wrist; the thenar and hypothenar eminences waste and flatten; the fingers cannot be spread out or approximated, on account of the paralysis of the Interossei, and become clawed. The injury to the nerves may follow direct violence or a gunshot wound.

The brachial plexus may also be injured by violent traction on the arm, or by efforts at reducing a dislocation of the shoulder-joint; and the amount of paralysis will depend upon the amount of injury to the constituent nerves. When the entire plexus is involved, the whole of the upper extremity will be paralyzed and anesthetic. In these cases the injury appears to be rather a tearing away of the roots of the nerves from the medulla spinalis, than a rupture of the nerves themselves. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as *crutch paralysis*. In these cases the radial seems most frequently to be the nerve implicated; the ulnar nerve suffers next in frequency. The median and radial nerves often suffer from "sleep palsies," paralysis from pressure coming on while the patient is profoundly asleep under the influence of alcohol or some narcotic.

Paralysis of the *long thoracic nerve* throws the Serratus anterior out of action, and may occur in porters in whom the nerve is exposed to injury as it crosses the posterior triangle of the neck. The inferior angle of the scapula is drawn toward the middle line, by the unopposed action of the Rhomboidei and Levator scapulae, and tends to project backward when the arm is held horizontally forward. The arm cannot be raised above the horizontal unless the inferior angle of the scapula is pushed lateralward for the patient.

The *axillary (circumflex) nerve*, on account of its course around the surgical neck of the humerus, is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-joint; paralysis of the Deltoides, and anesthesia of the skin over the lower part of that muscle, result. According to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it. Paralysis of the Deltoides renders abduction of the arm to the horizontal level impossible. The associated paralysis of the Teres minor is not easily demonstrated.

Hilton gave the axillary nerve as an illustration of a law which he laid down, that "the same trunks of nerves whose branches supply the groups of muscles moving a joint, furnish also a

¹ According to Hutchison, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx; and the one to the middle and ring fingers not higher than the first phalangeal joint.—London Hosp. Gaz., iii, 319.

distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source." In this way he explains the fact that an inflamed joint becomes rigid.

The *median nerve* is liable to injury in wounds of the forearm. In such cases there is loss of flexion of the second phalanges of all the fingers, and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and little fingers is effected by that portion of the *Flexor digitorum profundus* which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the *Interossei*. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. There is loss in the power of pronating the forearm; the *Brachioradialis* has the power of bringing the forearm into a position of mid-pronation, but beyond this no further pronation can be effected. The wrist can be flexed, if the hand is first adducted by the action of the *Flexor carpi ulnaris*. There is loss or impairment of sensation on the volar surfaces of the thumb, index, middle, and radial half of ring fingers, and on the dorsal surfaces of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation would be limited to the back of the last phalanx. In old cases the unopposed action of the *Interossei* produces backward dislocation of the interphalangeal joints. The thumb is extended and adducted to the index finger, cannot be flexed or abducted, and cannot be apposed to any one of the fingers; in consequence an "ape-like" hand is produced. More commonly, however, the nerve is injured just above the annular ligament when the power of flexion of the fingers and pronation of the forearm remain intact unless the *Flexor* tendons are also divided. This injury seriously interferes with the use of the hand, as, besides the wasting of the muscles of the thenar eminence, great trouble is experienced from the trophic changes which result about the skin and nails of the fingers which are anesthetic. In order to expose the median nerve, for the purpose of uniting the divided ends, supposing the injury to be just above the wrist, and incision should be made along the radial side of the tendon of the *palmaris longus*, which serves as a guide to the nerve.

The *ulnar nerve* is also liable to be injured in wounds of the forearm, such injury leading to impaired power of ulnar flexion, and upon an attempt being made to flex the wrist, the hand is drawn to the radial side from paralysis of the *Flexor carpi ulnaris*; there is inability to spread out the fingers from paralysis of the *Interossei*, and for the same reason the fingers, especially the ring and little fingers, cannot be flexed at the metacarpophalangeal joints or extended at the interphalangeal joints, and the hand assumes a claw shape from the action of the opposing muscles; there is loss of power of flexion in the little and ring fingers; and there is inability to adduct the thumb. The muscles of the hypothenar eminence become wasted. Sensation is lost, or impaired, in the skin supplied by the nerve. In order to expose the nerve in the lower part of the forearm, an incision should be made along the radial border of the tendon of the *Flexor carpi ulnaris*, and the nerve will be found lying on the ulnar side of the ulnar artery. This nerve may be also affected in cases of dislocation of the shoulder or fracture of the surgical neck of the humerus. Wasting of the muscles which it supplies is not uncommonly seen where a "cervical rib" is present, the lower end of the plexus passing between this and the first thoracic rib.

The *radial (musculospiral) nerve* is also frequently injured. In consequence of its close relationship to the humerus, it is often torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be contused against the bone by kicks or blows, or to be divided in wounds of the arm. When paralyzed, the hand is flexed at the wrist and lies flaccid. This is known as *wrist drop*. The fingers are also flexed, and on an attempt being made to extend them, the last two phalanges only will be extended, through the action of the *Interossei*; the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm be flexed so as to allow of the action of the *Biceps brachii*. The power of extension of the forearm is lost on account of paralysis of the *Triceps brachii*, if the injury to the nerve has taken place near its origin. In cases due to pressure, sensation is hardly affected; severe injury to the nerve occasions anesthesia over the area supplied by the superficial branch of the radial nerve, and, if the lesion be high up, on the lateral side of the upper arm and the back of the forearm (posterior brachial and dorsal antibrachial cutaneous branches) as well.

The nerve is best exposed by making an incision along the medial border of the *Brachioradialis*, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in the fascia indicating the border of the muscle is to be defined, and the deep fascia divided in this line. On raising the *Brachioradialis*, the nerve will be found lying between it and the *Brachialis*. The muscles supplied by the deep branch of the radial nerve are also particularly liable to be affected in chronic lead poisoning; here the affection is probably in the cells of the anterior column of the medulla spinalis. Incisions down to the neck of the radius posteriorly or on the lateral side should never be made, as the deep branch of the radial nerve would be severed.

The Thoracic Nerves (Nn. Thoracales).

The anterior divisions of the thoracic nerves (*rami anteriores; ventral divisions*) are twelve in number on either side. Eleven of them are situated between the ribs, and are therefore termed **intercostal**; the twelfth lies below the last rib. Each nerve is connected with the adjoining ganglion of the sympathetic trunk by a gray and a white *ramus communicans*. The intercostal nerves are distributed chiefly to the parietes of the thorax and abdomen, and differ from the anterior divisions of the other spinal nerves, in that each pursues an independent course, *i. e.*, there is no plexus formation. The first two nerves supply fibres to the upper limb in addition to their thoracic branches; the next four are limited in their distribution to the parietes of the thorax; the lower five supply the parietes of the thorax and abdomen. The twelfth thoracic is distributed to the abdominal wall and the skin of the buttock.

The First Thoracic Nerve.—The anterior division of the first thoracic nerve divides into two branches: one, the larger, leaves the thorax in front of the neck of the first rib, and enters the brachial plexus; the other and smaller branch, the **first intercostal nerve**, runs along the first intercostal space, and ends on the front of the chest as the first anterior cutaneous branch of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve as a rule gives off no lateral cutaneous branch; but sometimes it sends a small branch to communicate with the intercostobrachial. From the second thoracic nerve it frequently receives a connecting twig, which ascends over the neck of the second rib.

Posterior a

lateral cutaneous

Anterior cutaneous

FIG. 811.—Diagram of the course and branches of a typical intercostal nerve.

The Upper Thoracic Nerves (*nn. intercostales*).—The anterior divisions of the second, third, fourth, fifth, and sixth thoracic nerves, and the small branch from the first thoracic, are confined to the parietes of the thorax, and are named **thoracic intercostal nerves**. They pass forward (Fig. 811) in the intercostal spaces below the intercostal vessels. At the back of the chest they lie between the pleura and the posterior intercostal membranes, but soon pierce the latter and run between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the *Intercostales interni*, and, running amidst their fibres as far as

the costal cartilages, they gain the inner surfaces of the muscles and lie between them and the pleura. Near the sternum, they cross in front of the internal mammary artery and Transversus thoracis muscle, pierce the Intercostales interni, the anterior intercostal membranes, and Pectoralis major, and supply the integument of the front of the thorax and over the mamma, forming the anterior cutaneous branches of the thorax; the branch from the second nerve unites with the anterior supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments supply the Intercostales, the Subcostales, the Levatores costarum, the Serratus posterior superior, and the Transversus thoracis. At the front of the thorax some of these branches cross the costal cartilages from one intercostal space to another.

Lateral cutaneous branches (*rami cutanei laterales*) are derived from the intercostal nerves, about midway between the vertebræ and sternum; they pierce the Intercostales externi and Serratus anterior, and divide into anterior and posterior branches. The **anterior branches** run forward to the side and the forepart of the chest, supplying the skin and the mamma; those of the fifth and sixth nerves supply the upper digitations of the Obliquus externus abdominis. The **posterior branches** run backward, and supply the skin over the scapula and Latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve does not divide, like the others, into an anterior and a posterior branch; it is named the **intercostobrachial nerve** (Fig. 809). It pierces the Intercostalis externus and the Serratus anterior, crosses the axilla to the medial side of the arm, and joins with a filament from the medial brachial cutaneous nerve. It then pierces the fascia, and supplies the skin of the upper half of the medial and posterior part of the arm, communicating with the posterior brachial cutaneous branch of the radial nerve. The size of the intercostobrachial nerve is in inverse proportion to that of the medial brachial cutaneous nerve. A second intercostobrachial nerve is frequently given off from the lateral cutaneous branch of the third intercostal; it supplies filaments to the axilla and medial side of the arm.

The Lower Thoracic Nerves.—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh thoracic nerves are continued anteriorly from the intercostal spaces into the abdominal wall; hence they are named **thoracicoabdominal intercostal nerves**. They have the same arrangement as the upper ones as far as the anterior ends of the intercostal spaces, where they pass behind the costal cartilages, and between the Obliquus internus and Transversus abdominis, to the sheath of the Rectus abdominis, which they perforate. They supply the Rectus abdominis and end as the **anterior cutaneous branches** of the abdomen; they supply the skin of the front of the abdomen. The lower intercostal nerves supply the Intercostales and abdominal muscles; the last three send branches to the Serratus posterior inferior. About the middle of their course they give off **lateral cutaneous branches**. These pierce the Intercostales externi and the Obliquus externus abdominis, in the same line as the lateral cutaneous branches of the upper thoracic nerves, and divide into anterior and posterior branches, which are distributed to the skin of the abdomen and back; the anterior branches supply the digitations of the Obliquus externus abdominis, and extend downward and forward nearly as far as the margin of the Rectus abdominis; the posterior branches pass backward to supply the skin over the Latissimus dorsi.

The anterior division of the **twelfth thoracic nerve** is larger than the others; it runs along the lower border of the twelfth rib, often gives a communicating branch to the first lumbar nerve, and passes under the lateral lumbocostal arch. It then runs in front of the Quadratus lumborum, perforates the Transversus, and passes forward between it and the Obliquus internus to be distributed in the same manner as the lower intercostal nerves. It communicates with the iliohypogastric nerve of the lumbar plexus, and gives a branch to the Pyramidalis. The **lateral cutaneous**

branch of the last thoracic nerve is large, and does not divide into an anterior and a posterior branch. It perforates the *Obliqui internus* and *externus*, descends over the iliac crest in front of the lateral cutaneous branch of the iliohypogastric (Fig. 819), and is distributed to the skin of the front part of the gluteal region, some of its filaments extending as low as the greater trochanter.

Applied Anatomy.—The lower seven thoracic nerves and the iliohypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run downward and forward fairly equidistant from each other. The sixth and seventh supply the skin over the “pit of the stomach;” the eighth corresponds to about the position of the middle tendinous inscription of the *Rectus abdominis*; the tenth to the umbilicus; and the iliohypogastric supplies the skin over the pubis and subcutaneous inguinal ring. In many diseases affecting the nerve trunks at or near their origins, the pain is referred to their peripheral terminations. Thus, in Pott’s disease of the vertebrae, children often suffer from pain in the abdomen. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied around the abdomen, and in these cases the situation of the sense of constriction may serve to localize the disease in the vertebral column. In other cases where the bone disease is more extensive, and two or more nerves are involved, a more general, diffused pain in the abdomen is felt.

Again, it must be borne in mind that the nerves which supply the skin of the abdomen supply also the planes of muscle which constitute the greater part of the abdominal wall. Hence, any irritation applied to the peripheral ends of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more rapid response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

The nerves supplying the abdominal muscles and skin, derived from the lower intercostal nerves, are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in laceration of the abdominal viscera and in acute peritonitis, the muscles of the belly wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

The Lumbosacral Plexus (*Plexus Lumbosacralis*).

The anterior divisions of the lumbar, sacral, and coccygeal nerves form the lumbosacral plexus, the first lumbar nerve being frequently joined by a branch from the twelfth thoracic. For descriptive purposes this plexus is usually divided into three parts—the lumbar, sacral, and pudendal plexuses.

The Lumbar Nerves (*Nn. Lumbales*).

The anterior divisions of the lumbar nerves (*rami anteriores*) increase in size from above downward. They are joined, near their origins, by *gray rami communicantes* from the lumbar ganglia of the sympathetic trunk. These rami consist of long, slender branches which accompany the lumbar arteries around the sides of the vertebral bodies, beneath the *Psoas major*. Their arrangement is somewhat irregular: one ganglion may give rami to two lumbar nerves, or one lumbar nerve may receive rami from two ganglia. The first and second, and sometimes the third and fourth lumbar nerves are each connected with the lumbar part of the sympathetic trunk by a *white ramus communicans*.

The nerves pass obliquely outward behind the *Psoas major*, or between its fasciculi, distributing filaments to it and the *Quadratus lumborum*. The first three and the greater part of the fourth are connected together in this situation by anastomotic loops, and form the lumbar plexus. The smaller part of the fourth

joins with the fifth to form the **lumbosacral trunk**, which assists in the formation of the sacral plexus. The fourth nerve is named the **nervus furcalis**, from the fact that it is subdivided between the two plexuses.¹

The Lumbar Plexus (*plexus lumbalis*) (Figs. 812, 813).—The lumbar plexus is formed by the loops of communication between the anterior divisions of the first three and the greater part of the fourth lumbar nerves; the first lumbar often receives a branch from the last thoracic nerve. It is situated in the posterior part of the Psoas major, in front of the transverse processes of the lumbar vertebræ.

FIG. 812.—Plan of lumbar plexus.

The mode in which the plexus is arranged varies in different subjects. It differs from the brachial plexus in not forming an intricate interlacement, but the several nerves of distribution *arise* from one or more of the spinal nerves, in the following manner: the first lumbar nerve, frequently supplemented by a twig from the last thoracic, splits into an upper and lower branch; the upper and larger branch divides into the iliohypogastric and ilioinguinal nerves; the lower and smaller branch unites with a branch of the second lumbar to form the genitofemoral nerve. The remainder of the second nerve, and the third and fourth nerves, divide into ventral and dorsal divisions. The ventral division of the second unites with the ventral divisions of the third and fourth nerves to form the obturator nerve. The dorsal divisions of the second and third nerves divide into two branches, a smaller branch from each uniting to form the lateral femoral cutaneous nerve, and a larger branch

¹ In most cases the fourth lumbar is the *nervus furcalis*; but this arrangement is frequently departed from. The third is occasionally the lowest nerve which enters the lumbar plexus, giving at the same time some fibres to the sacral plexus, and thus forming the *nervus furcalis*; or both the third and fourth may be furcal nerves. When this occurs, the plexus is termed *high* or *prefixed*. More frequently the fifth nerve is divided between the lumbar and sacral plexuses, and constitutes the *nervus furcalis*; and when this takes place, the plexus is distinguished as a *low* or *postfixed* plexus. These variations necessarily produce corresponding modifications in the sacral plexus.

from each joining with the dorsal division of the fourth nerve to form the femoral nerve. The accessory obturator, when it exists, is formed by the union of two small branches given off from the third and fourth nerves.

FIG. 813.—The lumbar plexus and its branches.

The **branches** of the lumbar plexus may therefore be arranged as follows:

Iliohypogastric	1 L.
Ilioinguinal	1 L.
Genitofemoral	1, 2 L.
Dorsal divisions.	
Lateral femoral cutaneous	2, 3 L.
Femoral.	2, 3, 4 L.
Ventral divisions.	
Obturator	2, 3, 4 L.
Accessory obturator	3, 4 L.

The **Iliohypogastric Nerve** (*n. iliohypogastricus*) arises from the first lumbar nerve. It emerges from the upper part of the lateral border of the Psoas major, and crosses obliquely in front of the Quadratus lumborum to the iliac crest. It then perforates the posterior part of the Transversus abdominis, near the crest of the ilium, and

divides between that muscle and the Obliquus internus abdominis into a **lateral** and an **anterior cutaneous branch**.

The **lateral cutaneous branch** (*ramus cutaneus lateralis; iliac branch*) pierces the Obliqui internus and externus immediately above the iliac crest, and is distributed to the skin of the gluteal region, behind the lateral cutaneous branch of the last thoracic nerve (Fig. 819); the size of this branch bears an inverse proportion to that of the lateral cutaneous branch of the last thoracic nerve.

The **anterior cutaneous branch** (*ramus cutaneus anterior; hypogastric branch*) (Fig. 814) continues onward between the Obliquus internus and Transversus. It then pierces the Obliquus internus, becomes cutaneous by perforating the aponeurosis of the Obliquus externus about 2.5 cm. above the subcutaneous inguinal ring, and is distributed to the skin of the hypogastric region.

The iliohypogastric nerve communicates with the last thoracic and ilioinguinal nerves.

The **Ilioinguinal Nerve** (*n. ilioinguinalis*), smaller than the preceding, *arises* with it from the first lumbar nerve. It emerges from the lateral border of the Psoas major just below the iliohypogastric, and, passing obliquely across the Quadratus lumborum and Iliacus, perforates the Transversus abdominis, near the anterior part of the iliac crest, and communicates with the iliohypogastric nerve between the Transversus and the Obliquus internus. The nerve then pierces the Obliquus internus, distributing filaments to it, and, accompanying the spermatic cord through the subcutaneous inguinal ring, is distributed to the skin of the upper and medial part of the thigh, to the skin over the root of the penis and upper part of the scrotum in the male, and to the skin covering the mons pubis and labium majus in the female. The size of this nerve is in inverse proportion to that of the iliohypogastric. Occasionally it is very small, and ends by joining the iliohypogastric; in such cases, a branch from the iliohypogastric takes the place of the ilioinguinal, or the latter nerve may be altogether absent.

The **Genitofemoral Nerve** (*n. genitofemoralis; genitocrural nerve*) *arises* from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas major, and emerges from its medial border, close to the vertebral column, opposite the fibrocartilage between the third and fourth lumbar vertebrae; it then descends on the surface of the Psoas major, under cover of the peritoneum, and divides into the external spermatic and lumboinguinal nerves. Occasionally these two nerves emerge separately through the substance of the Psoas.

The **external spermatic nerve** (*n. spermaticus externus; genital branch of genitofemoral*) passes outward on the Psoas major, and pierces the fascia transversalis, or passes through the abdominal inguinal ring; it then descends behind the spermatic cord to the scrotum, supplies the Cremaster, and gives a few filaments to the skin of the scrotum. In the female, it accompanies the round ligament of the uterus, and is lost upon it.

The **lumboinguinal nerve** (*n. lumboinguinalis; femoral or crural branch of genitofemoral*) descends on the external iliac artery, sending a few filaments around it, and, passing beneath the inguinal ligament, enters the sheath of the femoral vessels, lying superficial and lateral to the femoral artery. It pierces the anterior layer of the sheath of the vessels and the fascia lata, and supplies the skin of the anterior surface of the upper part of the thigh (Fig. 814). On the front of the thigh it communicates with the anterior cutaneous branches of the femoral nerve. A few filaments from the lumboinguinal nerve may be traced to the femoral artery.

The **Lateral Femoral Cutaneous Nerve** (*n. cutaneus femoralis lateralis; external cutaneous nerve*) *arises* from the dorsal divisions of the second and third lumbar nerves. It emerges from the lateral border of the Psoas major about its middle, and crosses the Iliacus obliquely, toward the anterior superior iliac spine. It then

FIG. 814 - Cutaneous nerves of right lower extremity. Front view.

FIG. 815 - Diagram of segmental distribution of the cutaneous nerves of the right lower extremity. Front view.

The **anterior branch** becomes superficial about 10 cm. below the inguinal ligament, and divides into branches which are distributed to the skin of the anterior and lateral parts of the thigh, as far as the knee. The terminal filaments of this nerve frequently communicate with the anterior cutaneous branches of the femoral nerve, and with the infrapatellar branch of the saphenous nerve, forming with them the **patellar plexus**.

*Later
femor
cutane*

The **posterior branch** pierces the fascia lata, and subdivides into filaments which pass backward across the lateral and posterior surfaces of the thigh, supplying the skin from the level of the greater trochanter to the middle of the thigh.

*Ant.
cutaneous*

*Anterior division
of obturator
Med. br. of ant.
cutaneous*

The **Obturator Nerve** (*n. obturatorius*) arises from the ventral divisions of the second, third, and fourth lumbar nerves; the branch from the third is the largest, while that from the second is often very small. It descends through the fibres of the Psoas major, and emerges from its medial border near the brim of the pelvis; it then passes behind the common iliac vessels, and on the lateral side of the hypogastric vessels and ureter, which separate it from the ureter, and runs along the lateral wall of the lesser pelvis, above and in front of the obturator vessels, to the upper part of the obturator foramen. Here it enters the thigh, and divides into an anterior and a posterior branch, which are separated at first by some of the fibres of the Obturator externus, and lower down by the Adductor brevis.

Saphenous

The **anterior branch** (*ramus anterior*) (Fig. 816) leaves the pelvis in front of the Obturator externus and descends in front of the Adductor brevis, and behind the Pectineus and Adductor longus; at the lower border of the latter muscle it communicates with the anterior cutaneous

FIG. 816.—Nerves of the right lower extremity. Front view.

and saphenous branches of the femoral nerve, forming a kind of plexus. It then descends upon the femoral artery, to which it is finally distributed. Near the obturator foramen the nerve gives off an articular branch to the hip-joint. Behind the Pectineus, it distributes branches to the Adductor longus and Gracilis, and usually to the Adductor brevis, and in rare cases to the Pectineus; it receives a communicating branch from the accessory obturator nerve when that nerve is present.

Occasionally the communicating branch to the anterior cutaneous and saphenous branches of the femoral is continued down, as a cutaneous branch, to the thigh and leg. When this is so, it emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the medial side of the knee, where it pierces the deep fascia, communicates with the saphenous nerve, and is distributed to the skin of the tibial side of the leg as low down as its middle.

The **posterior branch** (*ramus posterior*) pierces the anterior part of the Obturator externus, and supplies this muscle; it then passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches which are distributed to the Adductor magnus and the Adductor brevis when the latter does not receive a branch from the anterior division of the nerve. It usually gives off an articular filament to the knee-joint.

The **articular branch for the knee-joint** is sometimes absent; it either perforates the lower part of the Adductor magnus, or passes through the opening which transmits the femoral artery, and enters the popliteal fossa; it then descends upon the popliteal artery, as far as the back part of the knee-joint, where it perforates the oblique popliteal ligament, and is distributed to the synovial membrane. It gives filaments to the popliteal artery.

The **Accessory Obturator Nerve** (*n. obturatorius accessorius*) (Fig. 813) is present in about 29 per cent. of cases. It is of small size, and *arises* from the ventral divisions of the third and fourth lumbar nerves. It descends along the medial border of the Psoas major, crosses the superior ramus of the pubis, and passes under the Pectineus, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its deep surface, another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. Occasionally the accessory obturator nerve is very small and is lost in the capsule of the hip-joint. When it is absent, the hip-joint receives two branches from the obturator nerve.

The **Femoral Nerve** (*n. femoralis; anterior crural nerve*) (Fig. 816), the largest branch of the lumbar plexus, *arises* from the dorsal divisions of the second, third, and fourth lumbar nerves. It descends through the fibres of the Psoas major, emerging from the muscle at the lower part of its lateral border, and passes down between it and the Iliacus, behind the iliac fascia; it then runs beneath the inguinal ligament, into the thigh, and splits into an anterior and a posterior division. Under the inguinal ligament, it is separated from the femoral artery by a portion of the Psoas major.

Within the abdomen the femoral nerve gives off small branches to the Iliacus, and a branch which is distributed upon the upper part of the femoral artery; the latter branch may arise in the thigh.

In the thigh the anterior division of the femoral nerve gives off anterior cutaneous and muscular branches. The anterior cutaneous branches comprise the intermediate and medial cutaneous nerves (Fig. 814).

The **intermediate cutaneous nerve** (*ramus cutaneus anterior; middle cutaneous nerve*) pierces the fascia lata (and generally the Sartorius) about 7.5 cm. below the inguinal ligament, and divides into two branches which descend in immediate proximity along the forepart of the thigh, to supply the skin as low as the front of the knee. Here they communicate with the medial cutaneous nerve and the

infrapatellar branch of the saphenous, to form the patellar plexus. In the upper part of the thigh the lateral branch of the intermediate cutaneous communicates with the lumboinguinal branch of the genitofemoral nerve.

The **medial cutaneous nerve** (*ramus cutaneus anterior; internal cutaneous nerve*) passes obliquely across the upper part of the sheath of the femoral artery, and divides in front, or at the medial side of that vessel, into two branches, an anterior and a posterior. The **anterior branch** runs downward on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches: one supplies the integument as low down as the medial side of the knee; the other crosses to the lateral side of the patella, communicating in its course with the infrapatellar branch of the saphenous nerve. The **posterior branch** descends along the medial border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the saphenous nerve, and gives off several cutaneous branches. It then passes down to supply the integument of the medial side of the leg. Beneath the fascia lata, at the lower border of the Adductor longus, it joins to form a plexiform net-work (**subsartorial plexus**) with branches of the saphenous and obturator nerves. When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the posterior branch of the medial cutaneous is small, and terminates in the plexus, occasionally giving off a few cutaneous filaments. The medial cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the medial side of the thigh, accompanying the long saphenous vein. One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh; a third pierces the fascia at its lower third.

MUSCULAR BRANCHES (*rami musculares*).—The nerve to the **Pectineus** arises immediately below the inguinal ligament, and passes behind the femoral sheath to enter the anterior surface of the muscle; it is often duplicated. The nerve to the **Sartorius** arises in common with the intermediate cutaneous.

The posterior division of the femoral nerve gives off the saphenous nerve, and muscular and articular branches.

The **Saphenous Nerve** (*n. saphenus; long or internal saphenous nerve*) (Fig. 816) is the largest cutaneous branch of the femoral nerve. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies in front of it, behind the aponeurotic covering of the adductor canal, as far as the opening in the lower part of the Adductor magnus. Here it quits the artery, and emerges from behind the lower edge of the aponeurotic covering of the canal; it descends vertically along the medial side of the knee behind the Sartorius, pierces the fascia lata, between the tendons of the Sartorius and Gracilis, and becomes subcutaneous. The nerve then passes along the tibial side of the leg, accompanied by the great saphenous vein, descends behind the medial border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the margin of the tibia, and ends at the ankle; the other passes in front of the ankle, and is distributed to the skin on the medial side of the foot, as far as the ball of the great toe, communicating with the medial branch of the superficial peroneal nerve.

BRANCHES.—The saphenous nerve, about the middle of the thigh, gives off a branch which joins the subsartorial plexus.

At the medial side of the knee it gives off a large **infrapatellar branch**, which pierces the Sartorius and fascia lata, and is distributed to the skin in front of the patella. This nerve communicates above the knee with the anterior cutaneous branches of the femoral nerve; below the knee, with other branches of the saphenous; and, on the lateral side of the joint, with branches of the lateral femoral cutaneous nerve, forming a plexiform net-work, the **plexus patellae**. The infrapatellar branch is occasionally small, and ends by joining the anterior cutaneous branches of the femoral, which supply its place in front of the knee.

Below the knee, the branches of the saphenous nerve are distributed to the skin of the front and medial side of the leg, communicating with the cutaneous branches of the femoral, or with filaments from the obturator nerve.

The **muscular branches** supply the four parts of the Quadriceps femoris. The branch to the Rectus femoris enters the upper part of the deep surface of the muscle, and supplies a filament to the hip-joint. The branch to the Vastus lateralis, of large size, accompanies the descending branch of the lateral femoral circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint. The branch to the Vastus medialis descends lateral to the femoral vessels in company with the saphenous nerve. It enters the muscle about its middle, and gives off a filament, which can usually be traced downward, on the surface of the muscle, to the knee-joint. The branches to the Vastus intermedius, two or three in number, enter the anterior surface of the muscle about the middle of the thigh; a filament from one of these descends through the muscle to the Articularis genu and the knee-joint. The **articular branch to the hip-joint** is derived from the nerve to the Rectus femoris.

The **articular branches to the knee-joint** are three in number. One, a long slender filament, is derived from the nerve to the Vastus lateralis; it penetrates the capsule of the joint on its anterior aspect. Another, derived from the nerve to the Vastus medialis, can usually be traced downward on the surface of this muscle to near the joint; it then penetrates the muscular fibres, and accompanies the articular branch of the highest genicular artery, pierces the medial side of the articular capsule, and supplies the synovial membrane. The third branch is derived from the nerve to the Vastus intermedius.

The Sacral and Coccygeal Nerves (Nn. Sacrales et Coccygeus).

The **anterior divisions of the sacral and coccygeal nerves** (*rami anteriores*) form the sacral and pudendal plexuses. The anterior divisions of the upper four sacral nerves enter the pelvis through the anterior sacral foramina, that of the fifth between the sacrum and coccyx, while that of the coccygeal nerve curves forward below the rudimentary transverse process of the first piece of the coccyx. The first and second sacral nerves are large; the third, fourth, and fifth diminish progressively from above downward. Each receives a gray ramus communicans from the corresponding ganglion of the sympathetic trunk, while from the third, and frequently from the second and the fourth sacral nerves, a white ramus communicans is given to the pelvic plexuses of the sympathetic.

The Sacral Plexus (*plexus sacralis*) (Fig. 817).—The sacral plexus is formed by the lumbosacral trunk, the anterior division of the first, and portions of the anterior divisions of the second and third sacral nerves.

The lumbosacral trunk comprises the whole of the anterior division of the fifth and a part of that of the fourth lumbar nerve; it appears at the medial margin of the Psoas major and runs downward over the pelvic brim to join the first sacral nerve. The anterior division of the third sacral nerve divides into an upper and a lower branch, the former entering the sacral and the latter the pudendal plexus.

The nerves forming the sacral plexus converge toward the lower part of the greater sciatic foramen, and unite to form a flattened band, from the anterior and posterior surfaces of which several branches arise. The band itself is continued as the **sciatic nerve**, which splits on the back of the thigh into the **tibial** and **common peroneal nerves**; these two nerves sometimes arise separately from the plexus, and in all cases their independence can be shown by dissection.

Relations.—The sacral plexus lies on the back of the pelvis between the Piriformis and the pelvic fascia (Fig. 818); in front of it are the hypogastric vessels, the ureter and the sigmoid colon. The superior gluteal vessels run between the lumbosacral trunk and the first sacral nerve, and the inferior gluteal vessels between the second and third sacral nerves.

All the nerves entering the plexus, with the exception of the third sacral, split into ventral and dorsal divisions, and the nerves arising from these are as follows:

	Ventral divisions.	Dorsal divisions.
Nerve to Quadratus femoris and Gemellus inferior	4, 5 L, 1 S.	.
Nerve to Obturator internus and Gemellus superior	5 L, 1, 2 S.	.
Nerve to Piriformis	(1) 2 S.
Superior gluteal	4, 5 L, 1 S.
Inferior gluteal	5 L, 1, 2 S.
Posterior femoral cutaneous	2, 3 S	1, 2 S.
Sciatic { Tibial	4, 5 L, 1, 2, 3 S.	
{ Common peroneal	4, 5 L, 1, 2 S.

FIG. 817.—Plan of sacral and pudendal plexuses.

The **Nerve to the Quadratus Femoris and Gemellus Inferior** arises from the ventral divisions of the fourth and fifth lumbar and first sacral nerves: it leaves the pelvis through the greater sciatic foramen, below the Piriformis, and runs down in front of the sciatic nerve, the Gemelli, and the tendon of the Obturator internus, and enters the anterior surfaces of the muscles; it gives an articular branch to the hip-joint.

The **Nerve to the Obturator Internus and Gemellus Superior** arises from the ventral divisions of the fifth lumbar and first and second sacral nerves. It leaves the pelvis through the greater sciatic foramen below the Piriformis, and gives off the branch to the Gemellus superior, which enters the upper part of the posterior surface of the muscle. It then crosses the ischial spine, reënters the pelvis through the lesser sciatic foramen, and pierces the pelvic surface of the Obturator internus.

FIG. 818.—Dissection of side wall of pelvis showing sacral and pudendal plexuses.

The **Nerve to the Piriformis** arises from the dorsal division of the second sacral nerve, or the dorsal divisions of the first and second sacral nerves, and enters the anterior surface of the muscle; this nerve may be double.

The **Superior Gluteal Nerve** (*n. gluteus superior*) arises from the dorsal divisions of the fourth and fifth lumbar and first sacral nerves: it leaves the pelvis through the greater sciatic foramen above the Piriformis, accompanied by the superior gluteal vessels, and divides into a superior and an inferior branch. The **superior branch** accompanies the upper branch of the deep division of the superior gluteal artery and ends in the Gluteus minimus. The **inferior branch** runs with the lower branch of the deep division of the superior gluteal artery across the Gluteus

minimus; it gives filaments to the Glutaei medius and minimus, and ends in the Tensor fasciae latae.

The **Inferior Gluteal Nerve** (*n. glutaeus inferior*) arises from the dorsal divisions of the fifth lumbar and first and second sacral nerves: it leaves the pelvis through the greater sciatic foramen, below the Piriformis, and divides into branches which enter the deep surface of the Glutaeus maximus.

The **Posterior Femoral Cutaneous Nerve** (*n. cutaneus femoralis posterior; small sciatic nerve*) is distributed to the skin of the perineum and posterior surface of the thigh and leg. It arises partly from the dorsal divisions of the first and second, and from the ventral divisions of the second and third sacral nerves, and issues from the pelvis through the greater sciatic foramen below the Piriformis. It then descends beneath the Glutaeus maximus with the inferior gluteal artery, and runs down the back of the thigh beneath the fascia lata, and over the long head of the Biceps femoris to the back of the knee; here it pierces the deep fascia and accompanies the small saphenous vein to about the middle of the back of the leg, its terminal twigs communicating with the sural nerve.

Its branches are all cutaneous, and are distributed to the gluteal region, the perineum, and the back of the thigh and leg.

The **gluteal branches** (*nn. clunium inferiores*), three or four in number, turn upward around the lower border of the Glutaeus maximus, and supply the skin covering the lower and lateral part of that muscle.

The **perineal branches** (*rami perineales*) are distributed to the skin at the upper and medial side of the thigh. One long perineal branch, **inferior pudendal** (*long scrotal nerve*), curves forward below and in front of the ischial tuberosity, pierces the fascia lata, and runs forward beneath the superficial fascia of the perineum to the skin of the scrotum in the male, and of the labium majus in the female. It communicates with the inferior hemorrhoidal and posterior scrotal nerves.

The **branches to the back of the thigh and leg** consist of numerous filaments derived from both sides of the nerve, and distributed to the skin covering the back and medial side of the thigh, the popliteal fossa, and the upper part of the back of the leg (Fig. 819).

The **Sciatic** (*n. ischiadicus; great sciatic nerve*) (Fig. 821) supplies nearly the whole of the skin of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nerve in the body, measuring 2 cm. in breadth, and is the continuation of the flattened band of the sacral plexus. It passes out of the pelvis through the greater sciatic foramen, below the Piriformis muscle. It descends between the greater trochanter of the femur and the tuberosity of the ischium, and along the back of the thigh to about its lower third, where it divides into two large branches, the tibial and common peroneal nerves. This division may take place at any point between the sacral plexus and the lower third of the thigh. When it occurs at the plexus, the common peroneal nerve usually pierces the Piriformis.

In the upper part of its course the nerve rests upon the posterior surface of the ischium, the nerve to the Quadratus femoris, the Obturator internus and Gemelli, and the Quadratus femoris; it is accompanied by the posterior femoral cutaneous nerve and the inferior gluteal artery, and is covered by the Glutaeus maximus. Lower down, it lies upon the Adductor magnus, and is crossed obliquely by the long head of the Biceps femoris.

The nerve gives off articular and muscular branches.

The **articular branches** (*rami articulares*) arise from the upper part of the nerve and supply the hip-joint, perforating the posterior part of its capsule; they are sometimes derived from the sacral plexus.

The **muscular branches** (*rami musculares*) are distributed to the Biceps femoris, Semitendinosus, Semimembranosus, and Adductor magnus. The nerve to the short head of the Biceps femoris comes from the common peroneal part of the sciatic,

while the other muscular branches *arise* from the tibial portion, as may be seen in those cases where there is a high division of the sciatic nerve.

FIG. 819.—Cutaneous nerves of right lower extremity. Posterior view

FIG. 820.—Diagram of the segmental distribution of the cutaneous nerves of the right lower extremity. Posterior view.

The **Tibial Nerve** (*n. tibialis; internal popliteal nerve*) (Fig. 821) the larger of the two terminal branches of the sciatic, *arises* from the anterior branches of the fourth and fifth lumbar and first, second, and third sacral nerves. It descends along the back of the thigh and through the middle of the popliteal fossa, to the lower part of the Popliteus muscle, where it passes with the popliteal artery beneath the arch of the Soleus. It then runs along the back of the leg with the posterior tibial vessels to the interval between the medial malleolus and the heel, where it divides beneath the lacinate ligament into the medial and lateral plantar nerves. In the thigh it is overlapped by the hamstring muscles above, and then becomes more superficial, and lies lateral to, and some distance from, the popliteal vessels; opposite the knee-joint, it is in close relation with these vessels, and crosses to the medial side of the artery. In the leg it is covered in the upper part of its course by the muscles of the calf; lower down by the skin, the superficial and deep fasciæ. It is placed on the deep muscles, and lies at first to the medial side of the posterior tibial artery, but soon crosses that vessel and descends on its lateral side as far as the ankle. In the lower third of the leg it runs parallel with the medial margin of the tendo calcaneus.

The **branches** of this nerve are: **articular, muscular, medial sural cutaneous, medial calcaneal, medial and lateral plantar.**

Articular branches (*rami articulares*), usually three in number, supply the knee-joint; two of these accompany the superior and inferior medial genicular arteries; and a third, the middle genicular artery. Just above the bifurcation of the nerve an articular branch is given off to the ankle-joint.

Muscular branches (*rami musculares*), four or five in number, *arise* from the nerve as it lies between the two heads of the Gastrocnemius muscle; they

¹ N. B.—In this diagram the medial sural cutaneous and peroneal anastomotic are not in their normal position. They have been displaced by the removal of the superficial muscles.

supply that muscle, and the Plantaris, Soleus, and Popliteus. The branch for the Popliteus turns around the lower border and is distributed to the deep surface of the muscle. Lower down, muscular branches *arise* separately or by a common trunk and supply the Soleus, Tibialis posterior, Flexor digitorum longus, and Flexor hallucis longus; the branch to the last muscle accompanies the peroneal artery; that to the Soleus enters the deep surface of the muscle.

The **medial sural cutaneous nerve** (*n. cutaneus surae medialis; n. communicans tibialis*) descends between the two heads of the Gastrocnemius, and, about the middle of the back of the leg, pierces the deep fascia, and unites with the anastomotic ramus of the common peroneal to form the sural nerve (Fig. 819).

The **sural nerve** (*n. suralis; short saphenous nerve*), formed by the junction of the medial sural cutaneous with the peroneal anastomotic branch, passes downward near the lateral margin of the tendo calcaneus, lying close to the small saphenous vein, to the interval between the lateral malleolus and the calcaneus. It runs forward below the lateral malleolus, and is continued as the **lateral dorsal cutaneous nerve** along the lateral side of the foot and little toe, communicating on the dorsum of the foot with the intermediate dorsal cutaneous nerve, a branch of the superficial peroneal. In the leg, its branches communicate with those of the posterior femoral cutaneous.

The **medial calcaneal branches** (*rami calcanei mediales; internal calcaneal branches*) perforate the lacinate ligament, and supply the skin of the heel and medial side of the sole of the foot.

The **medial plantar nerve** (*n. plantaris medialis; internal plantar nerve*) (Fig. 822), the larger of the two terminal divisions of the tibial nerve, accompanies the medial plantar artery. From its origin under the lacinate ligament it passes under cover of the Abductor hallucis, and, appearing between this muscle and the Flexor digitorum brevis, gives off a proper digital plantar nerve and finally divides opposite the bases of the metatarsal bones into three common digital plantar nerves.

BRANCHES.—The branches of the medial plantar nerve are: (1) **cutaneous**, (2) **muscular**, (3) **articular**, (4) a **proper digital nerve** to the medial side of the great toe, and (5) three **common digital nerves**.

The **cutaneous branches** pierce the plantar aponeurosis between the Abductor hallucis and the Flexor digitorum brevis and are distributed to the skin of the sole of the foot.

The **muscular branches** supply the Abductor hallucis, the Flexor digitorum brevis, the Flexor hallucis brevis, and the first Lumbricalis; these for the Abductor hallucis and Flexor digitorum brevis arise from the trunk of the nerve near its origin and enter the deep surfaces of the muscles; the branch of the Flexor hallucis brevis springs from the proper digital nerve to the medial side of the great toe, and that for the first Lumbricalis from the first common digital nerve.

The **articular branches** supply the articulations of the tarsus and metatarsus.

The **proper digital nerve of the great toe** (*nn. digitales plantares proprii; plantar digital branches*) supplies the Flexor hallucis brevis and the skin on the medial side of the great toe.

The **three common digital nerves** (*nn. digitales plantares communes*) pass between the divisions of the plantar aponeurosis, and each splits into two proper digital nerves—those of the first common digital nerve supply the adjacent sides of the great and second toes; those of the second, the adjacent sides of the second and third toes; and those of the third, the adjacent sides of the third and fourth toes. The third common digital nerve receives a communicating branch from the lateral plantar nerve; the first gives a twig to the first Lumbricalis. Each proper digital nerve gives off cutaneous and articular filaments; and opposite the last phalanx sends upward a dorsal branch, which supplies the structures around the nail, the continuation of the nerve being distributed to the ball of the toe. It will be

observed that these digital nerves are similar in their distribution to those of the median nerve in the hand.

The **Lateral Plantar Nerve** (*n. plantaris lateralis*; *external plantar nerve*) (Fig. 822) supplies the skin of the fifth toe and lateral half of the fourth, as well as most of the deep muscles, its distribution being similar to that of the ulnar nerve in the hand. It passes obliquely forward with the lateral plantar artery to the lateral side of the foot, lying between the Flexor digitorum brevis and Quadratus plantae; and, in the interval between the former muscle and the abductor digiti quinti, divides into a superficial and a deep branch. Before its division, it supplies the Quadratus plantae and Abductor digiti quinti.

The **superficial branch** (*ramus superficialis*) splits into a proper and a common digital nerve; the proper digital nerve supplies the lateral side of the little toe, the Flexor digiti quinti brevis, and the two Interossei of the fourth intermetatarsal space; the common digital nerve communicates with the third common digital branch of the medial plantar nerve and divides into two proper digital nerves which supply the adjoining sides of the fourth and fifth toes.

FIG. 822.—The plantar nerves.

FIG. 823.—Diagram of the segmental distribution of the cutaneous nerves of the sole of the foot.

The **deep branch** (*ramus profundus*; *muscular branch*) accompanies the lateral plantar artery on the deep surface of the tendons of the Flexor muscles and the Adductor hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the second, third, and fourth Lumbricales, and the Adductor hallucis.

The **Common Peroneal Nerve** (*n. peroneus communis*; *external popliteal nerve*; *peroneal nerve*) (Fig. 821), about one-half the size of the tibial, is derived from the dorsal branches of the fourth and fifth lumbar and the first and second sacral nerves. It descends obliquely along the lateral side of the popliteal fossa to the head of the fibula, close to the medial margin of the Biceps femoris muscle. It lies between the tendon of the Biceps femoris and lateral head of the Gastrocnemius muscle, winds around the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the superficial and deep peroneal nerves. Previous to its division it gives off articular and lateral sural cutaneous nerves.

The **articular branches** (*rami articulares*) are three in number; two of these accompany the superior and inferior lateral genicular arteries to the knee; the upper one occasionally *arises* from the trunk of the sciatic nerve. The third (*recurrent*) articular nerve is given off at the point of division of the common peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anterior to the front of the knee.

The **lateral sural cutaneous nerve** (*n. cutaneus surae lateralis; lateral cutaneous branch*) supplies the skin on the posterior and lateral surfaces of the leg; one branch, the **peroneal anastomotic** (*n. communicans fibularis*), *arises* near the head of the fibula, crosses the lateral head of the Gastrocnemius to the middle of the leg, and joins with the medial sural cutaneous to form the sural nerve. The peroneal anastomotic is occasionally continued down as a separate branch as far as the heel.

The **Deep Peroneal Nerve** (*n. peronaeus profundus; anterior tibial nerve*) (Fig. 816) begins at the bifurcation of the common peroneal nerve, between the fibula and upper part of the Peronaeus longus, passes obliquely forward beneath the Extensor digitorum longus to the front of the interosseous membrane, and comes into relation with the anterior tibial artery above the middle of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into a lateral and a medial terminal branch. It lies at first on the lateral side of the anterior tibial artery, then in front of it, and again on its lateral side at the ankle-joint.

In the leg, the deep peroneal nerve supplies **muscular branches** to the Tibialis anterior, Extensor digitorum longus, Peronaeus tertius, and Extensor hallucis proprius, and an **articular branch** to the ankle-joint.

The **lateral terminal branch** (*external or tarsal branch*) passes across the tarsus, beneath the Extensor digitorum brevis, and, having become enlarged like the dorsal interosseous nerve at the wrist, supplies the Extensor digitorum brevis. From the enlargement three minute **interosseous branches** are given off, which supply the tarsal joints and the metatarsophalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second Interosseus dorsalis muscle.

The **medial terminal branch** (*internal branch*) accompanies the dorsalis pedis artery along the dorsum of the foot, and, at the first interosseous space, divides into two **dorsal digital nerves** (*nn. digitales dorsales hallucis lateralis et digiti secundi medialis*) which supply the adjacent sides of the great and second toes, communicating with the medial dorsal cutaneous branch of the superficial peroneal nerve. Before it divides it gives off to the first space an **interosseous branch** which supplies the metatarsophalangeal joint of the great toe and sends a filament to the first Interosseus dorsalis muscle.

The **Superficial Peroneal Nerve** (*n. peronaeus superficialis; musculocutaneous nerve*) (Fig. 816) supplies the Peronei longus and brevis and the skin over the greater part of the dorsum of the foot. It passes forward between the Peronei and the Extensor digitorum longus, pierces the deep fascia at the lower third of the leg, and divides into a medial and an intermediate dorsal cutaneous nerve. In its course between the muscles, the nerve gives off muscular branches to the Peronei longus and brevis, and cutaneous filaments to the integument of the lower part of the leg.

The **medial dorsal cutaneous nerve** (*n. cutaneus dorsalis medialis; internal dorsal cutaneous branch*) passes in front of the ankle-joint, and divides into two **dorsal digital branches**, one of which supplies the medial side of the great toe, the other, the adjacent side of the second and third toes. It also supplies the integument of the medial side of the foot and ankle, and communicates with the saphenous nerve, and with the deep peroneal nerve (Fig. 814).

The **intermediate dorsal cutaneous nerve** (*n. cutaneus dorsalis intermedius; external dorsal cutaneous branch*), the smaller, passes along the lateral part of the dorsum of the foot, and divides into **dorsal digital branches**, which supply the contiguous

sides of the third and fourth, and of the fourth and fifth toes. It also supplies the skin of the lateral side of the foot and ankle, and communicates with the sural nerve (Fig. 814).

The branches of the superficial peroneal nerve supply the skin of the dorsal surfaces of all the toes excepting the lateral side of the little toe, and the adjoining sides of the great and second toes, the former being supplied by the lateral dorsal cutaneous nerve from the sural nerve, and the latter by the medial branch of the deep peroneal nerve. Frequently some of the lateral branches of the superficial peroneal are absent, and their places are then taken by branches of the sural nerve.

The Pudendal Plexus (*plexus pudendus*) (Fig. 817).—The pudendal plexus is not sharply marked off from the sacral plexus, and as a consequence some of the branches which spring from it may *arise* in conjunction with those of the sacral plexus. It lies on the posterior wall of the pelvis, and is usually formed by branches from the anterior divisions of the second and third sacral nerves, the whole of the anterior divisions of the fourth and fifth sacral nerves, and the coccygeal nerve.

It gives off the following branches:

Perforating cutaneous	2, 3 S.
Pudendal	2, 3, 4 S.
Visceral	3, 4 S.
Muscular	4 S.
Anococcygeal	4, 5 S. and Cocc.

The Perforating Cutaneous Nerve (*n. clunium inferior medialis*) usually *arises* from the posterior surface of the second and third sacral nerves. It pierces the lower part of the sacrotuberous ligament, and winding around the inferior border of the Glutæus maximus supplies the skin covering the medial and lower parts of that muscle.

The perforating cutaneous nerve may arise from the pudendal or it may be absent; in the latter case its place may be taken by a branch from the posterior femoral cutaneous nerve or by a branch from the third and fourth, or fourth and fifth, sacral nerves.

The Pudendal Nerve (*n. pudendus; internal pudic nerve*) derives its fibres from the ventral branches of the second, third, and fourth sacral nerves. It passes between the Piriformis and Coccygeus muscles and leaves the pelvis through the lower part of the greater sciatic foramen. It then crosses the spine of the ischium, and reënters the pelvis through the lesser sciatic foramen. It accompanies the internal pudendal vessels upward and forward along the lateral wall of the ischiorectal fossa, being contained in a sheath of the obturator fascia termed **Alcock's canal**, and divides into two terminal branches, viz., the **perineal nerve**, and the **dorsal nerve of the penis or clitoris**. Before its division it gives off the **inferior hemorrhoidal nerve**.

The inferior hemorrhoidal nerve (*n. hæmorrhoidalis inferior*) occasionally *arises* directly from the sacral plexus; it crosses the ischiorectal fossa, with the inferior hemorrhoidal vessels, toward the anal canal and the lower end of the rectum, and is distributed to the Sphincter ani externus and to the integument around the anus. Branches of this nerve communicate with the perineal branch of the posterior femoral cutaneous and with the posterior scrotal nerves at the forepart of the perineum.

The perineal nerve (*n. perinei*), the inferior and larger of the two terminal branches of the pudendal, is situated below the internal pudendal artery. It accompanies the perineal artery and divides into **posterior scrotal** (or **labial**) and **muscular branches**.

The posterior scrotal (or labial) branches (*nn. scrotales (or labiales) posteriores; superficial peroneal nerves*) are two in number, medial and lateral. They pierce the fascia of the urogenital diaphragm, and run forward along the lateral part of the urethral triangle in company with the posterior scrotal branches of the perineal

artery; they are distributed to the skin of the scrotum and communicate with the perineal branch of the posterior femoral cutaneous nerve. These nerves supply the labium majus in the female.

The **muscular branches** are distributed to the Transversus perinaei superficialis, Bulbocavernosus, Ischiocavernosus, and Constrictor urethrae. A branch, the **nerve to the bulb**, given off from the nerve to the Bulbocavernosus, pierces this muscle, and supplies the corpus cavernosum urethrae, ending in the mucous membrane of the urethra.

The **dorsal nerve of the penis** (*n. dorsalis penis*) is the deepest division of the pudendal nerve; it accompanies the internal pudendal artery along the ramus of the ischium; it then runs forward along the margin of the inferior ramus of the pubis, between the superior and inferior layers of the fascia of the urogenital diaphragm. Piercing the inferior layer it gives a branch to the corpus cavernosum penis, and passes forward, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, on to the dorsum of the penis, and ends on the glans penis. In the female this nerve is very small, and supplies the **clitoris** (*n. dorsalis clitoridis*).

The **Visceral Branches** arise from the third and fourth, and sometimes from the second, sacral nerves, and are distributed to the bladder and rectum and, in the female, to the vagina; they communicate with the pelvic plexuses of the sympathetic.

The **Muscular Branches** are derived from the fourth sacral, and supply the Levator ani, Coccygeus, and Sphincter ani externus. The branches to the Levator ani and Coccygeus enter their pelvic surfaces; that to the Sphincter ani externus (perineal branch) reaches the ischiorectal fossa by piercing the Coccygeus or by passing between it and the Levator ani. Cutaneous filaments from this branch supply the skin between the anus and the coccyx.

Anococcygeal Nerves (*nn. anococcygei*).—The fifth sacral nerve receives a communicating filament from the fourth, and unites with the coccygeal nerve to form the **coccygeal plexus**. From this plexus the anococcygeal nerves take origin; they consist of a few fine filaments which pierce the sacrotuberous ligament to supply the skin in the region of the coccyx.

Applied Anatomy.—The lumbar plexus passes through the Psoas major, and therefore in psoas abscess any or all of its branches may be irritated, causing severe pain in the part to which the irritated nerves are distributed. The genitofemoral nerve is the one which is most frequently implicated. This nerve is also of importance as it is concerned in one of the principal superficial reflexes employed in the investigation of diseases of the medulla spinalis. If the skin over the medial side of the thigh just below the inguinal ligament (the part supplied by the lumboinguinal nerve) be gently tickled in a male child, the testes will be drawn upward, through the action of the Cremaster muscle, supplied by the lumboinguinal nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The femoral nerve is in danger of being injured in fractures of the lesser pelvis, since the fracture most commonly takes place through the superior ramus of the pubis, at or near the point where this nerve crosses the bone. It is also liable to be pressed upon, and its functions impaired, by some tumors growing in the pelvis. Moreover, on account of its superficial position, it is exposed to injury in wounds and stabs in the groin. Its central origin is often affected in cases of infantile paralysis. When this nerve is paralyzed, the patient is unable to flex his hip completely, on account of the paralysis of the Iliacus; or to extend the knee on the thigh, on account of paralysis of the Quadriceps femoris; there is complete paralysis of the Sartorius, and partial paralysis of the Pectineus. There is loss of sensation down the front and medial side of the thigh, except in that part supplied by the lumboinguinal and ilioinguinal nerves. There is also loss of sensation down the medial side of the leg and foot as far as the ball of the great toe.

The obturator nerve is rarely paralyzed alone, but occasionally in association with the femoral. The principal interest attached to it is in connection with its supply to the knee; pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient does not always complain of pain in that articulation, but on the medial side of the knee, or in the knee-joint itself, both of these articulations being supplied by the obturator nerve, the final

distribution of the nerve being to the knee-joint. Again, the same thing occurs in sacroiliac disease; pain is complained of in the knee-joint, or on its medial side. The obturator nerve is in close relationship with the sacroiliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Further, in cancer of the sigmoid colon, and even in cases where masses of hardened feces are impacted in this portion of the gut, pain is complained of in the knee. The left obturator nerve lies beneath the sigmoid colon, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is paralyzed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outward of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the medial side of the thigh.

The sciatic nerve is liable to be pressed upon by various forms of pelvic tumor, giving rise to pain along its trunk, to which the term *sciatica* is applied. Tumors growing from the pelvic viscera, especially advanced cancer of the rectum, aneurisms of some of the branches of the hypogastric artery, calculus in the bladder when of large size, accumulation of feces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to sciatica. Outside the pelvis violent movements of the hip-joint, exostoses or other tumors growing from the margin of the greater sciatic foramen, may also give rise to the same condition. Most cases of sciatica, however, are due to neuritis of the sciatic nerve from exposure to cold, and it occurs more often in men than in women, in the latter half of life, and often in association with rheumatism, gout, or diabetes mellitus. The inflamed nerve is often sensitive to pressure, particularly in certain "tender spots," *e. g.*, near the posterior iliac spine, at the sciatic notch, about the middle of the back of the thigh, in the popliteal fossa, below the head of the fibula, behind the malleoli, on the dorsum of the foot, and pain is felt whenever extension of the leg is attempted, and the nerve is stretched. Paralysis of the sciatic nerve is rarely complete; when the lesion occurs high up there is palsy of the Biceps femoris, Semimembranosus, and Semitendinosus, and of the muscles below the knee. If the lesion be lower down, there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, which is supplied by the posterior femoral cutaneous, and in the upper half of the medial side of the leg, when the communicating branch of the obturator is large (see p. 980). Lesions of the common peroneal nerve cause paralysis of the Tibialis anterior, the Peronaei, the long Extensors of the toes, and the short Extensor on the dorsum of the foot. "Foot drop" follows, dorsal flexion of the toes and abduction of the foot becoming impossible. Later on talipes results, largely by the action of gravity or by the weight of the superincumbent bedclothes when the patient lies in bed, aided by the contracture of the unopposed posterior crural group of muscles.

The sciatic nerve has been frequently cut down upon and stretched, or has been acupunctured, for the relief of sciatica. In order to define it on the surface, a point is taken at the junction of the middle and lower thirds of a line stretching from the posterior superior spine of the ilium to the lateral part of the ischial tuberosity, and a line drawn from this to the middle of the upper part of the popliteal fossa. The line must be slightly curved with its convexity outward, and as it passes downward to the lower border of the Glutaeus maximus is slightly nearer to the ischial tuberosity than to the greater trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve beneath the fold of the buttock. The skin, superficial structures, and deep fascia having been divided, the hamstrings are defined, and pulled apart with retractors. The nerve will be found lying on the Adductor magnus and covered by the Biceps femoris. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the "dry" plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position, the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg.

The position of the common peroneal nerve, close behind the tendon of the Biceps femoris, on the lateral side of the popliteal fossa, should be remembered in subcutaneous division of the tendon. After the tendon is divided, the common peroneal nerve rises up as a cord and might be mistaken for a small undivided portion of the tendon. Where this nerve winds around the neck of the fibula, it is also liable to be severed accidentally if its exact situation is not kept in mind, and especial care must be used when dealing with sinuses leading down to carious bone in this situation. Section of the nerve results in complete "foot drop" from paralysis of the anterior tibial group of muscles and inversion of the foot from the unopposed action of the Tibialis posterior, the Peronaei being paralyzed, together with anesthesia of the parts supplied by the nerve, and, owing to loss of nutrition, the limb frequently becomes blue and cold, and may develop "trophic" sores.

two branches, which lie one on the lateral and the other on the medial side of that vessel.

The **lateral branch**, the larger of the two, distributes filaments to the internal carotid artery, and forms the **internal carotid plexus**.

The **medial branch** also distributes filaments to the internal carotid artery, and, continuing onward, forms the **cavernous plexus**.

The **internal carotid plexus** (*plexus caroticus internus; carotid plexus*) is situated on the lateral side of the internal carotid artery, and in the plexus there occasionally exists a small gangliform swelling, the **carotid ganglion**, on the under surface of the artery. The internal carotid plexus communicates with the semilunar ganglion, the abducent nerve, and the sphenopalatine ganglion; it distributes filaments to the wall of the carotid artery, and also communicates with the tympanic branch of the glossopharyngeal nerve.

The communicating branches with the abducent nerve consist of one or two filaments which join that nerve as it lies upon the lateral side of the internal carotid artery. The communication with the sphenopalatine ganglion is effected by a branch, the **deep petrosal**, given off from the plexus on the lateral side of the artery; this branch passes through the cartilage filling up the foramen lacerum, and joins the greater superficial petrosal to form the nerve of the pterygoid canal (*Vidian nerve*), which passes through the pterygoid canal to the sphenopalatine ganglion. The communication with the tympanic branch of the glossopharyngeal nerve is effected by the **caroticotympanic**, which may consist of two or three delicate filaments.

The **cavernous plexus** (*plexus cavernosus*) is situated below and medial to that part of the internal carotid artery which is placed by the side of the sella turcica in the cavernous sinus, and is formed chiefly by the medial division of the internal carotid nerve. It communicates with the oculomotor, the trochlear, the ophthalmic and the abducent nerves, and with the ciliary ganglion, and distributes filaments to the wall of the internal carotid artery. The branch of communication with the oculomotor nerve joins that nerve at its point of division; the branch to the trochlear nerve joins it as it lies on the lateral wall of the cavernous sinus; other filaments are connected with the under surface of the ophthalmic nerve; and a second filament joins the abducent nerve.

The **filaments of connection** with the ciliary ganglion *arise* from the anterior part of the cavernous plexus and enter the orbit through the superior orbital fissure; they may join the nasociliary branch of the ophthalmic nerve, or be continued forward as a separate branch.

The **terminal filaments** from the internal carotid and cavernous plexuses are prolonged as plexuses around the anterior and middle cerebral arteries and the ophthalmic artery; along the former vessels, they may be traced to the pia mater; along the latter, into the orbit, where they accompany each of the branches of the vessel. The filaments prolonged on to the anterior communicating artery connect the sympathetic nerves of the right and left sides.

THE CERVICAL PORTION OF THE SYMPATHETIC SYSTEM (PARS CERVICALIS S. SYMPATHICI).

The **cervical portion** of the sympathetic trunk consists of three ganglia, distinguished, according to their positions, as the **superior**, **middle**, and **inferior ganglia**, connected by intervening cords. This portion receives no white rami communicantes from the cervical spinal nerves; its spinal fibres are derived from the white rami of the upper thoracic nerves, and enter the corresponding thoracic ganglia of the sympathetic trunk, through which they ascend into the neck.

The **superior cervical ganglion** (*ganglion cervicale superius*), the largest of the three, is placed opposite the second and third cervical vertebræ. It is of a reddish-gray color, and usually fusiform in shape; sometimes broad and flattened, and occasionally constricted at intervals; it is believed to be formed by the coalescence of four ganglia, corresponding to the upper four cervical nerves. It is in relation, in *front*, with the sheath of the internal carotid artery and internal jugular vein; *behind*, with the Longus capitis muscle. (*Rectus Cap. Ant.*)

Its branches may be divided into **inferior, lateral, medial, and anterior**.

The **Inferior Branch** communicates with the middle cervical ganglion.

The **Lateral Branches** (*external branches*) consist of gray rami communicantes to the upper four cervical nerves and to certain of the cerebral nerves. Sometimes the branch to the fourth cervical nerve may come from the trunk connecting the upper and middle cervical ganglia. The branches to the cerebral nerves consist of delicate filaments, which run to the ganglion nodosum of the vagus, and to the hypoglossal nerve. A filament, the **jugular nerve**, passes upward to the base of the skull, and divides to join the petrous ganglion of the glossopharyngeal, and the jugular ganglion of the vagus.

The **Medial Branches** (*internal branches*) are peripheral, and are the **laryngopharyngeal branches** and the **superior cardiac nerve**.

The **laryngopharyngeal branches** (*rami laryngopharyngei*) pass to the side of the pharynx, where they join with branches from the glossopharyngeal, vagus, and external laryngeal nerves to form the **pharyngeal plexus**.

The **superior cardiac nerve** (*n. cardiacus superior*) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the trunk between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, and in front of the Longus colli muscle; and crosses in front of the inferior thyroid artery, and recurrent nerve. The course of the nerves on the two sides then differ. The **right nerve**, at the root of the neck, passes either in front of or behind the subclavian artery, and along the innominate artery to the back of the arch of the aorta, where it joins the deep part of the cardiac plexus. It is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down, one or two twigs from the vagus; and as it enters the thorax it is joined by a filament from the recurrent nerve. Filaments from the nerve communicate with the thyroid branches from the middle cervical ganglion. The **left nerve**, in the thorax, runs in front of the left common carotid artery and across the left side of the arch of the aorta, to the superficial part of the cardiac plexus.

The **Anterior Branches** (*nn. carotici externi*) ramify upon the common carotid artery and upon the external carotid artery and its branches, forming around each a delicate plexus, on the nerves composing which small ganglia are occasionally found. The plexuses accompanying some of these arteries have important communications with other nerves. That surrounding the external maxillary artery communicates with the submaxillary ganglion by a filament; and that accompanying the middle meningeal artery sends an offset to the otic ganglion, and a second, the **external petrosal nerve**, to the genicular ganglion of the facial nerve.

The **middle cervical ganglion** (*ganglion cervicale medium*) is the smallest of the three cervical ganglia, and is occasionally wanting. It is placed opposite the sixth cervical vertebra, usually in front of, or close to, the inferior thyroid artery. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

It sends gray rami communicantes to the fifth and sixth cervical nerves, and gives off the middle cardiac nerve.

The **Middle Cardiac Nerve** (*n. cardiacus medius; great cardiac nerve*), the largest of the three cardiac nerves, arises from the middle cervical ganglion, or from the

trunk between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck runs either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent nerve, and joins the right half of the deep part of the cardiac plexus. In the neck, it communicates with the superior cardiac and recurrent nerves. On the left side, the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left half of the deep part of the cardiac plexus.

The **inferior cervical ganglion** (*ganglion cervicale inferius*) is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib, on the medial side of the costocervical artery. Its form is irregular; it is larger in size than the preceding, and is frequently fused with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the seventh and eighth cervical nerves. It is connected to the middle cervical ganglion by two or more cords, one of which forms a loop around the subclavian artery and supplies offsets to it. This loop is named the **ansa subclavia** (*Viesssenii*).

The ganglion sends gray rami communicantes to the seventh and eighth cervical nerves.

It gives off the inferior cardiac nerve, and offsets to bloodvessels.

The **inferior cardiac nerve** (*n. cardiacus inferior*) arises from either the inferior cervical or the first thoracic ganglion. It descends behind the subclavian artery and along the front of the trachea, to join the deep part of the cardiac plexus. It communicates freely behind the subclavian artery with the recurrent nerve and the middle cardiac nerve.

The **offsets to bloodvessels** form plexuses on the subclavian artery and its branches. The plexus on the vertebral artery is continued on to the basilar, posterior cerebral, and cerebellar arteries. The plexus on the inferior thyroid artery accompanies the artery to the thyroid gland, and communicates with the recurrent and external laryngeal nerves, with the superior cardiac nerve, and with the plexus on the common carotid artery.

THE THORACIC PORTION OF THE SYMPATHETIC SYSTEM (PARS THORACALIS S. SYMPATHICI) (Fig. 825).

The thoracic portion of the sympathetic trunk consists of a series of ganglia, which usually correspond in number to that of the vertebræ; but, on account of the occasional coalescence of two ganglia, their number is uncertain. The thoracic ganglia rest against the heads of the ribs, and are covered by the costal pleura; the last two, however, are more anterior than the rest, and are placed on the sides of the bodies of the eleventh and twelfth thoracic vertebræ. The ganglia are small in size, and of a grayish color. The first, larger than the others, is of an elongated form, and frequently blended with the inferior cervical ganglion. They are connected together by the intervening portions of the trunk.

Two rami communicantes, a white and a gray, connect each ganglion with its corresponding spinal nerve.

The *branches from the upper five ganglia* are very small; they supply filaments to the thoracic aorta and its branches. Twigs from the second, third, and fourth ganglia enter the posterior pulmonary plexus.

The *branches from the lower seven ganglia* are large, and white in color; they distribute filaments to the aorta, and unite to form the greater, the lesser, and the lowest splanchnic nerves.

The **greater splanchnic nerve** (*n. splanchnicus major; great splanchnic nerve*) is white in color, firm in texture, and of a considerable size; it is formed by branches

from the fifth to the ninth or tenth thoracic ganglia, but the fibres in the higher roots may be traced upward in the sympathetic trunk as far as the first or second thoracic ganglion. It descends obliquely on the bodies of the vertebræ, perforates the crus of the Diaphragma, and ends in the cœliac ganglion. A ganglion (*ganglion splanchnicum*) exists on this nerve opposite the eleventh or twelfth thoracic vertebra.

n

ntes

na

FIG. 825.—Thoracic portion of the sympathetic trunk.

The **lesser splanchnic nerve** (*n. splanchnicus minor*) is formed by filaments from the ninth and tenth, and sometimes the eleventh thoracic ganglia, and from the cord between them. It pierces the Diaphragma with the preceding nerve, and joins the aorticorenal ganglion.

The **lowest splanchnic nerve** (*n. splanchnicus imus*; *least splanchnic nerve*) arises from the last thoracic ganglion, and, piercing the Diaphragma, ends in the renal plexus.

and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, are connected probably with all the thoracic ganglia, and are distributed to important organs in the abdominal cavity.

THE ABDOMINAL PORTION OF THE SYMPATHETIC SYSTEM (PARS ABDOMINALIS S. SYMPATHICI; LUMBAR PORTION OF GANGLIATED CORD) (Fig. 826).

The abdominal portion of the sympathetic trunk is situated in front of the vertebral column, along the medial margin of the Psoas major. It consists usually of four lumbar ganglia, connected together by interganglionic cords. It is continuous above with the thoracic portion beneath the medial lumbocostal arch; and below with the pelvic portion behind the common iliac artery. The ganglia are of small size, and placed much nearer the median line than are the thoracic ganglia.

Gray rami communicantes pass from all the ganglia to the lumbar spinal nerves. The first and second, and sometimes the third, lumbar nerves send white rami communicantes to the corresponding ganglia. The rami communicantes are of considerable length, and accompany the lumbar arteries around the sides of the bodies of the vertebræ, passing beneath the fibrous arches from which some of the fibres of the Psoas major arise.

Of the **branches of distribution**, some pass in front of the aorta, and join the aortic plexus; others descend in front of the common iliac arteries, and assist in forming the hypogastric plexus.

THE PELVIC PORTION OF THE SYMPATHETIC SYSTEM (PARS PELVINA S. SYMPATHICI).

The pelvic portion of each sympathetic trunk is situated in front of the sacrum, medial to the anterior sacral foramina. It consists of four or five small sacral ganglia, connected together by interganglionic cords, and continuous above with the abdominal portion. Below, the two pelvic sympathetic trunks converge, and end on the front of the coccyx in a small ganglion, the **ganglion impar**.

Gray rami communicantes pass from the ganglia to the sacral and coccygeal nerves. No white rami communicantes are given to this part of the gangliated cord, but the visceral branches which arise from the third and fourth, and sometimes from the second, sacral, and run directly to the pelvic plexuses, are regarded as white rami communicantes.

The **branches of distribution** communicate on the front of the sacrum with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, and others form a plexus, which accompanies the middle sacral artery and sends filaments to the **glomus coccygeum** (*coccygeal body*).

THE GREAT PLEXUSES OF THE SYMPATHETIC SYSTEM.

The great plexuses of the sympathetic are aggregations of nerves and ganglia, situated in the thoracic, abdominal, and pelvic cavities, and named the **cardiac**, **coeliac**, and **hypogastric plexuses**. They consist not only of sympathetic fibres derived from the ganglia, but of fibres from the medulla spinalis, which are conveyed through the white rami communicantes. From the plexuses branches are given to the thoracic, abdominal, and pelvic viscera.

The Cardiac Plexus (Plexus Cardiacus) (Fig. 824).

The **cardiac plexus** is situated at the base of the heart, and is divided into a **superficial part**, which lies in the concavity of the aortic arch, and a **deep part**, between the aortic arch and the trachea. The two parts are, however, closely connected.

The **superficial part of the cardiac plexus** lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the superior cardiac branch of the left sympathetic and the lower superior cervical cardiac branch of the left vagus. A small ganglion, the **cardiac ganglion of Wrisberg**, is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ligamentum arteriosum. The superficial part of the cardiac plexus gives branches (a) to the deep part of the plexus; (b) to the anterior coronary plexus; and (c) to the left anterior pulmonary plexus.

The **deep part of the cardiac plexus** is situated in front of the bifurcation of the trachea, above the point of division of the pulmonary artery, and behind the aortic arch. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic, and the cardiac branches of the vagus and recurrent nerves. The only cardiac nerves which do not enter into the formation of the deep part of the cardiac plexus are the superior cardiac nerve of the left sympathetic, and the lower of the two superior cervical cardiac branches from the left vagus, which pass to the superficial part of the plexus.

The branches from the **right half** of the deep part of the cardiac plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then continued onward to form part of the anterior coronary plexus; those behind the pulmonary artery distribute a few filaments to the right atrium, and are then continued onward to form part of the posterior coronary plexus.

The **left half** of the deep part of the plexus is connected with the superficial part of the cardiac plexus, and gives filaments to the left atrium, and to the anterior pulmonary plexus, and is then continued to form the greater part of the posterior coronary plexus.

The **Posterior Coronary Plexus** (*plexus coronarius posterior; left coronary plexus*) is larger than the anterior, and accompanies the left coronary artery; it is chiefly formed by filaments prolonged from the left half of the deep part of the cardiac plexus, and by a few from the right half. It gives branches to the left atrium and ventricle.

The **Anterior Coronary Plexus** (*plexus coronarius anterior; right coronary plexus*) is formed partly from the superficial and partly from the deep parts of the cardiac plexus. It accompanies the right coronary artery, and gives branches to the right atrium and ventricle.

The Celiac Plexus (Plexus Coeliacus; Solar Plexus) (Figs. 824, 827).

The **celiac plexus**, the largest of the three sympathetic plexuses, is situated at the level of the upper part of the first lumbar vertebra and is composed of two large ganglia, the **celiac ganglia**, and a dense net-work of nerve fibres uniting them together. It surrounds the celiac artery and the root of the superior mesenteric artery. It lies behind the stomach and the omental bursa, in front of the crura of the Diaphragma and the commencement of the abdominal aorta, and between the suprarenal glands. The plexus and the ganglia receive the greater and lesser splanchnic nerves of both sides and some filaments from the right vagus, and give off numerous secondary plexuses along the neighboring arteries.

The **Celiac Ganglia** (*ganglia coeliaca; semilunar ganglia*) are two large irregularly-shaped masses having the appearance of lymph glands and placed one on either side of the middle line in front of the crura of the Diaphragma close to the suprarenal glands, that on the right side being placed behind the inferior vena cava. The upper part of each ganglion is joined by the greater splanchnic nerve, while the

lower part, which is segmented off and named the **aorticorenal ganglion**, receives the lesser splanchnic nerve and gives off the greater part of the renal plexus.

FIG. 827.—The celiac ganglia with the sympathetic plexuses of the abdominal viscera radiating from the ganglia. (Toldt.)

The secondary plexuses springing from or connected with the celiac plexus are the

Phrenic.	Renal.
Hepatic.	Spermatic.
Lienal.	Superior mesenteric.
Superior gastric.	Abdominal aortic.
Suprarenal.	Inferior mesenteric.

The **phrenic plexus** (*plexus phrenicus*) accompanies the inferior phrenic artery to the Diaphragma, some filaments passing to the suprarenal gland. It arises from the upper part of the celiac ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. At the point

of junction of the right phrenic plexus with the phrenic nerve is a small ganglion (**ganglion phrenicum**). This plexus distributes branches to the inferior vena cava, and to the suprarenal and hepatic plexuses.

The **hepatic plexus** (*plexus hepaticus*), the largest offset from the coeliac plexus, receives filaments from the left vagus and right phrenic nerves. It accompanies the hepatic artery, ramifying upon its branches, and upon those of the portal vein in the substance of the liver. Branches from this plexus accompany all the divisions of the hepatic artery. A considerable plexus accompanies the gastroduodenal artery and is continued as the **inferior gastric plexus** on the right gastroepiploic artery along the greater curvature of the stomach, where it unites with offshoots from the lienal plexus.

The **lienal plexus** (*plexus lienalis; splenic plexus*) is formed by branches from the coeliac plexus, the left coeliac ganglion, and from the right vagus nerve. It accompanies the lienal artery to the spleen, giving off, in its course, subsidiary plexuses along the various branches of the artery.

The **superior gastric plexus** (*plexus gastricus superior; gastric or coronary plexus*) accompanies the left gastric artery along the lesser curvature of the stomach, and joins with branches from the left vagus.

The **suprarenal plexus** (*plexus suprarenalis*) is formed by branches from the coeliac plexus, from the coeliac ganglion, and from the phrenic and greater splanchnic nerves, a ganglion being formed at the point of junction with the latter nerve. The plexus supplies the suprarenal gland, being distributed chiefly to its medullary portion; its branches are remarkable for their large size in comparison with that of the organ they supply.

The **renal plexus** (*plexus renalis*) is formed by filaments from the coeliac plexus, the aorticorenal ganglion, and the aortic plexus. It is joined also by the smallest splanchnic nerve. The nerves from these sources, fifteen or twenty in number, have a few ganglia developed upon them. They accompany the branches of the renal artery into the kidney; some filaments are distributed to the spermatic plexus and, on the right side, to the inferior vena cava.

The **spermatic plexus** (*plexus spermaticus*) is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the internal spermatic artery to the testis. In the female, the **ovarian plexus** (*plexus arteriae ovaricae*) arises from the renal plexus, and is distributed to the ovary, and fundus of the uterus.

Applied Anatomy.—The intimate connection which exists between the renal and spermatic plexuses serves to explain the very frequent symptom in renal calculus, of pain which is referred to the body of the testis.

The **superior mesenteric plexus** (*plexus mesentericus superior*) is a continuation of the lower part of the coeliac plexus, receiving a branch from the junction of the right vagus nerve with the plexus. It surrounds the superior mesenteric artery, accompanies it into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery, viz., pancreatic branches to the pancreas; intestinal branches to the small intestine; and ileocolic, right colic, and middle colic branches, which supply the corresponding parts of the great intestine. The nerves composing this plexus are white in color and firm in texture; in the upper part of the plexus close to the origin of the superior mesenteric artery is a ganglion (**ganglion mesentericum superius**).

The **abdominal aortic plexus** (*plexus aorticus abdominalis; aortic plexus*) is formed by branches derived, on either side, from the coeliac plexus and ganglia, and receives filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; it also distributes filaments to the inferior vena cava.

The **inferior mesenteric plexus** (*plexus mesentericus inferior*) is derived chiefly from the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery, viz., the **left colic** and **sigmoid plexuses**, which supply the descending and sigmoid parts of the colon; and the **superior hemorrhoidal plexus**, which supplies the rectum and joins in the pelvis with branches from the pelvic plexuses.

The Hypogastric Plexus (*Plexus Hypogastricus*) (Fig. 824).

The **hypogastric plexus** is situated in front of the last lumbar vertebra and the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on either side from the aortic plexus, and from the lumbar ganglia; it divides, below, into two lateral portions which are named the **pelvic plexuses**.

The Pelvic Plexuses (Fig. 824).—The pelvic plexuses supply the viscera of the pelvic cavity, and are situated at the sides of the rectum in the male, and at the sides of the rectum and vagina in the female. They are formed on either side by a continuation of the hypogastric plexus, by the visceral branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the points of junction of these nerves small ganglia are found. From these plexuses numerous branches are distributed to the viscera of the pelvis. They accompany the branches of the hypogastric artery.

The **Middle Hemorrhoidal Plexus** (*plexus haemorrhoidalis medius*) arises from the upper part of the pelvic plexus. It supplies the rectum, and joins with branches of the superior hemorrhoidal plexus.

The **Vesical Plexus** (*plexus vesicalis*) arises from the forepart of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve fibres. They accompany the vesical arteries, and are distributed to the sides and fundus of the bladder. Numerous filaments also pass to the vesiculae seminales and ductus deferentes; those accompanying the ductus deferens join, on the spermatic cord, with branches from the spermatic plexus.

The **Prostatic Plexus** (*plexus prostaticus*) is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate vesiculae seminales and the corpora cavernosa of the penis and urethra. The nerves supplying the corpora cavernosa consist of two sets, the lesser and greater cavernous nerves, which arise from the forepart of the prostatic plexus, and, after joining with branches from the pudendal nerve, pass forward beneath the pubic arch.

The **lesser cavernous nerves** (*nn. cavernosi penis minores; small cavernous nerves*) perforate the fibrous covering of the penis, near its root.

The **greater cavernous nerve** (*n. cavernosus penis major; large cavernous plexus*) passes forward along the dorsum of the penis, joins with the dorsal nerve of the penis, and is distributed to the corpora cavernosa.

The **Vaginal Plexus** arises from the lower part of the pelvic plexus. It is distributed to the walls of the vagina, to the erectile tissue of the vestibule, and to the clitoris. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve fibres.

The **Uterine Plexus** accompanies the uterine artery to the side of the uterus, between the layers of the broad ligament; it communicates with the ovarian plexus.

Applied Anatomy.—Little is known as to the connection between the numerous microscopic alterations (pigmentation, atrophy, hemorrhage, fibrosis) that have been described in the sympathetic nervous system, and the functional changes that ensue therefrom. Grosser lesions due to stabs, bullet wounds, or the pressure of new growths, may cause either irritative or paralytic

of junction of the right phrenic plexus with the phrenic nerve is a small ganglion (**ganglion phrenicum**). This plexus distributes branches to the inferior vena cava, and to the suprarenal and hepatic plexuses.

The **hepatic plexus** (*plexus hepaticus*), the largest offset from the coeliac plexus, receives filaments from the left vagus and right phrenic nerves. It accompanies the hepatic artery, ramifying upon its branches, and upon those of the portal vein in the substance of the liver. Branches from this plexus accompany all the divisions of the hepatic artery. A considerable plexus accompanies the gastroduodenal artery and is continued as the **inferior gastric plexus** on the right gastroepiploic artery along the greater curvature of the stomach, where it unites with offshoots from the lienal plexus.

The **lienal plexus** (*plexus lienalis*; *splenic plexus*) is formed by branches from the coeliac plexus, the left **coeliac ganglion**, and from the right vagus nerve. It accompanies the lienal artery to the spleen, giving off, in its course, subsidiary plexuses along the various branches of the artery.

The **superior gastric plexus** (*plexus gastricus superior*; *gastric or coronary plexus*) accompanies the left gastric artery along the lesser curvature of the stomach, and joins with branches from the left vagus.

The **suprarenal plexus** (*plexus suprarenalis*) is formed by branches from the coeliac plexus, from the coeliac ganglion, and from the phrenic and greater splanchnic nerves, a ganglion being formed at the point of junction with the latter nerve. The plexus supplies the suprarenal gland, being distributed chiefly to its medullary portion; its branches are remarkable for their large size in comparison with that of the organ they supply.

The **renal plexus** (*plexus renalis*) is formed by filaments from the coeliac plexus, the aorticorenal ganglion, and the aortic plexus. It is joined also by the smallest splanchnic nerve. The nerves from these sources, fifteen or twenty in number, have a few ganglia developed upon them. They accompany the branches of the renal artery into the kidney; some filaments are distributed to the spermatic plexus and, on the right side, to the inferior vena cava.

The **spermatic plexus** (*plexus spermaticus*) is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the internal spermatic artery to the testis. In the female, the **ovarian plexus** (*plexus arteriae ovaricae*) arises from the renal plexus, and is distributed to the ovary, and fundus of the uterus.

Applied Anatomy.—The intimate connection which exists between the renal and spermatic plexuses serves to explain the very frequent symptom in renal calculus, of pain which is referred to the body of the testis.

The **superior mesenteric plexus** (*plexus mesentericus superior*) is a continuation of the lower part of the coeliac plexus, receiving a branch from the junction of the right vagus nerve with the plexus. It surrounds the superior mesenteric artery, accompanies it into the mesentery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery, viz., pancreatic branches to the pancreas; intestinal branches to the small intestine; and ileocolic, right colic, and middle colic branches, which supply the corresponding parts of the great intestine. The nerves composing this plexus are white in color and firm in texture; in the upper part of the plexus close to the origin of the superior mesenteric artery is a ganglion (**ganglion mesentericum superius**).

The **abdominal aortic plexus** (*plexus aorticus abdominalis*; *aortic plexus*) is formed by branches derived, on either side, from the coeliac plexus and ganglia, and receives filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; it also distributes filaments to the inferior vena cava.

The **inferior mesenteric plexus** (*plexus mesentericus inferior*) is derived chiefly from the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery, viz., the **left colic** and **sigmoid plexuses**, which supply the descending and sigmoid parts of the colon; and the **superior hemorrhoidal plexus**, which supplies the rectum and joins in the pelvis with branches from the pelvic plexuses.

The Hypogastric Plexus (Plexus Hypogastricus) (Fig. 824).

The **hypogastric plexus** is situated in front of the last lumbar vertebra and the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on either side from the aortic plexus, and from the lumbar ganglia; it divides, below, into two lateral portions which are named the **pelvic plexuses**.

The Pelvic Plexuses (Fig. 824).—The pelvic plexuses supply the viscera of the pelvic cavity, and are situated at the sides of the rectum in the male, and at the sides of the rectum and vagina in the female. They are formed on either side by a continuation of the hypogastric plexus, by the visceral branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the points of junction of these nerves small ganglia are found. From these plexuses numerous branches are distributed to the viscera of the pelvis. They accompany the branches of the hypogastric artery.

The **Middle Hemorrhoidal Plexus** (*plexus haemorrhoidalis medius*) arises from the upper part of the pelvic plexus. It supplies the rectum, and joins with branches of the superior hemorrhoidal plexus.

The **Vesical Plexus** (*plexus vesicalis*) arises from the forepart of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve fibres. They accompany the vesical arteries, and are distributed to the sides and fundus of the bladder. Numerous filaments also pass to the vesiculæ seminales and ductus deferentes; those accompanying the ductus deferens join, on the spermatic cord, with branches from the spermatic plexus.

The **Prostatic Plexus** (*plexus prostaticus*) is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate vesiculæ seminales and the corpora cavernosa of the penis and urethra. The nerves supplying the corpora cavernosa consist of two sets, the lesser and greater cavernous nerves, which arise from the forepart of the prostatic plexus, and, after joining with branches from the pudendal nerve, pass forward beneath the pubic arch.

The **lesser cavernous nerves** (*nn. cavernosi penis minores; small cavernous nerves*) perforate the fibrous covering of the penis, near its root.

The **greater cavernous nerve** (*n. cavernosus penis major; large cavernous plexus*) passes forward along the dorsum of the penis, joins with the dorsal nerve of the penis, and is distributed to the corpora cavernosa.

The **Vaginal Plexus** arises from the lower part of the pelvic plexus. It is distributed to the walls of the vagina, to the erectile tissue of the vestibule, and to the clitoris. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve fibres.

The **Uterine Plexus** accompanies the uterine artery to the side of the uterus, between the layers of the broad ligament; it communicates with the ovarian plexus.

Applied Anatomy.—Little is known as to the connection between the numerous microscopic alterations (pigmentation, atrophy, hemorrhage, fibrosis) that have been described in the sympathetic nervous system, and the functional changes that ensue therefrom. Grosser lesions due to stabs, bullet wounds, or the pressure of new growths, may cause either irritative or paralytic

symptoms. In *paralysis* of the cervical sympathetic on one side, the pupil is small and does not dilate when shaded or on the instillation of cocaine, although it contracts still farther when brightly illuminated; it also loses the ciliospinal reflex, failing to dilate when the skin of the neck is pinched. The palpebral fissure narrows from paralysis of the involuntary muscle of the eyelid, and the eyeball sinks backward into the orbit—enophthalmos—either from paralysis of Müller's orbital muscle which closes the inferior orbital fissure, or from wasting of the intraorbital fat. The superficial vessels of the face and scalp are at first dilated, but later they contract. Anidrosis, or absence of sweating, is often noted on the affected side. *Irritation* of the cervical sympathetic produces signs mainly the converse of those described above. We have no definite knowledge of the signs and symptoms that follow lesions of the thoracic or abdominal sympathetic systems. It is likely, however, that a number of nervous disorders characterized by persistent vascular disturbances, such as dilatation of the vessels with throbbing, flushing, sweating, and localized oedema, or contraction of the vessels with pallor, chilliness, pain, and malnutrition of the affected parts, are due to implication of the sympathetic nervous system. It is possible, too, that the rare condition of *progressive facial hemiatrophy*, coming on between the ages of ten and twenty, and producing marked unilateral shrinkage of all the tissues of the face, is primarily an affection of the sympathetic.

THE ORGANS OF THE SENSES AND THE COMMON INTEGUMENT.

THE organs of the senses may be divided into (a) those of the special senses of taste, smell, sight, and hearing, and (b) those associated with the general sensations of heat, cold, pain, pressure, etc.

THE PERIPHERAL ORGANS OF THE SPECIAL SENSES.

THE ORGAN OF TASTE (ORGANON GUSTUS).

The periphery gustatory or taste organs consist of certain modified epithelial cells arranged in flask-shaped groups termed **gustatory calyculi** (*taste-buds*), which are found on the tongue and adjacent parts. They occupy nests in the stratified epithelium, and are present in large numbers on the sides of the papillae vallatae (Fig. 828), and to a less extent on their opposed walls. They are also found on the

FIG. 828.—Vertical section of papilla foliata of the rabbit, crossing the folia. (Ranvier.) *g*, Serous gland. *c*, Gustatory calyculus. *n*, Nerve bundles. *p*, Central lamina of the corium. *p'*, Lateral lamina in which the nerve fibres run. *z*, Sinus-like vein which traverses the whole length of the folium.

fungiform papillae over the back part and sides of the tongue, and in the general epithelial covering of the same areas. They are very plentiful over the fimbriae linguae, and are also present on the under surface of the soft palate, and on the posterior surface of the epiglottis.

Structure.—Each taste bud is flask-like in shape (Fig. 829), its broad base resting on the corium, and its neck opening by an orifice, the **gustatory pore**, between the cells of the epithelium. The bud is formed by two kinds of cells: supporting cells and gustatory cells. The supporting cells are mostly arranged like the staves of a cask, and form an outer envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The **gustatory cells**

occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near the middle of the cell. The peripheral end of the cell terminates at the gustatory pore in a fine hair-like filament, the **gustatory hair**. The central process passes toward the deep extremity of the bud, and there ends in single or bifurcated varicosities. The nerve fibrils after losing their medullary sheaths enter the taste bud, and end in fine extremities between the gustatory cells; other nerve fibrils ramify between the supporting cells and terminate in fine extremities; these, however, are believed to be nerves of ordinary sensation and not gustatory.

*Gustatory pore and
gustatory hairs*

FIG 829.—Taste-bud, highly magnified.

Nerves of Taste.—The chorda tympani nerve, derived from the sensory root of the facial, is the nerve of taste for the anterior two-thirds of the tongue; the nerve for the posterior third is the glossopharyngeal.

THE ORGAN OF SMELL (ORGANON OLFACTORIUS; THE NOSE).

The **peripheral olfactory organ** or **organ of smell** consists of two parts: an outer, the **external nose**, which projects from the centre of the face; and an internal, the **nasal cavity**, which is divided by a septum into **right** and **left nasal chambers**.

The External Nose (*Nasus Externus*; Outer Nose).

The **external nose** is pyramidal in form, and its upper angle or **root** is connected directly with the forehead; its free angle is termed the **apex**. Its **base** is perforated by two elliptical orifices, the **nares**, separated from each other by an antero-posterior septum, the **columna**. The margins of the nares are provided with a number of stiff hairs, or **vibrissae**, which arrest the passage of foreign substances carried with the current of air intended for respiration. The lateral surfaces of the nose form, by their union in the middle line, the **dorsum nasi**, the direction of which varies considerably in different individuals; the upper part of the dorsum is supported by the nasal bones, and is named the **bridge**. The lateral surface ends below in a rounded eminence, the **ala nasi**.

Structure.—The frame-work of the external nose is composed of bones and cartilages; it is covered by the integument, and lined by mucous membrane.

The **bony frame-work** occupies the upper part of the organ; it consists of the nasal bones, and the frontal processes of the maxillae.

The **cartilaginous frame-work** (*cartilaginee nasi*) consists of five large pieces, viz., the **cartilage of the septum**, the **two lateral** and the **two greater alar cartilages**, and several smaller pieces, the **lesser alar cartilages** (Figs. 830, 831, 832). The various cartilages are connected to each other and to the bones by a tough fibrous membrane.

The **cartilage of the septum** (*cartilago septi nasi*) is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal cavities in front. Its anterior margin, thickest above, is connected with the nasal bones, and is continuous with the anterior margins of the lateral cartilages; below, it is connected to the medial crura of the greater alar cartilages by fibrous tissue. Its posterior margin is connected with the perpendicular plate of the ethmoid; its inferior margin with the vomer and the palatine processes of the maxillae.

It may be prolonged backward (especially in children) as a narrow process, the **sphenoidal process**, for some distance between the vomer and perpendicular plate of the ethmoid. The septal cartilage does not reach as far as the lowest part of the nasal septum. This is formed by the medial crura of the greater alar cartilages and by the skin; it is freely movable, and hence is termed the **septum mobile nasi**.

The **lateral cartilage** (*cartilago nasi lateralis*; *upper lateral cartilage*) is situated below the inferior margin of the nasal bone, and is flattened, and triangular in shape. Its anterior margin is thicker than the posterior, and is continuous above with the cartilage of the septum, but separated from it below by a narrow fissure; its superior margin is attached to the nasal bone and the frontal process of the maxilla; its inferior margin is connected by fibrous tissue with the greater alar cartilage.

The **greater alar cartilage** (*cartilago alaris major*; *lower lateral cartilage*) is a thin, flexible plate, situated immediately below the preceding, and bent upon itself in such a manner as to form the medial and lateral walls of the naris of its own side. The portion which forms the **medial wall** (*crus mediale*) is loosely connected with the corresponding portion of the opposite cartilage, the two forming, together with the thickened integument and subjacent tissue, the **septum mobile nasi**. The part which forms the **lateral wall** (*crus laterale*) is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the frontal process of the maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates, the **lesser alar cartilages** (*cartilaginee alares minores*; *sesamoid cartilages*). Above, it is connected by fibrous tissue to the lateral cartilage and front part of the cartilage of the septum; below, it falls short of the margin of the naris, the ala being completed by fatty and fibrous tissue covered by skin. In front, the greater alar cartilages are separated by a notch which corresponds with the apex of the nose.

FIG. 831.—Cartilages of the nose, seen from below

FIG. 832.—Bones and cartilages of septum of nose.
Right side.

The **muscles** acting on the external nose have been described in the section on Myology.

The **integument** of the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts; but over the tip and ala it is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The **arteries** of the external nose are the alar and septal branches of the external maxillary, which supply the ala and septum; the dorsum and sides being supplied from the dorsal nasal branch of the ophthalmic and the infraorbital branch of the internal maxillary. The **veins** end in the anterior facial and ophthalmic veins.

The **nerves** for the muscles of the nose are derived from the facial, while the skin receives branches from the infratrochlear and nasociliary branches of the ophthalmic, and from the infra-orbital of the maxillary.

The Nasal Cavity (Cavum Nasi; Nasal Fossa).

The nasal chambers are situated one on either side of the median plane. They open in front through the nares, and communicate behind through the choanæ with the nasal part of the pharynx. The **nares** are somewhat pear-shaped apertures, each measuring about 2.5 cm. antero-posteriorly and 1.25 cm. transversely at its widest part. The **choanæ** are two oval openings each measuring 2.5 cm. in the vertical, and 1.25 cm. in the transverse direction in a well-developed adult skull.

For the description of the bony boundaries of the nasal cavities, see pages 292 to 294.

Inside the aperture of the nostril is a slight dilatation, the **vestibule**, bounded laterally by the ala and lateral crus of the greater alar cartilage, and medially by the medial crus of the same cartilage. It is lined by skin containing hairs and sebaceous glands, and extends as a small recess toward the apex of the nose. Each nasal cavity, above and behind the vestibule, is divided into two parts: an **olfactory region**, consisting of the superior nasal concha and the opposed part of the septum, and a **respiratory region**, which comprises the rest of the cavity.

Pharyngeal orifice of auditory tube Pharyngeal recess

FIG. 833.—Lateral wall of nasal cavity

Lateral Wall (Figs. 833, 834).—On the lateral wall are the **superior, middle, and inferior nasal conchæ**, and below and lateral to each concha is the corresponding nasal passage or meatus. Above the superior concha is a narrow recess, the **sphenoethmoidal recess**, into which the sphenoidal sinus opens. The **superior meatus** is a short oblique passage extending about half-way along the upper border of the middle concha; the posterior ethmoidal cells open into the front part of this meatus. The **middle meatus** is below and lateral to the middle concha, and is

continued anteriorly into a shallow depression, situated above the vestibule and named the **atrium** of the middle meatus. On raising or removing the middle concha the lateral wall of this meatus is fully displayed. On it is a rounded elevation, the **bullæ ethmoidalis**, and below and in front of this is a curved cleft, the **hiatus semilunaris**.

The **bullæ ethmoidalis** is caused by the bulging of the middle ethmoidal cells which open on or immediately above it, and the size of the bulla varies with that of its contained cells.

oidal cells

oidal sinus

Bristle in opening of maxillary sinus Cus edge of inferior concha auditory tube accessory nasal recess

FIG. 334.—Lateral wall of nasal cavity; the three nasal conchæ have been removed.

The **hiatus semilunaris** is bounded inferiorly by the sharp concave margin of the **uncinate process** of the ethmoid bone, and leads into a curved channel, the **infundibulum**, bounded above by the **bullæ ethmoidalis** and below by the lateral surface of the **uncinate process** of the ethmoid. The anterior ethmoidal cells open into the front part of the infundibulum, and this in slightly over 50 per cent. of subjects is directly continuous with the frontonasal duct or passage leading from the frontal air sinus; but when the anterior end of the **uncinate process** fuses with the front part of the bulla, this continuity is interrupted and the frontonasal duct then opens directly into the anterior end of the middle meatus.

Below the **bullæ ethmoidalis**, and partly hidden by the inferior end of the **uncinate process**, is the **ostium maxillare**, or opening from the maxillary sinus; in a frontal section this opening is seen to be placed near the roof of the sinus. An accessory opening from the sinus is frequently present below the posterior end of the middle nasal concha. The **inferior meatus** is below and lateral to the inferior nasal concha; the nasolacrimal duct opens into this meatus under cover of the anterior part of the inferior concha.

Medial Wall (Fig. 832).—The medial wall or septum is frequently more or less deflected from the median plane, thus lessening the size of one nasal cavity and increasing that of the other; ridges or spurs of bone growing into one or other cavity from the septum are also sometimes present. Immediately over the incisive canal at the lower edge of the cartilage of the septum a depression, the **nasopalatine recess**, is seen. In the septum close to this recess a minute orifice may be discerned; it leads backward into a blind pouch, the rudimentary **vomeronasal organ of Jacobson**, which is supported by a strip of cartilage, the **vomeronasal cartilage**. This organ is well-developed in many of the lower animals, where it apparently plays a part in the sense of smell, since it is supplied by twigs of the olfactory nerve and lined by epithelium similar to that in the olfactory region of the nose.

The **roof** of the nasal cavity is narrow from side to side, except at its posterior part, and may be divided, from behind forward, into sphenoidal, ethmoidal, and frontonasal parts, after the bones which form it.

The **floor** is concave from side to side and almost horizontal antero-posteriorly; its anterior three-fourths are formed by the palatine process of the maxilla, its posterior fourth by the horizontal process of the palatine bone. In its antero-medial part, directly over the incisive foramen, a small depression, the **nasopalatine recess**, is sometimes seen; it points downward and forward and occupies the position of a canal which connected the nasal with the buccal cavity in early fetal life.

The Mucous Membrane (*membrana mucosa nasi*).—The nasal mucous membrane lines the nasal cavities, and is intimately adherent to the periosteum or perichondrium. It is continuous with the skin through the nares, and with the mucous membrane of the nasal part of the pharynx through the choanæ. From the nasal cavity its continuity with the conjunctiva may be traced, through the nasolacrimal and lacrimal ducts; and with the frontal, ethmoidal, sphenoidal, and maxillary sinuses, through the several openings in the meatuses. The mucous membrane is thickest, and most vascular, over the nasal conchæ. It is also thick over the septum; but it is very thin in the meatuses on the floor of the nasal cavities, and in the various sinuses.

Owing to the thickness of the greater part of this membrane, the nasal cavities are much narrower, and the middle and inferior nasal conchæ appear larger and more prominent than in the skeleton; also the various apertures communicating with the meatuses are considerably narrowed.

Structure of the Mucous Membrane (Fig. 835).—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the nose in which it is found. In the **respiratory region** it is columnar and ciliated. Interspersed among the columnar cells are goblet or mucin cells, while between their bases are found smaller pyramidal cells. Beneath the epithelium and its basement membrane is a fibrous layer infiltrated with lymph corpuscles, so as to form in many parts a diffuse adenoid tissue, and under this a nearly continuous layer of small and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the **olfactory region** the mucous membrane is yellowish in color and the epithelial cells are columnar and non-ciliated; they are of two kinds, supporting cells and olfactory cells. The **supporting cells** contain oval nuclei, which are situated in the deeper parts of the cells and constitute the zone of oval nuclei; the superficial part of each cell is columnar, and contains granules of yellow pigment, while its deep part is prolonged as a delicate process which ramifies and communicates with similar processes from neighboring cells, so as to form a net-work in the mucous membrane. Lying between the deep processes of the supporting cells are a number of bipolar nerve cells, the **olfactory cells**, each consisting of a small amount of granular protoplasm with a large spherical nucleus, and possessing two processes—a superficial one which runs between the columnar epithelial cells, and projects on the surface of the mucous membrane as a fine, hair-like process, the **olfactory hair**; the other or deep process runs inward, is frequently beaded, and is continued as the axon of an olfactory nerve fibre. Beneath the epithelium, and extending through the thickness of the mucous membrane, is a layer of tubular, often branched, glands, the **glands of Bowman**, identical in structure with serous glands.

Vessels and Nerves.—The arteries of the nasal cavities are the anterior and posterior ethmoidal branches of the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; the sphenopalatine branch of the internal maxillary, which supplies the mucous membrane covering the conchæ, the meatuses and septum; the septal branch of the superior labial of the external maxillary; the infraorbital and alveolar branches of the internal maxillary, which supply the lining membrane of the maxillary sinus; and the pharyngeal branch of the same artery, distributed to the sphenoidal sinus. The ramifications of these vessels form a close plexiform net-work, beneath and in the substance of the mucous membrane.

FIG. 835.—Section of the olfactory mucous membrane. (Cadiat.) a. Epithelium. b. Glands of Bowman. c. Nerve bundles.

The veins form a close cavernous plexus beneath the mucous membrane. This plexus is especially well-marked over the lower part of the septum and over the middle and inferior conchæ. Some of the veins open into the sphenopalatine vein; others join the anterior facial vein; some accompany the ethmoidal arteries, and end in the ophthalmic veins; and, lastly, a few communicate with the veins on the orbital surface of the frontal lobe of the brain, through the foramina in the cribriform plate of the ethmoid bone; when the foramen caecum is patent it transmits a vein to the superior sagittal sinus.

The lymphatics have already been described (p. 776).

The nerves of ordinary sensation are: the nasociliary branch of the ophthalmic, filaments from the anterior alveolar branch of the maxillary, the nerve of the pterygoid canal, the nasopalatine, the anterior palatine, and nasal branches of the sphenopalatine ganglion.

The nasociliary branch of the ophthalmic distributes filaments to the forepart of the septum and lateral wall of the nasal cavity. Filaments from the anterior alveolar nerve supply the inferior meatus and inferior concha. The nerve of the pterygoid canal supplies the upper and back part of the septum, and superior concha; and the upper nasal branches from the sphenopalatine ganglion have a similar distribution. The nasopalatine nerve supplies the middle of the septum. The anterior palatine nerve supplies the lower nasal branches to the middle and inferior conchæ.

FIG. 836.—Nerves of septum of nose. Right side.

The olfactory, the special nerve of the sense of smell, is distributed to the olfactory region. Its fibres arise from the bipolar olfactory cells and are destitute of medullary sheaths. They unite in fasciculi which form a plexus beneath the mucous membrane and then ascend in grooves or canals in the ethmoid bone; they pass into the skull through the foramina in the cribriform plate of the ethmoid and enter the under surface of the olfactory bulb, in which they ramify and form synapses with the dendrites of the mitral cells (Fig. 772).

The Accessory Sinuses of the Nose (Sinus Paranasales) (Figs. 833, 834, 837).

The **accessory sinuses** or **air cells of the nose** are the **frontal**, **ethmoidal**, **sphenoidal**, and **maxillary**; they vary in size and form in different individuals, and are lined by mucous membrane directly continuous with that of the nasal cavities.

The **frontal sinuses** (*sinus frontales*), situated behind the superciliary arches, are rarely symmetrical, and the septum between them frequently deviates to one or other side of the middle line. Their average measurements are as follows: height, 3 cm.; breadth, 2.5 cm.; depth from before backward, 2.5 cm. Each opens into the anterior part of the corresponding middle meatus of the nose through the frontonasal duct which traverses the anterior part of the labyrinth of the ethmoid. Absent at birth, they are generally fairly well developed between the seventh and eighth years, but only reach their full size after puberty.

FIG. 837.—Coronal section of nasal cavities.

The **ethmoidal air cells** (*cellulae ethmoidales*) consist of numerous thin-walled cavities situated in the ethmoidal labyrinth and completed by the frontal, maxilla, lacrimal, sphenoidal, and palatine. They lie between the upper parts of the nasal cavities and the orbits, and are separated from these cavities by thin bony laminae. On either side they are arranged in three groups, **anterior**, **middle**, and **posterior**. The anterior and middle groups open into the middle meatus of the nose, the former by way of the infundibulum, the latter on or above the bulla ethmoidalis. The posterior cells open into the superior meatus under cover of the superior nasal concha; sometimes one or more opens into the sphenoidal sinus. The ethmoidal cells begin to develop during fetal life.

The **sphenoidal sinuses** (*sinus sphenoidales*) contained within the body of the sphenoid vary in size and shape; owing to the lateral displacement of the intervening septum they are rarely symmetrical. The following are their average measurements: vertical height, 2.2 cm.; transverse breadth, 2 cm.; antero-posterior

depth, 2.2 cm. When exceptionally large they may extend into the roots of the pterygoid processes or great wings, and may invade the basilar part of the occipital bone. Each sinus communicates with the sphenoethmoidal recess by means of an aperture in the upper part of its anterior wall. They are present as minute cavities at birth, but their main development takes place after puberty.

The **maxillary sinus** (*sinus maxillaris*; *antrum of Highmore*), the largest of the accessory sinuses of the nose, is a pyramidal cavity in the body of the maxilla. Its base is formed by the lateral wall of the nasal cavity, and its apex extends into the zygomatic process. Its roof or orbital wall is frequently ridged by the infra-orbital canal, while its floor is formed by the alveolar process and is usually on a level with the floor of the nose; projecting into the floor are several conical elevations corresponding with the roots of the first and second molar teeth, and in some cases the floor is perforated by one or more of these roots. The size of the sinus varies in different skulls, and even on the two sides of the same skull. The following measurements are those of an average-sized sinus: vertical height opposite the first molar tooth, 3.75 cm.; transverse breadth, 2.5 cm.; antero-posterior depth, 3 cm. In the antero-superior part of its base is an opening through which it communicates with the lower part of the hiatus semilunaris; a second orifice is frequently seen in, or immediately behind, the hiatus. The maxillary sinus appears as a shallow groove on the medial surface of the bone about the fourth month of fetal life, but does not reach its full size until after the second dentition.¹

Applied Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the external nose, an aperture only being present; or perfect development on one side, and suppression or malformation on the other. Deformities which have been acquired are much more common, such as flattening of the nose, the result of syphilitic necrosis; or imperfect development of the nasal bones in cases of congenital syphilis; or a lateral deviation of the nose may result from fracture.

The skin over the alæ and apex of the nose is thick and closely adherent to subjacent parts; inflammation of this part is therefore very painful, on account of the tension. It is richly supplied with blood, and, the circulation here being terminal, vascular engorgement is liable to occur especially in women at the menopause, and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follicles, and these, as the result of intemperance, are apt to become affected and the nose reddened, congested, and irregularly swollen. To this the term "grog blossom" is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues. Epithelioma and rodent ulcer may attack the nose, the latter being the more common of the two. Lupus and syphilitic ulceration frequently affect the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the alæ of the nose than in any other situation.

To examine the nasal cavities, the head should be thrown back and the nose drawn upward, the parts being dilated by some form of speculum. The choanæ can be explored by reflected light from the mouth, through which they can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumors in the nasopharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The septum of the nose may be displaced or may deviate from the middle line; this may be the result of an injury or of some congenital defect. Sometimes the deviation may be so great that the septum may come into contact with the lateral wall of the nasal cavity, and may even become adherent to it, thus producing complete obstruction. Perforation of the septum is not an uncommon affection, and may arise from several causes: syphilitic or tuberculous ulceration, blood tumor or abscess of the septum. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside without treatment; but in the more violent hemorrhages of later life it may be necessary to plug the choanæ. A ready method of regulating the bulk of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

¹ The various measurements of the accessory sinuses of the nose are based on those given by Aldren Turner in his *Accessory Sinuses of the Nose*.

Foreign bodies, such as buttons, are frequently inserted into the nostrils by children, and require some care in removal, as unskilled attempts only result in pushing the foreign body farther into the nasal cavity. Bodies which remain in the nose for any length of time set up ulceration of the mucous membrane, sometimes spreading to the bone, and a profuse purulent discharge results. A condition of unilateral nasal discharge in a child is always suggestive of the presence of a foreign body. The removal of such objects is best effected by giving the child an anesthetic, opening the mouth with a gag, and placing the left forefinger in the nasopharynx, so as to prevent the escape of the body into the air passages; the foreign body is then removed through the anterior naris by a suitable scoop or forceps manipulated by the right hand.

Enlargement of the mucous membrane covering the inferior or middle nasal conchæ is a very frequent accompaniment of chronic nasal catarrh. In old-standing cases the bones themselves may become enlarged, constituting the "hypertrophied turbinals" which are so often the cause of nasal obstruction. In the case of the inferior concha either the anterior or posterior end is usually more especially affected, giving rise to a reddened mass of tissue often confused with a nasal polypus; the appearances, however, are totally different, as the true nasal polypi appear as glistening grayish-white bodies between the conchæ. Hypertrophy of the conchæ can be temporarily reduced to a great extent by the local application of cocaine, and if the reduction by this means is to practically the normal condition, then treatment by application of the galvano-cautery will be sufficient; otherwise the enlarged portion of the bone or bones will require removal by a wire snare after the attachment to the lateral wall of the nasal cavity has been freed, by special nasal scissors, in the case of enlargement of the anterior end, and by the spokeshave when the posterior end is enlarged. It is highly inadvisable to remove more than is necessary, as too free removal results in a dry condition of the air passages, which conduces to a chronic dry pharyngitis and laryngitis.

Nasal polypi are of frequent occurrence; in the common gelatinous form they spring from the lateral wall of the nasal cavity and project down between the conchæ, giving rise to obstructed nasal respiration. They are always accompanied by purulent discharge, and are due in all instances to small areas of carious bone in the region of the *bulla ethmoidalis*, or about the ethmoidal or sphenoidal air cells. They appear as glistening grayish-white bodies swinging on a pedicle, and the larger ones can be encircled with a cold wire snare and thus removed; usually, however, after the extirpation of the larger ones has been carried out, numerous small polypi can be seen springing from the region of their bases, and cauterization of such affected areas must be thoroughly carried out if a recurrence of the trouble is to be avoided. In bad cases a free curetting of the ethmoidal air cells may be called for after removal of the middle concha. Fibrous polypi are also more rarely met with, and these are of the nature of new growths; they most frequently spring from the base of the skull behind the choanæ and form pedunculated tumors occupying the nasopharynx. Malignant polypi also occur, most commonly originating in the maxillary sinus and projecting through its medial wall into the nasal cavity; for such cases removal of the maxilla offers the only hope of cure.

Suppuration in the accessory nasal sinuses is of frequent occurrence, and in connection with this the situations at which the various sinuses normally communicate with the nasal cavities, are important; thus one finds they fall into two main groups: the anterior, opening into the middle meatus, and draining the maxillary sinus, the frontal sinus, and the anterior ethmoidal air cells; and the posterior group, opening into the superior meatus and sphenothmoidal recess, and draining the posterior ethmoidal and sphenoidal air cells. Suppuration in the anterior group is the more common, and the pus can be seen running down over the anterior end of the inferior concha, whereas in the case of the posterior group the pus does not come forward, but runs back into the nasopharynx over the posterior end of the middle concha. Again, it is of importance to notice that the middle meatus is of such a form that pus running down from the frontal sinus is directed by the groove beneath the *bulla ethmoidalis* into the ostium of the maxillary sinus, so that the latter sinus may, in some cases, act as a secondary reservoir for pus discharged from the frontal sinus. All the accessory sinuses can be and are infected from the nasal cavity, but it should be noted that in the case of the maxillary sinus, the infection is frequently conveyed in another way, and that is from the teeth. This sinus is the one most frequently the seat of chronic suppuration and it often requires drainage; this can be carried out by drilling a hole through the alveolus after removal of a tooth, preferably the first molar, or by gouging away the anterior surface of the maxilla, after having reflected the gum, or by removing bone from the lateral wall of the inferior meatus of the nose. Simple drainage, however, is not usually sufficient, and more extensive operations have often to be performed. Distension of the walls of the maxillary antrum occurs as the result of new-growth or cyst formation within its cavity. Thus the facial surface may be prominently bulged outward, upward extension may displace the eyeball outward, or the nasal cavity on that side may be occluded, giving rise to unilateral obstruction. In some cases the disease will perforate the palatine process of the maxilla and a soft spot will be found under the mucoperiosteum. If the disease be malignant in nature, nothing short of excision of the maxilla is of any avail (see p. 300).

THE ORGAN OF SIGHT (ORGANON VISUS; THE EYE).

The **bulb of the eye** (*bulbus oculi*; *eyeball*), or **organ of sight**, is contained in the cavity of the orbit, where it is protected from injury and moved by the ocular muscles. Associated with it are certain accessory structures, viz., the muscles, fasciæ, eyebrows, eyelids, conjunctiva, and lacrimal apparatus.

The bulb of the eye is imbedded in the fat of the orbit, but is separated from it by a thin membranous sac, the **fascia bulbi** (page 1037). It is composed of segments of two spheres of different sizes. The anterior segment is one of a small sphere; it is transparent, and forms about one-sixth of the bulb. It is more prominent than the posterior segment, which is one of a larger sphere, and is opaque, and forms about five-sixths of the bulb. The term **anterior pole** is applied to the central point of the anterior curvature of the bulb, and that of **posterior pole** to the central point of its posterior curvature; a line joining the two poles forms the **optic axis**. The axes of the two bulbs are nearly parallel, and therefore do not correspond to the axes of the orbits, which are directed forward and lateralward. The optic nerves follow the direction of the axes of the orbits, and are therefore not parallel; each enters its eyeball 3 mm. to the nasal side and a little below the level of the posterior pole. The bulb measures rather more in its transverse and antero-posterior diameters than in its vertical diameter, the former amounting to about 24 mm., the latter to about 23.5 mm.; in the female all three diameters are rather less than in the male; its antero-posterior diameter at birth is about 17.5 mm., and at puberty from 20 to 21 mm.

The bulb of the eye is composed of three **tunics**, and of three **refracting media**.

The Tunics of the Eye (Fig. 838).

From without inward the three tunics are: (1) A fibrous tunic, consisting of the **sclera** behind and the **cornea** in front; (2) a vascular pigmented tunic, comprising, from behind forward, the **choroid**, **ciliary body**, and **iris**; and (3) a nervous tunic, the **retina**.

The Fibrous Tunic (*tunica fibrosa oculi*).—The sclera and cornea (Fig. 838) form the fibrous tunic of the bulb of the eye; the sclera is opaque, and constitutes the posterior five-sixths of the tunic; the cornea is transparent, and forms the anterior sixth.

The Sclera.—The sclera has received its name from its extreme density and hardness; it is a firm, unyielding membrane, serving to maintain the form of the bulb. It is much thicker behind than in front; the thickness of its posterior part is 1 mm. Its **external surface** is of white color, and is in contact with the inner surface of the fascia of the bulb; it is quite smooth, except at the points where the Recti and Obliqui are inserted into it; its anterior part is covered by the conjunctival membrane. Its **inner surface** is brown in color and marked by grooves, in which the ciliary nerves and vessels are lodged; it is separated from the outer surface of the choroid by an extensive lymph space (**spatium perichorioideale**) which is traversed by an exceedingly fine cellular tissue, the **lamina suprachorioidea**. Behind it is pierced by the optic nerve, and is continuous through the fibrous sheath of this nerve with the dura mater. Where the optic nerve passes through the sclera, the latter forms a thin cribriform lamina, the **lamina cribrosa sclerae**; the minute orifices in this lamina serve for the transmission of the nervous filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve fibres. One of these openings, larger than the rest, occupies the centre of the lamina; it transmits the central artery and vein of the retina. Around the entrance of the optic nerve are numerous

small apertures for the transmission of the ciliary vessels and nerves, and about midway between this entrance and the sclerocorneal junction are four or five large apertures for the transmission of veins (*venae vorticosae*). In front, the sclera is directly continuous with the cornea, the line of union being termed the **sclerocorneal junction**. In the inner part of the sclera close to this junction is a circular canal, the *sinus venosus sclerae* (*canal of Schlemm*). In a meridional section of this region this sinus presents the appearance of a cleft, the outer wall of which consists of the firm tissue of the sclera, while its inner wall is formed by a triangular mass of trabecular tissue (Fig. 839); the apex of the mass is directed forward and is continuous with the posterior elastic lamina of the cornea. The sinus is lined by endothelium and communicates internally with the anterior chamber of the eye and externally with the anterior ciliary veins.

Nerve sheath

FIG. 838.—Horizontal section of the eyeball.

Structure.—The sclera is formed of white fibrous tissue intermixed with fine elastic fibres; flattened connective-tissue corpuscles, some of which are pigmented, are contained in cell spaces between the fibres. The fibres are aggregated into bundles, which are arranged chiefly in a longitudinal direction. Its *vessels* are not numerous, the capillaries being of small size, uniting at long and wide intervals. Its *nerves* are derived from the ciliary nerves, but their exact mode of ending is not known.

The Cornea.—The cornea is the projecting transparent part of the external tunic, and forms the anterior sixth of the surface of the bulb. It is almost circular in outline, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly and projects like a dome in front of the sclera. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, being more pronounced in youth than in advanced life. The cornea is dense and of uniform thickness throughout; its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in diameter. Immediately in front of the sclerocorneal junction the cornea bulges inward as a thickened

rim, and behind this there is a distinct furrow between the attachment of the iris and the sclerocorneal junction. This furrow has been named by Arthur Thomson¹ the **sulcus circularis corneae**; it is bounded externally by the trabecular tissue already described as forming the inner wall of the sinus venosus sclerae. Between this tissue and the anterior surface of the attached margin of the iris is an angular recess, named the **iridial angle** or **filtration angle** of the eye (Fig. 839). Immediately outside the filtration angle is a projecting rim of scleral tissue which appears in a meridional section as a small triangular area, termed the **scleral spur**. Its base is continuous with the inner surface of the sclera immediately to the outer side of the filtration angle and its apex is directed forward and inward. To the anterior sloping margin of this spur are attached the bundles of trabecular tissue just referred to; from its posterior margin the meridional fibres of the Ciliaris muscle arise.

Cornea

FIG. 839.—Enlarged general view of the iridial angle. (Arthur Thomson.)

Structure (Fig. 840).—The cornea consists from before backward of four layers, viz.: (1) the **corneal epithelium**, continuous with that of the conjunctiva; (2) the **substantia propria**; (3) the **posterior elastic lamina**; and (4) the **endothelium** of the anterior chamber.

The **corneal epithelium** (*epithelium corneae*; *anterior layer*) covers the front of the cornea and consists of several layers of cells. The cells of the deepest layer are columnar; then follow two or three layers of polyhedral cells, the majority of which are prickly cells similar to those found in the stratum mucosum of the cuticle. Lastly, there are three or four layers of squamous cells, with flattened nuclei.

The **substantia propria** is fibrous, tough, unyielding, and perfectly transparent. It is composed of about sixty flattened lamellæ, superimposed one on another. These lamellæ are made up of bundles of modified connective tissue, the fibres of which are directly continuous with those

¹ *Atlas of the Eye*, Clarendon Press, Oxford, 1912.

of the sclera. The fibres of each lamella are for the most part parallel with one another, but at right angles to those of adjacent lamellæ. Fibres, however, frequently pass from one lamella to the next.

The lamellæ are connected with each other by an interstitial cement substance, in which are spaces, the **corneal spaces**. These are stellate in shape and communicate with one another by numerous offsets. Each contains a cell, the **corneal corpuscle**, resembling in form the space in which it is lodged, but not entirely filling it.

FIG. 840.—Vertical section of human cornea from near the margin. (Waldeyer) Magnified. 1 Epithelium. 2. Anterior elastic lamina. 3 substantia propria. 4 Posterior elastic lamina. 5. Endothelium of the anterior chamber. a. Oblique fibres in the anterior layer of the substantia propria. b. Lamellæ the fibres of which are cut across, producing a dotted appearance. c. Corneal corpuscles appearing fusiform in section. d. Lamellæ the fibres of which are cut longitudinally. e. Transition to the sclera, with more distinct fibrillation, and surmounted by a thicker epithelium. f. Small bloodvessels cut across near the margin of the cornea.

The layer immediately beneath the corneal epithelium presents certain characteristics which have led some anatomists to regard it as a distinct membrane, and it has been named the **anterior elastic lamina** (*lamina elastica anterior*; *anterior limiting layer*; *Bowman's membrane*). It differs, however, from the posterior elastic lamina, in presenting evidence of fibrillar structure, and in not having the same tendency to curl inward, or to undergo fracture, when detached from the other layers of the cornea. It consists of extremely closely interwoven fibrils, similar to those found in the substantia propria, but contains no corneal corpuscles. It may be regarded as a condensed part of the substantia propria.

The **posterior elastic lamina** (*lamina elastica posterior*; *membrane of Deacemet*; *membrane of Demours*) covers the posterior surface of the substantia propria, and is an elastic, transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water,

alcohol, or acids. When stripped from the substantia propria it curls up, or rolls upon itself with the attached surface innermost.

At the margin of the cornea the posterior elastic lamina breaks up into fibres which form the trabecular tissue already described (p. 1008); the spaces between the trabeculae are termed the **spaces of the angle of the iris** (*spaces of Fontana*); they communicate with the sinus venosus sclerae and with the anterior chamber at the filtration angle. Some of the fibres of this trabecular tissue are continued into the substance of the iris, forming the **pectinate ligament of the iris**; while others are connected with the forepart of the sclera and choroid.

The **endothelium of the anterior chamber** (*endothelium camerae anterioris*; *posterior layer*; *corneal endothelium*) covers the posterior surface of the elastic lamina, is reflected on to the front of the iris, and also lines the spaces of the angle of the iris; it consists of a single stratum of polygonal, flattened, nucleated cells.

Vessels and Nerves.—The cornea is a non-vascular structure, the capillary vessels ending in loops at its circumference. Lymphatic vessels have not yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these channels are lined by an endothelium. The **nerves** are numerous and are derived from the ciliary nerves. Around the periphery of the cornea they form an **annular plexus**, from which fibres enter the substantia propria. They lose their medullary sheaths and ramify throughout its substance in a delicate net-work, and their terminal filaments form a firm and closer plexus on the surface of the cornea proper, beneath the epithelium. This is termed the **subepithelial plexus**, and from it fibrils are given off which ramify between the epithelial cells, forming an **intraepithelial plexus**.

Dissection.—In order to separate the sclera and cornea, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water and held between the finger and thumb. The sclera is then carefully incised, in the equator of the globe, until the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclera divided around its entire circumference, and removed in separate portions. The front segment being then drawn forward, the handle of the scalpel should be pressed gently against it at its connection with the iris, and, these being separated, a quantity of perfectly transparent fluid will escape; this is the aqueous humor. In the course of the dissection the ciliary nerves (Fig. 841) may be seen lying in the loose cellular tissue between the choroid and sclera or continued in delicate grooves on the inner surface of the latter membrane.

The Vascular Tunic (*tunica vasculosa oculi*) (Figs. 841, 842, 843).—The vascular tunic of the eye is formed from behind forward by the choroid, the ciliary body, and the iris.

The choroid invests the posterior five-sixths of the bulb, and extends as far forward as the ora serrata of the retina. The ciliary body connects the choroid to the circumference of the iris. The iris is a circular diaphragm behind the cornea, and presents near its centre a rounded aperture, the **pupil**.

FIG. 841.—The choroid and iris. (Enlarged.)

The Choroid (*chorioidea*).—The choroid is a thin, highly vascular membrane, of a dark brown or chocolate color, investing the posterior five-sixths of the globe; it is pierced behind by the optic nerve, and in this situation is firmly adherent to the sclera. It is thicker behind than in front. Its outer surface is loosely connected by the lamina suprachorioidea with the sclera; its inner surface is attached to the pigmented layer of the retina.

Structure.—The choroid consists mainly of a dense capillary plexus, and of small arteries and veins carrying blood to and returning it from this plexus. On its external surface is a thin

membrane, the *lamina suprachorioides*, composed of delicate non-vascular lamellæ—each lamella consisting of a net-work of fine elastic fibres among which are branched pigment cells. The spaces between the lamellæ are lined by endothelium, and open freely into the perichoroidal lymph space, which, in its turn, communicates with the periscleral space by the perforations in the sclera through which the vessels and nerves are transmitted.

Ciliary artery

Short cili

for ciliary artery

FIG. 842.—The arteries of the choroid and iris. The greater part of the sclera has been removed. (Enlarged.)

Internal to this lamina is the *choroid proper*, consisting of two layers: an outer, composed of small arteries and veins, with pigment cells interspersed between them; and an inner, consisting of a capillary plexus. The *outer layer* (*lamina vasculosa*) consists, in part, of the larger branches of the short ciliary arteries which run forward between the veins, before they bend inward to end in the capillaries, but is formed principally of veins, named, from their arrangement, the *venae*

vorticossæ. They converge to four or five equidistant trunks, which pierce the sclera about midway between the sclero-corneal junction and the entrance of the optic nerve. Interspersed between the vessels are dark star-shaped pigment cells, the processes of which, communicating with those of neighboring cells, form a delicate net-work or stroma, which toward the inner surface of the choroid loses its pigmentary character. The *inner layer* (*lamina choriocapillaris*) consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels; the net-work is closer and finer in the posterior than in the anterior part of the choroid. About 1.25 cm. behind the cornea its meshes become larger, and are continuous with those of the ciliary processes. These two laminae are connected by a *stratum intermedium* consisting of fine elastic fibres. On the inner surface of the lamina choriocapillaris is a very thin, structureless, or faintly

FIG. 843.—The veins of the choroid (Enlarged.)

fibrous membrane, called the *lamina basalis*; it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

Tapetum. This name is applied to the outer and posterior part of the choroid, which in many animals presents an iridescent appearance.

Dissection.—The ciliary body should now be examined. It may be exposed, either by detaching the iris from its connection with the Ciliaris muscle, or by making a transverse section of the globe, and examining it from behind.

The Ciliary Body (*corpus ciliare*).—The ciliary body comprises the **orbiculus ciliaris**, the **ciliary processes**, and the **Ciliaris muscle**.

The **orbiculus ciliaris** is a zone of about 4 mm. in width, directly continuous with the anterior part of the choroid; it presents numerous ridges arranged in a radial manner (Fig. 844).

FIG. 844.—Interior of anterior half of bulb of eye.

The **ciliary processes** (*processus ciliares*) are formed by the inward folding of the various layers of the choroid, *i. e.*, the choroid proper and the lamina basalis, and are received between corresponding foldings of the suspensory ligament of the lens. They are arranged in a circle, and form a sort of frill behind the iris, around the margin of the lens (Fig. 844). They vary from sixty to eighty in number, lie side by side, and may be divided into large and small; the former are about 2.5 mm. in length, and the latter, consisting of about one-third of the entire number, are situated in spaces between them, but without regular arrangement. They are attached by their periphery to three or four of the ridges of the orbiculus ciliaris, and are continuous with the layers of the choroid: their opposite extremities are free and rounded, and are directed toward the posterior chamber of the eyeball and circumference of the lens. In front, they are continuous with the periphery of the iris. Their posterior surfaces are connected with the suspensory ligament of the lens.

Structure.—The ciliary processes (Figs. 845, 846) are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. Their posterior surfaces are covered by a bilaminar layer of black pigment cells, which is continued forward from the retina, and is named the **pars ciliaris retinae**. In the stroma of the ciliary processes there are also stellate pigment cells, but these are not so numerous as in the choroid itself.

The **Ciliaris muscle** (*m. ciliaris*; *Bowman's muscle*) consists of unstriated fibres: it forms a grayish, semitransparent, circular band, about 3 mm. broad, on the outer surface of the forepart of the choroid. It is thickest in front, and consists of two sets of fibres, **meridional** and **circular**. The meridional fibres, much the more numerous, arise from the posterior margin of the scleral spur (page 1019); they run backward, and are attached to the ciliary processes and orbiculus ciliaris. One bundle, according to Waldeyer, is inserted into the sclera. The circular fibres are internal to the meridional ones, and in a meridional section appear as a triangular zone

behind the filtration angle and close to the circumference of the iris. They are well-developed in hypermetropic, but are rudimentary or absent in myopic eyes. The Ciliaris muscle is the chief agent in accommodation, *i. e.*, in adjusting the eye to the vision of near objects. When it contracts it draws forward the ciliary processes, relaxes the suspensory ligament of the lens, and thus allows the lens to become more convex.

The Iris.—The iris has received its name from its various colors in different individuals. It is a thin, circular, contractile disk, suspended in the aqueous humor between the cornea and lens, and perforated a little to the nasal side of its centre by a circular aperture, the **pupil**. By its periphery it is continuous with the ciliary body, and is also connected with the posterior elastic lamina of the cornea by means of the pectinate ligament; its surfaces are flattened, and look forward and backward, the ante-

rior toward the cornea, the posterior toward the ciliary processes and lens. The iris divides the space between the lens and the cornea into an anterior and a posterior chamber. The **anterior chamber** of the eye is bounded in front by the posterior surface of the cornea; behind by the front of the iris and the central part of the lens. The **posterior chamber** is a narrow chink behind the peripheral part of the iris, and in front of the suspensory ligament of the lens and the ciliary processes. In the adult the two chambers communicate through the pupil, but in the fetus up to the seventh month they are separated by the *membrana pupillaris*.

Structure.—The iris is composed of the following structures:

1. In front is a layer of flattened endothelial cells placed on a delicate hyaline basement membrane. This layer is continuous with the endothelium covering the posterior elastic lamina of the cornea, and in individuals with dark-colored irides the cells contain pigment granules.

2. The **stroma** (*stroma iridis*) of the iris consists of fibres and cells. The former are made up of delicate bundles of fibrous tissue; a few fibres at the circumference of the iris have a circular direction; but the majority radiate toward the pupil, forming by their interlacement, delicate meshes, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. In dark eyes many of them contain pigment granules, but in blue eyes and the eyes of albinos they are unpigmented.

3. The **muscular fibres** are involuntary, and consist of circular and radiating fibres. The **circular fibres** form the Sphincter pupillae; they are arranged in a narrow band about 1 mm. in width which surrounds the margin of the pupil toward the posterior surface of the iris; those near the free margin are closely aggregated; those near the periphery of the band are somewhat separated and form incomplete circles. The **radiating fibres** form the Dilator pupillae; they converge from the circumference toward the centre, and blend with the circular fibres near the margin of the pupil.

4. The posterior surface of the iris is of a deep purple tint, being covered by two layers of pigmented columnar epithelium, continuous at the periphery of the iris with the pars ciliaris retinae. This pigmented epithelium is named the **pars iridica retinae**, or, from the resemblance of its color to that of a ripe grape, the **uvea**.

The color of the iris is produced by the reflection of light from dark pigment cells underlying a translucent tissue, and is therefore determined by the amount of the pigment and its distribution throughout the texture of the iris. The number and the situation of the pigment cells differ in different irides. In the albino pigment is absent; in the various shades of blue eyes the pigment cells are confined to the posterior surface of the iris, whereas in gray, brown, and black eyes pigment is found also in the cells of the stroma and in those of the endothelium on the front of the iris.

Circulus major; 6, its branches radiating through the iris. 7. Circulus minor around the pupil.

Vessels and Nerves.—The **arteries of the iris** are derived from the long and anterior ciliary arteries, and from the vessels of the ciliary processes (see p. 650). Each of the two long ciliary arteries, having reached the attached margin of the iris, divides into an upper and lower branch; these anastomose with corresponding branches from the opposite side and thus encircle the iris; into this vascular circle (*circulus arteriosus major*) the anterior ciliary arteries pour their blood, and from it vessels converge to the free margin of the iris, and there communicate and form a second circle (*circulus arteriosus minor*) (Figs. 846 and 847).

The **nerves of the choroid and iris** are the long and short ciliary; the former being branches of the nasociliary nerve, the latter of the ciliary ganglion. They pierce the sclera around the entrance of the optic nerve, run forward in the perichoroidal space, and supply the bloodvessels of the choroid. After reaching the iris they form a plexus around its attached margin; from this are derived non-medullated fibres which end in the Sphincter and Dilatator pupillae; their exact mode of termination has not been ascertained. Other fibres from the plexus end in a net-work on the anterior surface of the iris. The fibres derived through the motor root of the ciliary ganglion from the oculomotor nerve, supply the Sphincter, while those derived from the sympathetic supply the Dilatator.

Membrana Pupillaris.—In the fetus, the pupil is closed by a delicate vascular membrane, the **membrana pupillaris**, which divides the space in which the iris is suspended into two distinct chambers. The vessels of this membrane are partly derived from those of the margin of the iris and partly from those of the capsule of the lens; they have a looped arrangement, and converge toward each other without anastomosing. About the sixth month the membrane begins to disappear by absorption from the centre toward the circumference, and at birth only a few fragments are present; in exceptional cases it persists.

Optic

Macula

Retina

FIG. 848.—Interior of posterior half of bulb of left eye. The veins are darker in appearance than the arteries.

The Retina (*tunica interna*).—The retina is a delicate nervous membrane, upon which the images of external objects are received. Its outer surface is in contact with the choroid; its inner with the hyaloid membrane of the vitreous body. Behind, it is continuous with the optic nerve; it gradually diminishes in thickness from behind forward, and extends nearly as far as the ciliary body, where it appears to end in a jagged margin, the **ora serrata**. Here the nervous tissues of the retina end, but a thin prolongation of the membrane extends forward over the back of the ciliary processes and iris, forming the **pars ciliaris retinae** and **pars iridica retinae** already referred to. This forward prolongation consists of the pigmentary layer of the retina together with a stratum of columnar epithelium. The retina is soft, semitransparent, and of a purple tint in the fresh state, owing to the presence of a coloring material named **rhodopsin** or **visual purple**; but it soon becomes clouded, opaque, and bleached when exposed to sunlight. Exactly in the centre of the posterior part of the retina, corresponding to the axis of the eye, and at a point in which the sense of vision is most perfect, is an oval yellowish area, the **macula lutea**; in the macula is a central depression, the **fovea centralis** (Fig. 848). At the fovea centralis the retina is exceedingly thin, and the dark color of the choroid is

distinctly seen through it. About 3 mm. to the nasal side of the macula lutea is the entrance of the optic nerve (*optic disk*), the circumference of which is slightly raised to form an eminence (*colliculus nervi optici*) (Fig. 849); the *arteria centralis retinae* pierces the centre of the disk. This is the only part of the surface of the retina which is insensitive to light, and it is termed the **blind spot**.

FIG. 849.—The terminal portion of the optic nerve and its entrance into the eyeball, in horizontal section. (Toldt.)

Structure (Figs. 850, 851).—The retina consists of an outer pigmented layer and an inner nervous stratum or retina proper.

The **pigmented layer** consists of a single stratum of cells. When viewed from the outer surface these cells are smooth and hexagonal in shape; when seen in section each cell consists of an outer non-pigmented part containing a large oval nucleus and an inner pigmented portion which extends as a series of straight thread-like processes between the rods, this being especially the case when the eye is exposed to light. In the eyes of albinos the cells of this layer are destitute of pigment.

Retina Proper.—The nervous structures of the retina proper are supported by a series of non-nervous or sustentacular fibres, and, when examined microscopically by means of sections made perpendicularly to the surface of the retina, are found to consist of seven layers, named from within outward as follows:

1. Stratum opticum.
2. Ganglionic layer.
3. Inner plexiform layer.
4. Inner nuclear layer, or layer of inner granules.
5. Outer plexiform layer.
6. Outer nuclear layer, or layer of outer granules.
7. Layer of rods and cones.

1. The **stratum opticum** or **layer of nerve fibres** is formed by the expansion of the fibres of the optic nerve; it is thickest near the *porus opticus*, gradually diminishing toward the *ora serrata*. As the nerve fibres pass through the *lamina cribrosa sclerae*, they lose their medullary sheaths and are continued onward through the choroid and retina as simple axis-cylinders. When they reach the internal surface of the retina they radiate from their point of entrance over this surface grouped in bundles, and in many places arranged in plexuses. Most of the fibres are centripetal, and are the direct continuations of the axis-cylinder processes of the cells of the ganglionic layer, but a few of them are centrifugal and ramify in the inner plexiform and inner nuclear layers, where they end in enlarged extremities.

FIG. 850.—Section of retina. (Magnified.) a. *Membrana limitans interna*. b. *Stratum opticum*. c. *Ganglionic layer*. d. *Inner plexiform layer*. e. *Inner nuclear layer*. f. *Outer plexiform layer*. g. *Outer nuclear layer*. h. *Membrana limitans externa*. i. *Layer of rods and cones*. k. *Pigmented layer*. m. *Fibres of Müller*.

2. The **ganglionic layer** consists of a single layer of large ganglion cells, except in the macula lutea, where there are several strata. The cells are somewhat flask-shaped; the rounded internal surface of each resting on the stratum opticum, and sending off an axon which is prolonged into it. From the opposite end numerous dendrites extend into the inner plexiform layer, where they branch and form flattened arborizations at different levels. The ganglion cells vary much in size, and the dendrites of the smaller ones as a rule arborize in the inner plexiform layer as soon as they enter it; while those of the larger cells ramify close to the inner nuclear layer.

3. The **inner plexiform layer** is made up of a dense reticulum of minute fibrils formed by the interlacement of the dendrites of the ganglion cells with those of the cells of the inner nuclear layer; within this reticulum a few branched spongioblasts are sometimes imbedded.

4. The **inner nuclear layer** or **layer of inner granules** is made up of a number of closely packed cells, of which there are three varieties, viz.: bipolar cells, horizontal cells, and amacrine cells.

FIG. 851.—Plan of retinal neurons. (After Cajal)

The **bipolar cells**, by far the most numerous, are round or oval in shape, and each is prolonged into an inner and an outer process. They are divisible into rod bipolars and cone bipolars. The inner processes of the **rod bipolars** run through the inner plexiform layer and arborize around the bodies of the cells of the ganglionic layer; their outer processes end in the outer plexiform layer in tufts of fibrils around the button-like ends of the inner processes of the rod granules. The inner processes of the **cone bipolars** ramify in the inner plexiform layer in contact with the dendrites of the ganglionic cells.

The **horizontal cells** lie in the outer part of the inner nuclear layer and possess somewhat flattened cell bodies. Their dendrites divide into numerous branches in the outer plexiform layer, while their axons run horizontally for some distance and finally ramify in the same layer.

The **amacrine cells** are placed in the inner part of the inner nuclear layer, and are so named because they have not yet been shown to possess axis-cylinder processes. Their dendrites undergo extensive ramification in the inner plexiform layer.

5. The **outer plexiform layer** is much thinner than the inner; but, like it, consists of a dense net-work of minute fibrils derived from the processes of the horizontal cells of the preceding layer, and the outer processes of the rod and cone bipolar granules, which ramify in it, forming arborizations around the enlarged ends of the rod fibres and with the branched foot plates of the cone fibres.

6. The **outer nuclear layer** or **layer of outer granules**, like the inner nuclear layer, contains several strata of oval nuclear bodies; they are of two kinds, viz.: rod and cone granules, so

named on account of their being respectively connected with the rods and cones of the next layer. The **rod granules** are much the more numerous, and are placed at different levels throughout the layer. Their nuclei present a peculiar cross-striped appearance, and prolonged from either extremity of each cell is a fine process; the outer process is continuous with a single rod of the layer of rods and cones; the inner ends in the outer plexiform layer in an enlarged extremity, and is imbedded in the tuft into which the outer processes of the rod bipolar cells break up. In its course it presents numerous varicosities. The **cone granules**, fewer in number than the rod granules, are placed close to the *membrana limitans externa*, through which they are continuous with the cones of the layer of rods and cones. They do not present any cross-striation, but contain a pyriform nucleus, which almost completely fills the cell. From the inner extremity of the granule a thick process passes into the outer plexiform layer, and there expands into a pyramidal enlargement or foot plate, from which are given off numerous fine fibrils, that come in contact with the outer processes of the cone bipolars.

7. **The Layer of Rods and Cones** (*Jacob's membrane*).—The elements composing this layer are of two kinds, **rods** and **cones**, the former being much more numerous than the latter except in the macula lutea. The **rods** are cylindrical, of nearly uniform thickness, and are arranged perpendicularly to the surface. Each rod consists of two segments, an outer and inner, of about equal lengths. The segments differ from each other as regards refraction and in their behavior toward coloring reagents; the inner segment is stained by carmine, iodine, etc.; the outer segment is not stained by these reagents, but is colored yellowish brown by osmic acid. The outer segment is marked by transverse striæ, and tends to break up into a number of thin disks superimposed on one another; it also exhibits faint longitudinal markings. The deeper part of the inner segment is indistinctly granular; its more superficial part presents a longitudinal striation, being composed of fine, bright, highly refracting fibrils. The visual purple or rhodopsin is found only in the outer segments.

The **cones** are conical or flask-shaped, their broad ends resting upon the *membrana limitans externa*, the narrow-pointed extremity being turned to the choroid. Like the rods, each is made up of two segments, outer and inner; the outer segment is a short conical process, which, like the outer segment of the rod, exhibits transverse striæ. The inner segment resembles the inner segment of the rods in structure, presenting a superficial striated and deep granular part, but differs from it in size and shape, being bulged out laterally and flask-shaped. The chemical and optical characters of the two portions are identical with those of the rods.

Supporting Frame-work of the Retina.—The nervous layers of the retina are connected together by a supporting frame-work, formed by the **sustentacular fibres of Müller**; these fibres pass through all the nervous layers, except that of the rods and cones. Each begins on the inner surface of the retina by an expanded, often forked base, which sometimes contains a spheroidal body staining deeply with hematoxylin, the edges of the bases of adjoining fibres being united to form the *membrana limitans interna*. As the fibres pass through the nerve fibre and ganglionic layers they give off a few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the bipolar cells, while in the outer nuclear layer they form a network around the rod- and cone-fibrils, and unite to form the **external limiting membrane** at the bases of the rods and cones. At the level of the inner nuclear layer each sustentacular fibre contains a clear oval nucleus.

Macula Lutea and Fovea Centralis.—In the macula lutea the nerve fibres are wanting as a continuous layer, the ganglionic layer consists of several strata of cells, there are no rods, but only cones, which are longer and narrower than in other parts, and in the outer nuclear layer there are only cone-granules, the processes of which are very long and arranged in curved lines. In the fovea centralis the only parts present are (1) the cones; (2) the outer nuclear layer, the cone-fibres of which are almost horizontal in direction; (3) an exceedingly thin inner plexiform layer. The pigmented layer is thicker and its pigment more pronounced than elsewhere. The color of the macula seems to imbue all the layers except that of the rods and cones; it is of a rich yellow, deepest toward the centre of the macula, and does not appear to be due to pigment cells, but simply to a staining of the constituent parts.

At the **ora serrata** the nervous layers of the retina end abruptly, and the retina is continued onward as a single layer of columnar cells covered by the pigmented layer. This double layer is known as the **pars ciliaris retinae**, and can be traced forward from the ciliary processes on to the back of the iris, where it is termed the **pars iridica retinae** or **uvea**.

The **arteria centralis retinae** (Fig. 848) and its accompanying vein pierce the optic nerve, and enter the bulb of the eye through the porus opticus. The artery immediately bifurcates into an upper and a lower branch, and each of these again divides into a medial or nasal and a lateral or temporal branch, which at first run between the hyaloid membrane and the nervous layer; but they soon enter the latter, and pass forward, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. The macula receives two small branches (superior and inferior macular arteries) from the temporal branches and small twigs directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no bloodvessels. The branches of the *arteria centralis*

retinae do not anastomose with each other—in other words they are terminal arteries. In the fetus, a small vessel, the *arteria hyaloidea*, passes forward as a continuation of the *arteria centralis retinae* through the vitreous humor to the posterior surface of the capsule of the lens.

The Refracting Media.

The refracting media are three, viz.:

Aqueous humor.

Vitreous body.

Crystalline lens.

The Aqueous Humor (*humor aqueus*).—The aqueous humor fills the anterior and posterior chambers of the eyeball. It is small in quantity, has an alkaline reaction, and consists mainly of water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

The Vitreous Body (*corpus vitreum*).—The vitreous body forms about four-fifths of the bulb of the eye. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, the *hyaloid fossa*, for the reception of the lens. It is transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the *hyaloid membrane*. It has been supposed, by Hannover, that from its surface numerous thin lamellæ are prolonged inward in a radiating manner, forming spaces in which the fluid is contained. In the adult, these lamellæ cannot be detected even after careful microscopic examination in the fresh state, but in preparations hardened in weak chromic acid it is possible to make out a distinct lamellation at the periphery of the body. In the centre of the vitreous body, running from the entrance of the optic nerve to the posterior surface of the lens, is a canal, the *hyaloid canal*, filled with lymph and lined by a prolongation of the hyaloid membrane. This canal, in the embryonic vitreous body, conveyed the *arteria hyaloidea* from the central artery of the retina to the back of the lens. The fluid from the vitreous body is nearly pure water; it contains, however, some salts, and a little albumin.

The *hyaloid membrane* envelopes the vitreous body. The portion in front of the *ora serrata* is thickened by the accession of radial fibres and is termed the *zonula ciliaris* (*zonule of Zinn*). Here it presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they adhere, as is shown by the fact that when they are removed some of their pigment remains attached to the zonula. The *zonula ciliaris* splits into two layers, one of which is thin and lines the hyaloid fossa; the other is named the **suspensory ligament of the lens**: it is thicker, and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the meridional fibres of the Ciliaris muscle, so that the lens is allowed to become more convex. Behind the suspensory ligament there is a sacculated canal, the *spatia zonularis* (*canal of Petit*), which encircles the equator of the lens; it can be easily inflated through a fine blowpipe inserted under the suspensory ligament.

No bloodvessels penetrate the vitreous body, so that its nutrition must be carried on by vessels of the retina and ciliary processes, situated upon its exterior.

The Crystalline Lens (*lens crystallina*).—The crystalline lens, enclosed in its capsule, is situated immediately behind the iris, in front of the vitreous body, and encircled by the ciliary processes, which slightly overlap its margin.

The **capsule of the lens** (*capsula lentis*) is a transparent, structureless membrane which closely surrounds the lens, and is thicker in front than behind. It is brittle but highly elastic, and when ruptured the edges roll up with the outer surface innermost. It rests, behind, in the hyaloid fossa in the forepart of the vitreous body; in front, it is in contact with the free border of the iris, but recedes from it

at the circumference, thus forming the posterior chamber of the eye; it is retained in its position chiefly by the suspensory ligament of the lens, already described.

The **lens** is a transparent, biconvex body, the convexity of its anterior being less than that of its posterior surface. The central points of these surfaces are termed respectively the **anterior** and **posterior poles**; a line connecting the poles constitutes the **axis** of the lens, while the marginal circumference is termed the **equator**.

Structure.—The lens is made up of soft cortical substance and a firm, central part, the **nucleus** (Fig. 852). Faint lines (*radii lentis*) radiate from the poles to the equator. In the adult there may be six or more of these lines, but in the fetus they are only three in number and diverge from each other at angles of 120° (Fig. 853); on the anterior surface one line ascends vertically and the other two diverge downward; on the posterior surface one ray descends vertically and the other two diverge upward. They correspond with the free edges of an equal number of septa composed of an amorphous substance, which dip into the substance of the lens. When the lens has been hardened it is seen to consist of a series of concentrically arranged laminae, each of which is interrupted at the septa referred to. Each lamina is built up of a number of hexagonal, ribbon-like lens fibres, the edges of which are more or less serrated—the serrations fitting between those of neighboring fibres, while the ends of the fibres come into apposition at the septa. The fibres run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibres pass from pole to pole; they are arranged in such a way that those which begin near the pole on one surface of the lens end near the peripheral extremity of the plane on the other, and *vice versa*. The fibres of the outer layers of the lens are nucleated, and together form a nuclear layer, most distinct toward the equator. The anterior surface of the lens is covered by a layer of transparent, columnar, nucleated epithelium. At the equator the cells become elongated, and their gradual transition into lens fibres can be traced (Fig. 855).

FIG. 852.—The crystalline lens, hardened and divided. (Enlarged.)

FIG. 853.—Diagram to show the direction and arrangement of the radiating lines on the front and back of the fetal lens. A. From the front. B. From the back.

In the **fetus**, the lens is nearly spherical, and has a slightly reddish tint; it is soft and breaks down readily on the slightest pressure. A small branch from the *arteria centralis retinae* runs forward, as already mentioned, through the vitreous body to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network, which covers the posterior surface of the capsule, and they are continuous around the margin of the capsule with the vessels of the pupillary membrane, and with those of the iris. In the **adult**, the lens is colorless, transparent, firm in texture, and devoid of vessels. In **old age** it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increased in density (Fig. 854).

Vessels and Nerves.—The **arteries** of the bulb of the eye are the long, short, and anterior ciliary arteries, and the *arteria centralis retinae*. They have already been described (see p. 650).

The **ciliary veins** are seen on the outer surface of the choroid, and are named, from their arrangement, the *venae vorticosae*; they converge to four or five equidistant trunks which pierce the sclera midway between the sclerocorneal junction and the *porus opticus*. Another set of veins accompanies the anterior ciliary arteries. All of these veins open into the ophthalmic veins.

The **ciliary nerves** are derived from the nasociliary nerve and from the ciliary ganglion.

Applied Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) an external epithelial layer, developed from the ectoderm, and continuous with the epithelial covering of the rest of the body, so that its lesions resemble those of the epidermis; (2) the cornea proper, derived from the mesoderm, and associated in its diseases with

the fibrovascular structures of the body; and (3) the posterior elastic lamina with its endothelium, also derived from the mesoderm and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the serous and synovial membranes of the body.

The cornea contains no bloodvessels except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on its anterior surface. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of the angle of the iris. This lack of a direct blood supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In cases of *granular lids*, there is a peculiar affection of the cornea, called *pannus*, in which the anterior layers of the cornea become vascularized, and a rich net-work of bloodvessels may be seen upon it; and in interstitial keratitis new vessels extend into the cornea, giving it a pinkish hue to which the term "salmon patch" is applied. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the choroid and sclera, and the cornea becomes anesthetic.

The sclera has very few bloodvessels and nerves. As the bloodvessels approach the corneal margin the arrangement is peculiar. Some branches pass through the sclera to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forward to the cornea, forming its marginal plexus. In inflammation of the sclera and episcleral tissue these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the *zone of ciliary injection*. In inflammation of the iris and ciliary body this zone is present, since the sclera speedily becomes involved when these structures are inflamed. But in inflammation of the cornea the sclera is seldom much affected, though the two are structurally continuous. This would appear to be due to the fact, that the nutrition of the cornea is derived from a different source than that of the sclera. The sclera may be ruptured without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hemorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclera and has been found under the conjunctiva. Wounds of the sclera are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia.

FIG. 854.—Profile views of the lens at different periods of life.
1. In the fetus. 2. In adult life. 3. In old age.

FIG. 855.—Section through the margin of the lens, showing the transition of the epithelium into the lens fibres. (Babuchin.)

One of the functions of the choroid is to provide nutrition for the retina, and to convey vessels and nerves to the ciliary body and iris. Inflammation of the choroid is therefore followed by grave disturbances in the nutrition of the retina, and is attended with early interference with

vision. Its diseases bear a considerable analogy to those which affect the skin, and it is one of the places from which melanotic sarcomata may grow. These tumors contain a large amount of pigment in their cells, and originate only in those parts where pigment is naturally present.

The iris may be absent, either in part or altogether as a congenital condition, and in some instances the pupillary membrane may remain persistent, though it is rarely complete. Again, the iris may be the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, clearly due in a great number of cases to an arrest in development. In these cases the cleft is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the porus opticus. In some rarer cases the gap is found in other parts of the iris, and is not then associated with any deficiency of the choroid. Wounds of the iris, especially if complicated with injury to the ciliary body, may be followed by serious consequences. If septic matter is introduced, and a suppurative inflammation is set up, complete loss of vision may result; and, what is perhaps of greater consequence, similar inflammatory changes may be set up in the sound eye, from spreading of the infective process through the connective tissue surrounding the optic nerve to the chiasma, and thence along the opposite nerve to the sound eye. The iris is abundantly supplied with bloodvessels and nerves, and is very prone to become inflamed, and when inflamed, in consequence of the intimate relationship which exists between the vessels of the iris and choroid, this latter tunic is very liable to participate in the inflammation. The iris is covered with epithelium, and partakes of the character of a serous membrane, and, like these structures, is apt to pour out a plastic exudation, when inflamed, and contract adhesions, either to the cornea in front (*synechia anterior*), or to the capsule of the lens behind (*synechia posterior*). In iritis the lens may become involved, and the condition known as *secondary cataract* may be set up. Tumors occasionally commence in the iris; of these, cysts, which are usually congenital, and sarcomatous tumors, are the most common. Gummata are not infrequently found in this situation. In some forms of injury of the eyeball, as from the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be detached from the Ciliaris muscle.

The retina, with the exception of its pigment layer and its vessels, is perfectly transparent when examined by the ophthalmoscope, so that its diseased conditions are recognized by its loss of transparency. In retinitis, for instance, there is more or less dense and extensive opacity of its structure, and not infrequently extravasations of blood into its substance. Hemorrhages may also take place into the retina, from rupture of a bloodvessel without inflammation. The retina may become displaced from effusion of serum between it and the choroid, or by blows on the eyeball, or may occur without apparent cause in progressive myopia, and in this case the ophthalmoscope shows an opaque, tremulous cloud. Glioma, a form of sarcoma, is occasionally met with in connection with the retina.

The lens has no bloodvessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, and displacements, are among its congenital defects. Opacities may occur from injury, senile changes, or malnutrition. These opacities give rise to *cataract*, of which the senile variety, is the most common. They vary as to the part of the lens in which the opacity commences and are classified accordingly, as nuclear, cortical, lamellar, anterior, and posterior polar. Senile changes may take place in the lens, impairing its elasticity and rendering it harder than in youth, so that it loses its power of altering its curvature to suit the requirements of near vision. This condition is known as *presbyopia*. And, finally, the lens may be dislocated or displaced by blows upon the eyeball; and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the "filtration angle," and the other as the "dangerous area." The *filtration angle* is the circumcorneal zone immediately in front of the iris. Here are situated the spaces of the angle of the iris, which communicate with the sinus venosus sclerae through which the chief transudation of fluid from the eye is believed to take place. If any obstruction to this transudation occur, increased intra-ocular tension is set up, and the disease known as *glaucoma* results. The *dangerous area of the eye* is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is apt to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected with it by nervous and vascular supplies.

The Accessory Organs of the Eye (*Organa Oculi Accessoria*).

The accessory organs of the eye include the **ocular muscles**, the **fasciæ**, the **eyebrows**, the **eyelids**, the **conjunctiva**, and the **lacrimal apparatus**.

The Ocular Muscles (*musculi oculi*).—The ocular muscles are the:

Levator palpebrae superioris.	Rectus medialis.
Rectus superior.	Rectus lateralis.
Rectus inferior.	Obliquus superior.
	Obliquus inferior.

Dissection.—To open the cavity of the orbit, remove the skull-cap and brain; then saw through the frontal bone at the inner extremity of the supraorbital ridge, and externally at its junction with the zygomatic bone. Break in pieces the thin roof of the orbit by a few slight blows of the hammer, and take it away; drive forward the superciliary portion of the frontal bone by a smart stroke, but do not remove it, as that would destroy the pulley of the *Obliquus superior*. When the fragments are cleared away, the periosteum of the orbit will be exposed; this being removed, together with the fat which fills the cavity of the orbit, the several muscles of this region can be examined. The dissection will be facilitated by distending the globe of the eye. In order to effect this, puncture the optic nerve near the eyeball with a curved needle, and push the needle onward into the globe; insert the point of a blowpipe through this aperture, and force a little air into the cavity of the eyeball; then apply a ligature around the nerve so as to prevent the air escaping. The globe being now drawn forward, the muscles will be put upon the stretch.

Tendon of Obliquus superior
.....

Orbicularis oculi

superior tarsus

Upper eyelid

eyelid
or tarsus

laris oculi

FIG. 856.—Sagittal section of right orbital cavity.

The **Levator palpebrae superioris** (Fig. 856) is thin, flat, and triangular in shape. It *arises* from the under surface of the small wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin of the *Rectus superior*. At its origin, it is narrow and tendinous, but soon becomes broad and fleshy, and ends anteriorly in a wide aponeurosis which splits into three lamellæ. The superficial lamella blends with the upper part of the orbital septum, and is prolonged forward above the superior tarsus to the palpebral part of the *Orbicularis oculi*, and to the deep surface of the skin of the upper eyelid. The middle lamella, largely made up of non-striped muscular fibres, is inserted into the upper margin of the superior tarsus, while the deepest lamella blends with an expansion from the sheath of the *Rectus superior* and with it is attached to the superior fornix of the conjunctiva.

Whitnall¹ has pointed out that the upper part of the sheath of the Levator palpebrae becomes thickened in front and forms, above the anterior part of the muscle, a transverse ligamentous band which is attached to the sides of the orbital cavity. On the medial side it is mainly fixed to the pulley of the Obliquus superior, but some fibres are attached to the bone behind the pulley and a slip passes forward and bridges over the supraorbital notch; on the lateral side it is fixed to the capsule of the lacrimal gland and to the frontal bone. In front of the transverse ligamentous band the sheath is continued over the aponeurosis of the Levator palpebrae, as a thin connective-tissue layer which is fixed to the upper orbital margin immediately behind the attachment of the orbital septum. When the Levator palpebrae contracts, the lateral and medial parts of the ligamentous band are stretched and check the action of the muscle; the retraction of the upper eyelid is checked also by the orbital septum coming into contact with the transverse part of the ligamentous band.

Great wing of sphenoid

FIG. 857.—Muscles of the right orbit.

The **four Recti** (Fig. 857) arise from a fibrous ring (*annulus tendineus communis*) which surrounds the upper, medial, and lower margins of the optic foramen and encircles the optic nerve (Fig. 858). The ring is completed by a tendinous bridge prolonged over the lower and medial part of the superior orbital fissure and attached to a tubercle on the margin of the great wing of the sphenoid, bounding the fissure. Two specialized parts of this fibrous ring may be made out: a lower, the **ligament or tendon of Zinn**, which gives origin to the Rectus inferior, part of the Rectus internus, and the lower head of origin of the Rectus lateralis; and an upper, which gives origin to the Rectus superior, the rest of the Rectus medialis, and the upper head of the Rectus lateralis. This upper band is sometimes termed the **superior tendon of Lockwood**. Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion into the sclera, about 6 mm. from the margin of the cornea. Between the two heads of the Rectus lateralis is a narrow interval, through which pass the two divisions of the oculomotor nerve, the nasociliary nerve, the abducent nerve, and the ophthalmic vein. Although these muscles present a common origin and are inserted in a similar manner into the sclera, there are certain differences to be observed in them as regards their length and breadth. The Rectus medialis is the broadest, the Rectus lateralis the longest, and the Rectus superior the thinnest and narrowest.

The **Obliquus oculi superior** (*superior oblique*) is a fusiform muscle, placed at the upper and medial side of the orbit. It arises immediately above the margin of the optic foramen, above and medial to the origin of the Rectus superior, and, passing forward, ends in a rounded tendon, which plays in a fibrocartilaginous ring or pulley attached to the trochlear fovea of the frontal bone. The contiguous surfaces of the tendon and ring are lined by a delicate mucous sheath, and enclosed in a thin

¹ Journal of Anatomy and Physiology, vol. xlv.

fibrous investment. The tendon is reflected backward, lateralward, and downward beneath the Rectus superior to the lateral part of the bulb of the eye, and is inserted into the sclera, behind the equator of the eyeball, the insertion of the muscle lying between the Rectus superior and Rectus lateralis.

The **Obliquus oculi inferior** (*inferior oblique*) is a thin, narrow muscle, placed near the anterior margin of the floor of the orbit. It arises from the orbital surface of the maxilla, lateral to the lacrimal groove. Passing lateralward, backward, and upward, at first between the Rectus inferior and the floor of the orbit, and then between the bulb of the eye and the Rectus lateralis, it is inserted into the lateral part of the sclera between the Rectus superior and Rectus lateralis, near to, but somewhat behind the insertion of the Obliquus superior.

Abducent n

Inf. ramus of oculomotor nerve Inf. orbital fissure Optic foramen

FIG. 858.—Dissection showing origins of right ocular muscles, and nerves entering by the superior orbital fissure.

Nerves.—The Levator palpebrae superioris, Obliquus inferior, and the Recti superior, inferior, and medialis are supplied by the oculomotor nerve; the Obliquus superior, by the trochlear nerve; the Rectus lateralis, by the abducent nerve.

Actions.—The Levator palpebrae raises the upper eyelid, and is the direct antagonist of the Orbicularis oculi. The four Recti are attached to the bulb of the eye in such a manner that, acting singly, they will turn its corneal surface either upward, downward, medialward, or lateralward, as expressed by their names. The movement produced by the Rectus superior or Rectus inferior is not quite a simple one, for inasmuch as each passes obliquely lateralward and forward to the bulb of the eye, the elevation or depression of the cornea is accompanied by a certain deviation medialward, with a slight amount of rotation. These latter movements are corrected by the Obliqui, the Obliquus inferior correcting the medial deviation caused by the Rectus superior and the Obliquus superior that caused by the Rectus inferior. The contraction of the Rectus lateralis or Rectus medialis, on the other hand, produces a purely horizontal movement. If any two neighboring Recti of one eye act together they carry the globe of the eye in the diagonal of these directions, viz., upward and medialward, upward and lateralward, downward and medialward, or downward and lateralward. Sometimes the corresponding Recti of the two eyes act in unison, and at other times the opposite Recti act together. Thus, in turning the eyes to the right, the Rectus lateralis of the right eye will act in unison with the Rectus medialis of the left eye; but if both eyes are directed to an object in the middle line at a short distance, the two Recti mediales will act in unison. The movement of circumduction, as in looking around a room, is performed by the successive actions of the four Recti. The Obliqui rotate the eyeball on its

antero-posterior axis, the superior directing the cornea downward and lateralward, and the inferior directing it upward and lateralward; these movements are required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of either eye.

A layer of non-striped muscle, the **Orbitalis muscle** of H. Müller, may be seen bridging across the inferior orbital fissure.

Optic nerve

or tarsus

Fascia bulbi

or tarsus

FIG. 859.—The right eye in sagittal section, showing the fascia bulbi (semidiagrammatic). (Testut.)

The **fascia bulb** (*capsule of Ténon*) (Fig. 859) is a thin membrane which envelops the bulb of the eye from the optic nerve to the ciliary region, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is separated from the outer surface of the sclera by the **periscleral lymph space**. This lymph space is continuous with the subdural and subarachnoid cavities, and is traversed by delicate bands of connective tissue which extend between the fascia and the sclera. The fascia is perforated behind by the ciliary vessels and nerves, and fuses with the sheath of the optic nerve and with the sclera around the entrance of the optic nerve. In front it blends with the ocular conjunctiva, and with it is attached to the ciliary region of the eyeball. It is perforated by the tendons of the ocular muscles, and is reflected backward on each as a tubular sheath. The sheath of the Obliquus superior is carried as far as the fibrous pulley of that muscle; that on the Obliquus inferior reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the Recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the Rectus superior blends with the tendon of the Levator palpebrae; that of the Rectus inferior is attached to the inferior tarsus. The expansions from the sheaths of the Recti lateralis and medialis are strong, especially that from the latter muscle, and are attached to the lacrimal and zygomatic bones respectively. As they prob-

ably check the actions of these two Recti they have been named the **medial** and **lateral check ligaments**. Lockwood has described a thickening of the lower part of the *facia bulbi*, which he has named the **suspensory ligament of the eye**. It is slung like a hammock below the eyeball, being expanded in the centre, and narrow at its extremities which are attached to the zygomatic and lacrimal bones respectively.¹

The **orbital fascia** forms the periosteum of the orbit. It is loosely connected to the bones and can be readily separated from them. Behind, it is united with the *dura mater* by processes which pass through the optic foramen and superior orbital fissure, and with the sheath of the optic nerve. In front, it is connected with the periosteum at the margin of the orbit, and sends off a process which assists in forming the orbital septum. From it two processes are given off; one to enclose the lacrimal gland, the other to hold the pulley of the *Obliquus superior* in position.

Applied Anatomy.—The positions and exact areas of insertion of the tendons of the Recti *medialis* and *lateralis* into the bulb of the eye should be carefully examined from the front, as the surgeon is often required to divide one or other of the muscles for the cure of strabismus. In convergent strabismus, which is the more common form of the disease, the eye is turned medialward, requiring the division of the Rectus *medialis*. In the divergent form, which is more rare, the eye is turned lateralward, the Rectus *lateralis* being especially implicated. The deformity produced in either case may be remedied by division of one or the other muscle. The operation is thus performed: the lids are to be well separated; the eyeball is rotated lateralward or medialward, and the conjunctiva raised by a pair of forceps, and incised immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclera; the submucous areolar tissue is then divided, and into the small aperture thus made, a blunt hook is passed upward between the muscle and the bulb, and the tendon of the muscle divided by a pair of blunt-pointed scissors passed between the hook and the bulb.

A more recent operation is that of *advancement* in which either the Rectus *medialis* or Rectus *lateralis* (depending on the form of strabismus) is shortened. The muscle is exposed in the same manner; a portion is then cut out of it and the cut ends are sew together.

The **eyebrows** (*supercilia*) are two arched eminences of integument, which surmount the upper circumference of the orbits, and support numerous short, thick hairs, directed obliquely on the surface. The eyebrows consist of thickened integument, connected beneath with the *Orbicularis oculi*, *Corrugator*, and *Frontalis* muscles.

The **eyelids** (*palpebrae*) are two thin, movable folds, placed in front of the eye, protecting it from injury by their closure. The upper eyelid is the larger, and the more movable of the two, and is furnished with an elevator muscle, the *Levator palpebrae superioris*. When the eyelids are open, an elliptical space, the **palpebral fissure** (*rima palpebrarum*), is left between their margins, the angles of which correspond to the junctions of the upper and lower eyelids, and are called the **palpebral commissures** or **canthi**.

The **lateral palpebral commissure** (*commissura palpebrarum lateralis*; *external canthus*) is more acute than the medial, and the eyelids here lie in close contact with the bulb of the eye: but the **medial palpebral commissure** (*commissura palpebrarum medialis*; *internal canthus*) is prolonged for a short distance toward the nose, and the two eyelids are separated by a triangular space, the **lacus lacrimalis** (Fig. 860). At the basal angles of the lacus lacrimalis, on the margin of each eyelid, is a small conical elevation, the **lacrimal papilla**, the apex of which is pierced by a small orifice, the **punctum lacrimale**, the commencement of the lacrimal duct.

The **eyelashes** (*cilia*) are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row: those of the upper eyelid, more numerous and longer than those of the lower, curve upward; those of the lower

¹ C. B. Lockwood, *Journal of Anatomy and Physiology*, vol. xx.

eyelid curve downward, so that they do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of a number of glands, the **ciliary glands**, arranged in several rows close to the free margin of the lid; they are regarded as enlarged and modified sudoriferous glands.

Structure of the Eyelids.—The eyelids are composed of the following structures taken in their order from without inward: integument, areolar tissue, fibres of the *Orbicularis oculi*, tarsus, orbital septum, tarsal glands and conjunctiva. The upper eyelid has, in addition, the aponeurosis of the *Levator palpebrae superioris* (Fig. 861).

Openings of tarsal
glands

1

FIG. 860.—Front of left eye with eyelids separated to show medial canthus.

The **integument** is extremely thin, and continuous at the margins of the eyelids with the conjunctiva.

The **subcutaneous areolar tissue** is very lax and delicate, and seldom contains any fat.

The **palpebral fibres of the *Orbicularis oculi*** are thin, pale in color, and possess an involuntary action.

The **tarsi (tarsal plates)** (Fig. 862) are two thin elongated plates of dense connective tissue, about 2.5 cm. in length; one is placed in each eyelid, and contributes to its form and support. The **superior tarsus (tarsus superior; superior tarsal plate)**, the larger, is of a semilunar form, about 10 mm. in breadth at the centre, and gradually narrowing toward its extremities. To the anterior surface of this plate the aponeurosis of the *Levator palpebrae superioris* is attached. The **inferior tarsus (tarsus inferior; inferior tarsal plate)**, the smaller, is thin, elliptical in form, and has a vertical diameter of about 5 mm. The free or ciliary margins of these plates are thick and straight.

The attached or orbital margins are connected to the circumference of the orbit by the orbital septum. The lateral angles are attached to the zygomatic bone by the lateral palpebral raphé. The medial angles of the two plates end at the lacus lacimalis, and are attached to the frontal process of the maxilla by the medial palpebral ligament (page 468).

The **orbital septum (septum orbitale; palpebral ligament)** is a membranous sheet, attached to the edge of the orbit, where it is continuous with the periosteum. In the upper eyelid it blends by its peripheral circumference with the tendon of the *Levator palpebrae superioris* and the superior tarsus, in the lower eyelid with the inferior tarsus. Medially it is thin, and, becoming separated from the medial palpebral ligament, is fixed to the lacrimal bone immediately behind the lacrimal sac. The septum is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp.

FIG. 861.—Sagittal section through the upper eyelid. (After Waldeyer.) a. Skin. b. *Orbicularis oculi*. b'. Marginal fasciculus of *Orbicularis* (ciliary bundle). c. *Levator palpebrae*. d. Conjunctiva. e. Tarsus. f. Tarsal gland. g. Sebaceous gland. h. Eyelashes. i. Small hairs of skin. j. Sweat glands. k. Posterior tarsal glands.

The Tarsal Glands (*glandulae tarsales* [*Meibomi*]; *Meibomian glands*) (Fig. 863).—The tarsal glands are situated upon the inner surfaces of the eyelids, between the tarsi and conjunctiva, and may be distinctly seen through the latter on everting the eyelids, presenting an appearance like parallel strings of pearls. There are about thirty in the upper eyelid, and somewhat fewer in the lower. They are imbedded in grooves in the inner surfaces of the tarsi, and correspond in length with the breadth of these plates; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margins of the lids by minute foramina.

FIG. 862.—The tarsi and their ligaments. Right eye; front view (Testut.)

Structure.—The tarsal glands are modified sebaceous glands, each consisting of a single straight tube or follicle, with numerous small lateral diverticula. The tubes are supported by a basement membrane, and are lined at their mouths by stratified epithelium; the deeper parts of the tubes and the lateral offshoots are lined by a layer of polyhedral cells.

Puncta lacrimalia

FIG. 863.—The tarsal glands, etc., seen from the inner surface of the eyelids.

The **conjunctiva** is the mucous membrane of the eye. It lines the inner surfaces of the eyelids or palpebræ, and is reflected over the forepart of the sclera and cornea.

The **Palpebral Portion** (*tunica conjunctiva palpebrarum*) is thick, opaque, highly vascular, and covered with numerous papillæ, its deeper part presenting a considerable amount of lymphoid tissue. At the margins of the lids it becomes

continuous with the lining membrane of the ducts of the tarsal glands, and, through the lacrimal ducts, with the lining membrane of the lacrimal sac and nasolacrimal duct. At the lateral angle of the upper eyelid the ducts of the lacrimal gland open on its free surface; and at the medial angle it forms a semilunar fold, the *plica semilunaris*. The line of reflection of the conjunctiva from the upper eyelid on to the bulb of the eye is named the *superior fornix*, and that from the lower lid the *inferior fornix*.

The **Bulbar Portion** (*tunica conjunctiva bulbi*).—Upon the *sclera* the conjunctiva is loosely connected to the bulb of the eye; it is thin, transparent, destitute of papillæ, and only slightly vascular. Upon the *cornea*, the conjunctiva consists only of epithelium, constituting the epithelium of the cornea, already described (see page 1019). *Lymphatics* arise in the conjunctiva in a delicate zone around the cornea, and run to the ocular conjunctiva.

In and near the fornices, but more plentiful in the upper than in the lower eyelid, a number of convoluted tubular glands open on the surface of the conjunctiva. Other glands, analogous to lymphoid follicles, and called by Henle *trachoma glands*, are found in the conjunctiva, and, according to Strohmeyer, are chiefly situated near the medial palpebral commissure. They were first described by Brush, in his description of Peyer's patches of the small intestine, as "identical structures existing in the under eyelid of the ox."

The *caruncula lacrimalis* is a small, reddish, conical-shaped body, situated at the medial palpebral commissure, and filling up the *lacus lacrimalis*. It consists of a small island of skin containing sebaceous and sudoriferous glands, and is the source of the whitish secretion which constantly collects in this region. A few slender hairs are attached to its surface. Lateral to the caruncula is a slight semilunar fold of conjunctiva, the concavity of which is directed toward the cornea; it is called the *plica semilunaris*. Müller found smooth muscular fibres in this fold; in some of the domesticated animals it contains a thin plate of cartilage.

The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause they terminate in a peculiar form of tactile corpuscle, which he terms "terminal bulb."

The **Lacrimal Apparatus** (*apparatus lacrimalis*) (Fig. 864) consists of (a) the *lacrimal gland*, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye; (b) the *lacrimal ducts*, the *lacrimal sac*, and the *nasolacrimal duct*, by which the fluid is conveyed into the cavity of the nose.

The **Lacrimal Gland** (*glandula lacrimalis*).—The lacrimal gland is lodged in the lacrimal fossa, on the medial side of the zygomatic process of the frontal bone. It is of an oval form, about the size and shape of an almond, and consists of two portions, described as the superior and inferior lacrimal glands. The *superior lacrimal gland* is connected to the periosteum of the orbit by a few fibrous bands, and rests upon the tendons of the *Recti superior* and *lateralis*, which separate it from the bulb of the eye. The *inferior lacrimal gland* is separated from the superior by a fibrous septum, and projects into the back part of the upper eyelid, where its deep surface is related to the conjunctiva. The ducts of the glands, from six to twelve in number, run obliquely beneath the conjunctiva for a short distance, and open along the upper and lateral half of the superior conjunctival fornix.

Structures of the Lacrimal Gland (Fig. 865).—In structure and general appearance the lacrimal resembles the serous salivary glands (p. 1137). In the recent state the cells are so crowded with granules that their limits can hardly be defined. They contain oval nuclei, and the cell protoplasm is finely fibrillated.

The **Lacrimal Ducts** (*ductus lacrimalis*; *lacrimal canals*).—The lacrimal ducts, one in each eyelid, commence at minute orifices, termed *puncta lacrimalia*, on the summits of the *papillæ lacrimales*, seen on the margins of the lids at the lateral extremity of the *lacus lacrimalis*. The *superior duct*, the smaller and shorter of the

two, at first ascends, and then bends at an acute angle, and passes medialward and downward to the lacrimal sac. The **inferior duct** at first descends, and then runs almost horizontally to the lacrimal sac. At the angles they are dilated into **ampullæ**; their walls are dense in structure and their mucous lining is covered by stratified squamous epithelium, placed on a basement membrane. Outside the latter is a layer

FIG. 864.—The lacrimal apparatus. Right side.

FIG. 865.—Alveoli of lacrimal gland.

of striped muscle, continuous with the lacrimal part of the *Orbicularis oculi*; at the base of each lacrimal papilla the muscular fibres are circularly arranged and form a kind of sphincter.

The Lacrimal Sac (*saccus lacrimalis*).—The lacrimal sac is the upper dilated end of the nasolacrimal duct, and is lodged in a deep groove formed by the lacrimal bone and frontal process of the maxilla. It is oval in form and measures from 12 to 15 mm. in length; its upper end is closed and rounded; its lower is continued into the nasolacrimal duct. Its superficial surface is covered by a fibrous expansion derived from the medial palpebral ligament, and its deep surface is crossed by the lacrimal part of the *Orbicularis oculi* (page 467), which is attached to the crest on the lacrimal bone.

Structure.—The lacrimal sac consists of a fibrous elastic coat, lined internally by mucous membrane: the latter is continuous, through the lacrimal ducts, with the conjunctiva, and through the nasolacrimal duct with the mucous membrane of the nasal cavity.

The Nasolacrimal Duct (*ductus nasolacrimalis*; *nasal duct*).—The nasolacrimal duct is a membranous canal, about 18 mm. in length, which extends from the lower part of the lacrimal sac to the inferior meatus of the nose, where it ends by a somewhat expanded orifice, provided with an imperfect valve, the **plica lacrimalis** (*Hasneri*), formed by a fold of the mucous membrane. It is contained in an osseous canal, formed by the maxilla, the lacrimal bone, and the inferior nasal concha; it is narrower in the middle than at either end, and is directed downward, backward, and a little lateralward. The mucous lining of the lacrimal sac and nasolacrimal duct is covered with columnar epithelium, which in places is ciliated.

Applied Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin covering them is thin and delicate, and is supported on a quantity of loose areolar subcutaneous tissue, devoid of fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighboring cicatrices, and thus produce an eversion of the lid, known as *ectropion*. Inversion of the lids (*entropion*) from spasm of the *Orbicularis oculi* or from chronic inflammation of the palpebral conjunctiva may also occur. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as *navi*. Rodent ulcer frequently commences about the medial palpebral commissure. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue, the extravasation of blood may be so great as to produce considerable swelling of the eyelids and complete closure of the eye, and the same is the case when

inflammatory products are poured out. The follicles of the eyelashes, or the sebaceous glands associated with these follicles, may be the seat of inflammation, constituting the ordinary *stye*. The tarsal glands are affected in the so-called *tarsal tumor*, which, according to some, is caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The ciliary follicles are liable to become inflamed, constituting the disease known as *blepharitis ciliaris*. Irregular or disorderly growth of the eyelashes not infrequently occurs, some of them being turned toward the eyeball and producing inflammation and ulceration of the cornea, and possibly eventually complete destruction of the eye. The Orbicularis oculi may be the seat of spasm, either in the form of slight quivering of the lids; or repeated twitchings, most commonly due to errors of refraction in children; or more continuous spasms, due to some irritation of the trigeminal or facial nerve. The Orbicularis oculi may be paralyzed with the other facial muscles. Under these circumstances the patient is unable to close the lids, and, if he attempts to do so, rolls the eyeball upward under the upper eyelid. The tears overflow from displacement of the lower eyelid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. *Ptosis*, or dropping of the upper eyelid, may be congenital, or may be due to paralysis of the Levator palpebrae superioris, in which case there will probably be other symptoms of implication of the oculomotor nerve. The eyelids may be the seat of bruises, wounds, or burns. Following *burns*, adhesion of the margins of the lids to each other, or adhesion of the lids to the bulb, may take place. They are sometimes the seat of emphysema, after fracture of some of the thin bones forming the medial wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostril through the lacerated structures into the connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling characteristic of this affection.

Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface, during the movements of the eyelids and the eye on each other. The conjunctiva is often involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a burn, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclera, which is present in inflammation of the deeper structures of the bulb of the eye. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off toward the corneal margin; they anastomose freely and form a dense net-work, and they can be emptied or displaced by gentle pressure. Inflammation of the underlying sclera, ciliary body, or iris is a far more serious condition; the injection is in the deeper vessels of the eye, and as seen through the sclera presents a diffuse and dull purplish or violet zone of circumcorneal discoloration.

The *lacrimal gland* is occasionally, though rarely, the seat of inflammation, either acute or chronic; it is also sometimes the seat of tumors, benign or malignant, and for these may require removal. This may be done by an incision through the skin, just below the eyebrow; and the gland, being invested with a special capsule, may be isolated and removed, without opening the general cavity of the orbit. The lacrimal ducts may be obstructed, either as a congenital defect or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The lacrimal ducts may also become occluded as a result of burns or injury; overflow of the tears may in addition result from deviation of the puncta, or from chronic inflammation of the lacrimal sac. This latter condition is set up by some obstruction to the nasolacrimal duct, frequently occurring in tuberculous subjects. In consequence of this the tears and mucus accumulate in the lacrimal sac and distend it. Suppuration in the lacrimal sac is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers, in cases where the lacrimal passages were previously quite healthy. It may lead to lacrimal fistula from an abscess forming in the sac, which bursts or is opened on the surface; the condition is often seen in badly nourished, tuberculous children.

THE ORGAN OF HEARING (ORGANON AUDITUS; THE EAR).

The **ear**, or **organ of hearing**, is divisible into three parts: the **external ear**, the **middle ear** or **tympanic cavity**, and the **internal ear** or **labyrinth**.

The External Ear.

The **external ear** consists of the expanded portion named the **auricula** or **pinna**, and the **external acoustic meatus**. The former projects from the side of the head

and serves to collect the vibrations of the air by which sound is produced; the latter leads inward from the bottom of the auricula and conducts the vibrations to the tympanic cavity.

The **Auricula** or **Pinna** (Fig. 866) is of an ovoid form, with its larger end directed upward. Its lateral surface is irregularly concave, directed slightly forward, and presents numerous eminences and depressions to which names have been assigned.

The prominent rim of the auricula is called the **helix**; where the helix turns downward behind, a small tubercle, the **auricular tubercle of Darwin**, is frequently seen; this tubercle is very evident about the sixth month of fetal life when the whole auricula has a close resemblance to that of some of the adult monkeys. Another curved prominence, parallel with and in front of the helix, is called the **antihelix**; this divides above into two crura, between which is a triangular depression, the **fossa triangularis**. The narrow-curved depression between the helix and the antihelix is called the **scapha**; the antihelix describes a curve around a deep, capacious cavity, the **concha**, which is partially divided into two parts by the **crus** or commencement of the helix; the upper part is termed the **cymba conchae**, the lower part the **cavum conchae**. In front of the concha, and projecting backward over the meatus, is a small pointed eminence, the **tragus**, so called from its being generally covered on its under surface with a tuft of hair, resembling a goat's beard.

FIG. 866.—The auricula. Lateral surface.

Opposite the tragus, and separated from it by the **intertragic notch**, is a small tubercle, the **antitragus**. Below this is the **lobule**, composed of tough areolar and adipose tissues, and wanting the firmness and elasticity of the rest of the auricula.

The cranial surface of the auricula presents elevations which correspond to the depressions on its lateral surface and after which they are named, *e. g.*, **eminentia conchae**, **eminentia triangularis**, etc.

Structure.—The auricula is composed of a thin plate of yellow fibrocartilage, covered with integument, and connected to the surrounding parts by ligaments and muscles; and to the commencement of the external acoustic meatus by fibrous tissue.

The **skin** is thin, closely adherent to the cartilage, and covered with fine hairs furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa. On the tragus and antitragus the hairs are strong and numerous. The skin of the auricula is continuous with that lining the external acoustic meatus.

The **cartilage of the auricula** (*cartilago auriculæ*; *cartilage of the pinna*) (Figs. 867, 868) consists of a single piece; it gives form to this part of the ear, and upon its surface are found the eminences and depressions above described. It is absent from the lobule; it is deficient, also, between the tragus and beginning of the helix, the gap being filled up by dense fibrous tissue. At the front part of the auricula, where the helix bends upward, is a small projection of cartilage, called the *spina helcis*, while in the lower part of the helix the cartilage is prolonged downward as a tail-like process, the *cauda helcis*; this is separated from the antihelix by a fissure, the *fissura antitragohelicina*. The cranial aspect of the cartilage exhibits a transverse furrow, the *sulcus antihelcis transversus*, which corresponds with the inferior crus of the antihelix and separates the *eminentia conchae* from the *eminentia triangularis*. The *eminentia conchae* is crossed by a vertical ridge (*ponticulus*), which gives attachment to the *Auricularis posterior* muscle. In the cartilage of the auricula are two fissures, one behind the *crus helcis* and another in the tragus.

The **ligaments of the auricula** (*ligamenti auricularia* [Valsalva]; *ligaments of the pinna*) consist of two sets: (1) **extrinsic**, connecting it to the side of the head; (2) **intrinsic**, connecting various parts of its cartilage together.

The **extrinsic ligaments** are two in number, anterior and posterior. The *anterior ligament* extends from the tragus and *spina helcis* to the root of the zygomatic process of the temporal bone. The *posterior ligament* passes from the posterior surface of the concha to the outer surface of the mastoid process.

The chief **intrinsic ligaments** are: (a) a strong fibrous band, stretching from the tragus to the commencement of the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (b) a band between the antihelix and the cauda helix. Other less important bands are found on the cranial surface of the pinna.

FIG. 867.—Cranial surface of cartilage of right auricle.

The **muscles of the auricle** (Fig. 868) consist of two sets: (1) the **extrinsic**, which connect it with the skull and scalp and move the auricle as a whole; and (2) the **intrinsic**, which extend from one part of the auricle to another.

The **extrinsic muscles** are the Auriculares anterior, superior, and posterior.

The *Auricularis anterior* (*Attrahens aurem*), the smallest of the three, is thin, fan-shaped, and its fibers are pale and indistinct. It arises from the lateral edge of the galea aponeurotica, and its fibres converge to be inserted into a projection on the front of the helix.

The *Auricularis superior* (*Attolens aurem*), the largest of the three, is thin and fan-shaped. Its fibres arise from the galea aponeurotica, and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the auricle.

The *Auricularis posterior* (*Retrahens aurem*) consists of two or three fleshy fasciculi, which arise from the mastoid portion of the temporal bone by short aponeurotic fibres. They are inserted into the lower part of the cranial surface of the concha.

Actions.—In man, these muscles possess very little action: the *Auricularis anterior* draws the auricle forward and upward; the *Auricularis superior* slightly raises it; and the *Auricularis posterior* draws it backward.

The **intrinsic muscles** are the:

Helix major.	Antitragicus.
Helix minor.	Transversus auriculæ.
Tragicus.	Obliquus auriculæ.

FIG. 868.—The muscles of the auricle.

The *Helix major* is a narrow vertical band situated upon the anterior margin of the helix. It arises below, from the spina helix, and is inserted into the anterior border of the helix, just where it is about to curve backward.

The *Helix minor* is an oblique fasciculus, covering the crus helix.

The *Tragicus* is a short, flattened vertical band on the lateral surface of the tragus.

The *Antitragicus* arises from the outer part of the antitragus, and is inserted into the cauc helicis and antihelix.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the eminentia conchæ to the prominence corresponding with the scapha.

The *Obliquus auriculæ*, also on the cranial surface, consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

Nerves. The Auriculares anterior and superior and the intrinsic muscles on the lateral surface are supplied by the temporal branch of the facial nerve, the Auricularis posterior and the intrinsic muscles on the cranial surface by the posterior auricular branch of the same nerve.

The **arteries of the auricle** are the posterior auricular from the external carotid, the anterior auricular from the superficial temporal, and a branch from the occipital artery.

The **veins** accompany the corresponding arteries.

The **sensory nerves** are: the great auricular, from the cervical plexus; the auricular branch of the vagus; the auriculotemporal branch of the mandibular nerve; and the lesser occipital from the cervical plexus.

Cartilages of auricle

<i>Cartilaginous part of ext. acoustic meatus</i>	<i>Bony part of ext. acoustic meatus</i>
---	--

FIG. 869 -External and middle ear, opened from the front. Right side

The **External Acoustic Meatus** (*meatus acusticus externus*; *external auditory canal* or *meatus*) extends from the bottom of the concha to the tympanic membrane (FIG. 869, 870). It is about 4 cm. in length if measured from the tragus; from the bottom of the concha its length is about 2.5 cm. It forms an S-shaped curve, and is directed at first inward, forward, and slightly upward (*pars externa*); it then passes inward and backward (*pars media*), and lastly is carried inward, forward, and slightly downward (*pars interna*). It is an oval cylindrical canal, the greatest diameter being directed downward and backward at the external orifice, but nearly horizontal at the inner end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the **isthmus**, in the osseous portion, about 2 cm. from the bottom of the concha. The tympanic membrane, which closes the inner end of the meatus, is obliquely directed; in consequence of this the floor and anterior wall of the meatus are longer than the roof and posterior wall.

The external acoustic meatus is formed partly by cartilage and membrane, and partly by bone, and is lined by skin.

The **cartilaginous portion** (*meatus acusticus externus cartilagineus*) is about 8 mm. in length; it is continuous with the cartilage of the auricula, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at the upper and back part of the meatus, its place being supplied by fibrous membrane; two or three deep fissures are present in the anterior part of the cartilage.

The **osseous portion** (*meatus acusticus externus osseus*) is about 16 mm. in length, and is narrower than the cartilaginous portion. It is directed inward and a little forward, forming in its course a slight curve the convexity of which is upward and backward. Its inner end is smaller than the outer, and sloped, the anterior wall

FIG. 870.—Horizontal section through left ear; upper half of section.

projecting beyond the posterior for about 4 mm.; it is marked, except at its upper part, by a narrow groove, the **tympanic sulcus**, in which the circumference of the tympanic membrane is attached. Its outer end is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the auricula. The front and lower parts of the osseous portion are formed by a curved plate of bone, the tympanic part of the temporal, which, in the fetus, exists as a separate ring (**annulus tympanicus**), incomplete at its upper part (page 245).

The **skin** lining the meatus is very thin; adheres closely to the cartilaginous and osseous portions of the tube, and covers the outer surface of the tympanic membrane. After maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which secrete the ear-wax; their structure resembles that of the sudoriferous glands.

Relations of the Meatus.—In front of the osseous part is the condyle of the mandible, which however, is frequently separated from the cartilaginous part by a portion of the parotid gland. The movements of the jaw influence to some extent the lumen of this latter portion. Behind the osseous part are the mastoid air cells, separated from the meatus by a thin layer of bone.

The **arteries** supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The **nerves** are chiefly derived from the auriculotemporal branch of the mandibular nerve and the auricular branch of the vagus.

The *Tragicus* is a short, flattened vertical band on the lateral surface of the tragus.

The *Antitragicus* arises from the outer part of the antitragus, and is inserted into the cauda helix and antihelix.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the eminentia conchæ to the prominence corresponding with the scapha.

The *Obliquus auriculæ*, also on the cranial surface, consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

Nerves—The Auriculares anterior and superior and the intrinsic muscles on the lateral surface are supplied by the temporal branch of the facial nerve, the Auricularis posterior and the intrinsic muscles on the cranial surface by the posterior auricular branch of the same nerve.

The *arteries of the auricle* are the posterior auricular from the external carotid, the anterior auricular from the superficial temporal, and a branch from the occipital artery.

The *veins* accompany the corresponding arteries.

The *sensory nerves* are: the great auricular, from the cervical plexus; the auricular branch of the vagus; the auriculotemporal branch of the mandibular nerve; and the lesser occipital from the cervical plexus.

Cartilages of auricula

<i>Cartilaginous part of ext. acoustic meatus</i>	<i>Bony part of ext. acoustic meatus</i>
---	--

FIG. 869. —External and middle ear, opened from the front. Right side.

The **External Acoustic Meatus** (*meatus acusticus externus*; *external auditory canal* or *meatus*) extends from the bottom of the concha to the tympanic membrane (Figs. 869, 870). It is about 4 cm. in length if measured from the tragus; from the bottom of the concha its length is about 2.5 cm. It forms an S-shaped curve, and is directed at first inward, forward, and slightly upward (*pars externa*); it then passes inward and backward (*pars media*), and lastly is carried inward, forward, and slightly downward (*pars interna*). It is an oval cylindrical canal, the greatest diameter being directed downward and backward at the external orifice, but nearly horizontally at the inner end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the *isthmus*, in the osseous portion, about 2 cm. from the bottom of the concha. The tympanic membrane, which closes the inner end of the meatus, is obliquely directed; in consequence of this the floor and anterior wall of the meatus are longer than the roof and posterior wall.

The external acoustic meatus is formed partly by cartilage and membrane, and partly by bone, and is lined by skin.

The **cartilaginous portion** (*meatus acusticus externus cartilagineus*) is about 8 mm. in length; it is continuous with the cartilage of the auricula, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at the upper and back part of the meatus, its place being supplied by fibrous membrane; two or three deep fissures are present in the anterior part of the cartilage.

The **osseous portion** (*meatus acusticus externus osseus*) is about 16 mm. in length, and is narrower than the cartilaginous portion. It is directed inward and a little forward, forming in its course a slight curve the convexity of which is upward and backward. Its inner end is smaller than the outer, and sloped, the anterior wall

FIG. 870.—Horizontal section through left ear; upper half of section.

projecting beyond the posterior for about 4 mm.; it is marked, except at its upper part, by a narrow groove, the **tympanic sulcus**, in which the circumference of the tympanic membrane is attached. Its outer end is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the auricula. The front and lower parts of the osseous portion are formed by a curved plate of bone, the tympanic part of the temporal, which, in the fetus, exists as a separate ring (**annulus tympanicus**), incomplete at its upper part (page 245).

The **skin** lining the meatus is very thin; adheres closely to the cartilaginous and osseous portions of the tube, and covers the outer surface of the tympanic membrane. After maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which secrete the ear-wax; their structure resembles that of the sudoriferous glands.

Relations of the Meatus. In front of the osseous part is the condyle of the mandible, which however, is frequently separated from the cartilaginous part by a portion of the parotid gland. The movements of the jaw influence to some extent the lumen of this latter portion. Behind the osseous part are the mastoid air cells, separated from the meatus by a thin layer of bone.

The **arteries** supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The **nerves** are chiefly derived from the auriculotemporal branch of the mandibular nerve and the auricular branch of the vagus.

Applied Anatomy.—Malformations, such as imperfect development of the external parts, supernumerary auricles, or absence of the meatus, are occasionally met with. The skin of the auricula is thin and richly supplied with blood, but in spite of this it is often the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual underlying subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (*hematoma auris*), usually the result of traumatism, but not necessarily due to this cause; it is said to occur most frequently in the ears of the insane. Keloid sometimes grows in the auricula around the puncture made for earrings, and epithelioma occasionally affects this part. Deposits of urate of soda are often met with in the auricula in gouty subjects.

The external acoustic meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the greater part of the canal and tympanic membrane can be brought into view. In using this instrument, it is advisable that the auricula should be drawn upward, backward, and a little outward, so as to render the meatus as straight as possible. The points to be noted are: the presence of wax or foreign bodies; the size of the meatus; and the condition of the tympanic membrane. Accumulation of wax is often a cause of deafness, and may give rise to very serious consequences, such as ulceration of the membrane; it is best removed by syringing. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the meatus may be removed with tolerable facility by means of a minute hook or loop of fine wire, aided by reflected light; but when they have slipped beyond the narrow middle part of the meatus their removal is in no wise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the tympanic membrane and possibly the contents of the tympanic cavity. The calibre of the external acoustic meatus may be narrowed by inflammation of its lining membrane; by periostitis; by polypi; or by exostoses.

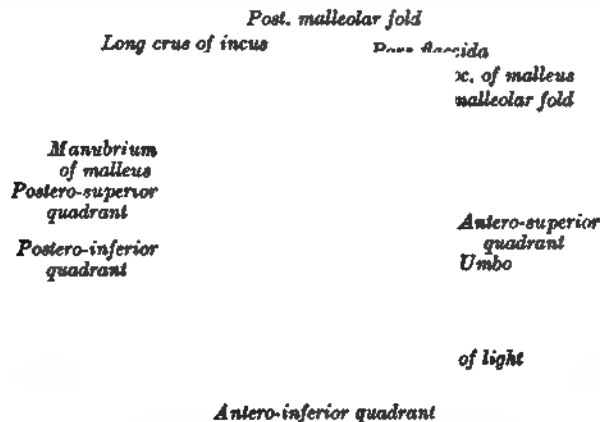

FIG. 871.—Right tympanic membrane as seen through a speculum.

At the point of junction of the osseous and cartilaginous portions an obtuse angle, which projects into the tube at its antero-inferior wall, is formed; this produces a sort of constriction and renders it a narrow portion of the meatus—an important point to be remembered in connection with the presence of foreign bodies in the meatus. The shortness of the meatus in children should be borne in mind in introducing the aural speculum, so that it be not pushed in too far, at the risk of injuring the tympanic membrane; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. Just in front of the membrane is a well-marked depression, situated on the floor of the meatus, and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upward and backward, the greater part of the tympanic membrane is rendered visible (Fig. 871). It is a pearly-gray membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle (about fifty-five degrees), while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upward, is a reddish-yellow streak; this is the handle of the malleus, which is inserted into the membrane. At the upper part of this streak, close to the roof of the meatus, a little white, rounded prominence is plainly to be seen; this is the lateral or short process of the malleus, projecting against the membrane. The tympanic membrane

does not present a plane surface; on the contrary, its centre is drawn inward, on account of its connection with the manubrium of the malleus, and thus the external surface is rendered concave.

The connections of the nerves of the meatus explain the fact of the occurrence, in cases of irritation of the meatus, of constant coughing and sneezing, from implication of the vagus, and the vomiting which may follow syringing the ears of children, and the occasional heart failure similarly induced in elderly people. No doubt also the association of earache with toothache or with cancer of the tongue is due to implication of the mandibular branch of the trigeminal nerve, which supplies also the teeth and the tongue. The upper half of the tympanic membrane is much more vascular than the lower half; for this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

The Middle Ear or Tympanic Cavity (Cavum Tympani; Drum; Tympanum).

The middle ear or tympanic cavity is an irregular, laterally compressed space within the temporal bone. It is filled with air, which is conveyed to it from the nasal part of the pharynx through the auditory tube. It contains a chain of movable bones, which connect its lateral to its medial wall, and serve to convey the vibrations communicated to the tympanic membrane across the cavity to the internal ear.

The tympanic cavity consists of two parts: the **tympanic cavity proper**, opposite the tympanic membrane, and the **attic** or **epitympanic recess**, above the level of the membrane; the latter contains the upper half of the malleus and the greater part of the incus. Including the attic, the vertical and antero-posterior diameters of the cavity are each about 15 mm. The transverse diameter measures about 6 mm. above and 4 mm. below; opposite the centre of the tympanic membrane it is only about 2 mm. The tympanic cavity is bounded laterally by the tympanic membrane; medially, by the lateral wall of the internal ear; it communicates, behind, with the tympanic antrum and through it with the mastoid air cells, and in front with the auditory tube (Fig. 869).

The **Tegmental Wall or Roof** (*paries tegmentalis*) is formed by a thin plate of bone, the **tegmen tympani**, which separates the cranial and tympanic cavities. It is situated on the anterior surface of the petrous portion of the temporal bone close to its angle of junction with the squama temporalis; it is prolonged backward so as to roof in the tympanic antrum, and forward to cover in the semicanal for the Tensor tympani muscle. Its lateral edge corresponds with the remains of the petrosquamous suture.

The **Jugular Wall or Floor** (*paries jugularis*) is narrow, and consists of a thin plate of bone (**fundus tympani**) which separates the tympanic cavity from the jugular fossa. It presents, near the labyrinthine wall, a small aperture for the passage of the tympanic branch of the glossopharyngeal nerve.

The **Membranous or Lateral Wall** (*paries membranacea; outer wall*) is formed mainly by the tympanic membrane, partly by the ring of bone into which this membrane is inserted. This ring of bone is incomplete at its upper part, forming a notch (**notch of Rivinus**), close to which are three small apertures: the **iter chordae posterius**, the **petrotympanic fissure**, and the **iter chordae anterior**.

The **iter chordae posterius** (*apertura tympanica canaliculi chordae*) is situated in the angle of junction between the mastoid and membranous wall of the tympanic cavity immediately behind the tympanic membrane and on a level with the upper end of the manubrium of the malleus; it leads into a minute canal, which descends in front of the canal for the facial nerve, and ends in that canal near the stylo-mastoid foramen. Through it the chorda tympani nerve enters the tympanic cavity.

The **petrotympanic fissure** (*fissura petrotympanica; Glaserian fissure*) opens just above and in front of the ring of bone into which the tympanic membrane is

inserted; in this situation it is a mere slit about 2 mm. in length. It lodges the anterior process and anterior ligament of the malleus, and gives passage to the anterior tympanic branch of the internal maxillary artery.

The *iter chordae anterior* (*canal of Huguier*) is placed at the medial end of the petrotympanic fissure; through it the chorda tympani nerve leaves the tympanic cavity.

The **Tympanic Membrane** (*membrana tympani*) (Figs. 871, 872) separates the tympanic cavity from the bottom of the external acoustic meatus. It is a thin

semitransparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downward and inward so as to form an angle of about fifty-five degrees with the floor of the meatus. Its longest diameter is downward and forward, and measures from 9 to 10 mm.; its shortest diameter measures from 8 to 9 mm. The greater part of its circumference is thickened and forms a **fibrocartilaginous ring** which is fixed in the **tympanic sulcus** at the inner end of the meatus. This sulcus is deficient superiorly at the notch of Rivinus and from the ends of this notch two bands, the **anterior** and **posterior malleolar fold**, are prolonged to the lateral process of the malleus. The small, somewhat triangular part of the membrane situated above the folds is lax and thin, and is named the **pars flaccida**; in it a small orifice is sometimes seen. The manubrium of the malleus is firmly attached to the medial surface of the membrane as far as its centre, where it draws toward the tympanic cavity; the lateral surface of the membrane is thin, concave, and the most depressed part of this concavity is named the **umbo**.

FIG. 872.—The tympanic membrane viewed from within. (Testut.) The malleus has been resected immediately beyond its lateral process, in order to show the tympanomalleolar folds and the *membrana flaccida*. 1. Tympanic membrane. 2. Umbo. 3. Handle of the malleus. 4. Lateral process. 5. Anterior tympanomalleolar fold. 6. Posterior tympanomalleolar fold. 7. *Pars flaccida*. 8. Anterior pouch of Tröltsch. 9. Posterior pouch of Tröltsch. 10. Fibrocartilaginous ring. 11. Petrotympanic fissure. 12. Auditory tube. 13. *Iter chordae posterior*. 14. *Iter chordae anterior*. 15. Fossa incudis for short crus of the incus. 16. Prominentia styloidea.

Structure.—The tympanic membrane is composed of three strata: a **lateral** (*cutaneous*), an **intermediate** (*fibrous*), and a **medial** (*mucous*). The **cutaneous stratum** is derived from the integument lining the meatus. The **fibrous stratum** consists of two layers: a radiate stratum, the fibres of which diverge from the manubrium of the malleus, and a circular stratum, the fibres of which are plentiful around the circumference but sparse and scattered near the centre of the membrane. Branched or dendritic fibres, as pointed out by Grüber, are also present especially in the posterior half of the membrane.

Vessels and Nerves.—The **arteries** of the tympanic membrane are derived from the **auricular branch** of the internal maxillary, which ramifies beneath the cutaneous stratum; from the **stylomastoid branch** of the posterior auricular, and **tympanic branch** of the internal maxillary, which are distributed on the mucous surface. The **superficial veins** open into the external jugular; those on the deep surface drain partly into the transverse sinus and vein of the dura mater, and partly into a plexus on the auditory tube. The membrane receives its **nerve supply** from the **auriculotemporal branch** of the mandibular, the **auricular branch** of the vagus, and the **tympanic branch** of the glossopharyngeal.

The **Labyrinthic or Medial Wall** (*paries labyrinthica*; *inner wall*) (Fig. 873) is vertical in direction, and presents for examination the **fenestrae vestibuli**, the **cochleae**, the **promontory**, and the **prominence of the facial canal**.

The **fenestra vestibuli** (*fenestra ovalis*) is a reniform opening leading from the tympanic cavity into the vestibule of the internal ear; its long diameter is horizontal, and its convex border is upward. In the recent state it is occupied by the base of the stapes, the circumference of which is fixed by the annular ligament to the margin of the foramen.

The **fenestra cochleae** (*fenestra rotunda*) is situated below and a little behind the fenestra vestibuli, from which it is separated by a rounded elevation, the **promontory**. It is placed at the bottom of a funnel-shaped depression and, in the macerated bone, leads into the cochlea of the internal ear; in the recent state it is closed by a membrane, the **secondary tympanic membrane**, which is concave toward the tympanic cavity, convex toward the cochlea. This membrane consists of three layers: an external, or mucous, derived from the mucous lining of the tympanic cavity; an internal, from the lining membrane of the cochlea; and an intermediate, or fibrous layer.

canal

anal

Mastoid cells DIVIDE IN STYLOMASTOID FORAMEN

FIG. 873.—Coronal section of right temporal bone.

The **promontory** (*promontorium*) is a rounded hollow prominence, formed by the projection outward of the first turn of the cochlea; it is placed between the fenestrae, and is furrowed on its surface by small grooves, for the lodgement of branches of the tympanic plexus. A minute spicule of bone frequently connects the promontory to the pyramidal eminence.

The **prominence of the facial canal** (*prominentia canalis facialis*; *prominence of aqueduct of Fallopius*) indicates the position of the bony canal in which the facial nerve is contained; this canal traverses the labyrinthine wall of the tympanic cavity above the fenestra vestibuli, and behind that opening curves nearly vertically downward along the mastoid wall.

The **mastoid** or **posterior wall** (*paries mastoidea*) is wider above than below, and presents for examination the **entrance to the tympanic antrum**, the **pyramidal eminence**, and the **fossa incudis**.

The **entrance to the antrum** is a large irregular aperture, which leads backward from the epitympanic recess into a considerable air space, named the **tympanic** or **mastoid antrum** (see page 240). The antrum communicates behind and below with the **mastoid air cells**, which vary considerably in number, size, and form; the antrum and mastoid air cells are lined by mucous membrane, continuous with that lining the tympanic cavity. On the medial wall of the entrance to the antrum is a rounded eminence, situated above and behind the prominence of the facial canal; it corresponds with the position of the ampullated ends of the superior and lateral semicircular canals.

The **pyramidal eminence** (*eminentia pyramidalis*; *pyramid*) is situated immediately behind the fenestra vestibuli, and in front of the vertical portion of the facial canal; it is hollow, and contains the Stapedius muscle; its summit projects forward toward the fenestra vestibuli, and is pierced by a small aperture which transmits the tendon of the muscle. The cavity in the pyramidal eminence is prolonged downward and backward in front of the facial canal, and communicates with it by a minute aperture which transmits a twig from the facial nerve to the Stapedius muscle.

The **fossa incudis** is a small depression in the lower and back part of the epitympanic recess; it lodges the short crus of the incus.

The **Carotid** or **Anterior Wall** (*paries carotica*) is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone perforated by the tympanic branch of the internal carotid artery, and by the deep petrosal nerve which connects the sympathetic plexus on the internal carotid artery with the tympanic plexus on the promontory. At the upper part of the anterior wall are the orifice of the semicanal for the Tensor tympani muscle and the tympanic orifice of the auditory tube, separated from each other by a thin horizontal plate of bone, the **septum canalis musculotubarii**. These canals run from the tympanic cavity forward and downward to the retiring angle between the squama and the petrous portion of the temporal bone.

The **semicanal for the Tensor tympani** (*semicanalis m. tensoris tympani*) is the superior and the smaller of the two; it is cylindrical and lies beneath the tegmen tympani. It extends on to the labyrinthine wall of the tympanic cavity and ends immediately above the fenestra vestibuli.

The **septum canalis musculotubarii** (*processus cochleariformis*) passes backward below this semicanal, forming its lateral wall and floor; it expands above the anterior end of the fenestra vestibuli and terminates there by curving laterally so as to form a pulley over which the tendon of the muscle passes.

The **auditory tube** (*tuba auditiva*; *Eustachian tube*) is the channel through which the tympanic cavity communicates with the nasal part of the pharynx. Its length is about 36 mm., and its direction is downward, forward, and medialward, forming an angle of about 45 degrees with the sagittal plane and one of from 30 to 40 degrees with the horizontal plane. It is formed partly of bone, partly of cartilage and fibrous tissue (Fig. 869).

The **osseous portion** (*pars osseo tubae auditivae*) is about 12 mm. in length. It begins in the carotid wall of the tympanic cavity, below the septum canalis musculotubarii, and, gradually narrowing, ends at the angle of junction of the squama and the petrous portion of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion.

The **cartilaginous portion** (*pars cartilaginea tubae auditivae*), about 24 mm. in length, is formed of a triangular plate of elastic fibrocartilage, the apex of which is attached to the margin of the medial end of the osseous portion of the tube, while its base lies directly under the mucous membrane of the nasal part of the pharynx, where it forms an elevation, the **torus tubarius** or **cushion**, behind the pharyngeal orifice of the tube. The upper edge of the cartilage is curled upon itself, being bent later-

so as to present on transverse section the appearance of a hook; a groove or furrow is thus produced, which is open below and laterally, and this part of the canal is completed by fibrous membrane. The cartilage lies in a groove between the petrous part of the temporal and the great wing of the sphenoid; this groove ends opposite the middle of the medial pterygoid plate. The cartilaginous and bony portions of the tube are not in the same plane, the former inclining downward a little more than the latter. The diameter of the tube is not uniform throughout, being greatest at the pharyngeal orifice, least at the junction of the bony and cartilaginous portions, and again increased toward the tympanic cavity; the narrowest part of the tube is termed the **isthmus**. The position and relations of the pharyngeal orifice are described with the nasal part of the pharynx. The mucous membrane of the tube is continuous in front with that of the nasal part of the pharynx, and behind with that of the tympanic cavity; it is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and near the pharyngeal orifice a considerable amount of adenoid tissue, which has been named by Gerlach the **tube tonsil**. The tube is opened during deglutition by the Salpingopharyngeus and Dilator tubae. The latter arises from the hook of the cartilage and from the membranous part of the tube, and blends below with the Tensor veli palatini.

The Auditory Ossicles (*Ossicula Auditus*).

The tympanic cavity contains a chain of three movable ossicles, the **malleus**, **incus**, and **stapes**. The first is attached to the tympanic membrane, the last to the circumference of the fenestra vestibuli, the incus being placed between and connected to both by delicate articulations.

The **Malleus** (Fig. 874), so named from its fancied resemblance to a hammer, consists of a **head**, **neck**, and three processes, viz., the **manubrium**, the **anterior** and **lateral processes**.

The **head** (*capitulum mallei*) is the large upper extremity of the bone; it is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent. The facet for articulation with the incus is constricted near the middle, and consists of an upper larger and lower smaller part, which form nearly a right angle with each other. Opposite the constriction the lower margin of the facet projects in the form of a process, the **cog-tooth** or **spur of the malleus**.

The **neck** (*collum mallei*) is the narrow contracted part just beneath the head; below it, is a prominence, to which the various processes are attached.

The **manubrium mallei** (*handle*) is connected by its lateral margin with the tympanic membrane. It is directed downward, medialward, and backward; it decreases in size toward its free end, which is curved slightly forward, and flattened transversely. On its medial side, near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted.

The **anterior process** (*processus anterior* [Folii]; *processus gracilis*) is a delicate spicule, which springs from the eminence below the neck and is directed forward

FIG. 874.—Left malleus. A. From behind. B. From within.

The *Tragicus* is a short, flattened vertical band on the lateral surface of the tragus.

The *Antitragicus* arises from the outer part of the antitragus, and is inserted into the cauda helieis and antihelix.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the eminentia conchæ to the prominence corresponding with the scapha.

The *Obliquus auriculæ*, also on the cranial surface, consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

Nerves.—The Auriculares anterior and superior and the intrinsic muscles on the lateral surface are supplied by the temporal branch of the facial nerve, the Auricularis posterior and the intrinsic muscles on the cranial surface by the posterior auricular branch of the same nerve.

The *arteries of the auricle* are the posterior auricular from the external carotid, the anterior auricular from the superficial temporal, and a branch from the occipital artery.

The *veins* accompany the corresponding arteries.

The *sensory nerves* are: the great auricular, from the cervical plexus; the auricular branch of the vagus; the auriculotemporal branch of the mandibular nerve; and the lesser occipital from the cervical plexus.

Cartilages of auricle

<i>Cartilaginous part of ext. acoustic meatus</i>	<i>Bony part of ext. acoustic meatus</i>
---	--

FIG. 869.—External and middle ear, opened from the front. Right side

The **External Acoustic Meatus** (*meatus acusticus externus*; *external auditory canal or meatus*) extends from the bottom of the concha to the tympanic membrane (Figs. 869, 870). It is about 4 cm. in length if measured from the tragus; from the bottom of the concha its length is about 2.5 cm. It forms an S-shaped curve, and is directed at first inward, forward, and slightly upward (*pars externa*); it then passes inward and backward (*pars media*), and lastly is carried inward, forward, and slightly downward (*pars interna*). It is an oval cylindrical canal, the greatest diameter being directed downward and backward at the external orifice, but nearly horizontally at the inner end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the *isthmus*, in the osseous portion, about 2 cm. from the bottom of the concha. The tympanic membrane, which closes the inner end of the meatus, is obliquely directed; in consequence of this the floor and anterior wall of the meatus are longer than the roof and posterior wall.

The external acoustic meatus is formed partly by cartilage and membrane, and partly by bone, and is lined by skin.

The **cartilaginous portion** (*meatus acusticus externus cartilagineus*) is about 8 mm. in length; it is continuous with the cartilage of the auricula, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at the upper and back part of the meatus, its place being supplied by fibrous membrane; two or three deep fissures are present in the anterior part of the cartilage.

The **osseous portion** (*meatus acusticus externus osseus*) is about 16 mm. in length, and is narrower than the cartilaginous portion. It is directed inward and a little forward, forming in its course a slight curve the convexity of which is upward and backward. Its inner end is smaller than the outer, and sloped, the anterior wall

FIG. 870.—Horizontal section through left ear; upper half of section.

projecting beyond the posterior for about 4 mm.; it is marked, except at its upper part, by a narrow groove, the **tympanic sulcus**, in which the circumference of the tympanic membrane is attached. Its outer end is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the auricula. The front and lower parts of the osseous portion are formed by a curved plate of bone, the tympanic part of the temporal, which, in the fetus, exists as a separate ring (**annulus tympanicus**), incomplete at its upper part (page 245).

The **skin** lining the meatus is very thin; adheres closely to the cartilaginous and osseous portions of the tube, and covers the outer surface of the tympanic membrane. After maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which secrete the ear-wax; their structure resembles that of the sudoriferous glands.

Relations of the Meatus.—In front of the osseous part is the condyle of the mandible, which, however, is frequently separated from the cartilaginous part by a portion of the parotid gland. The movements of the jaw influence to some extent the lumen of this latter portion. Behind the osseous part are the mastoid air cells, separated from the meatus by a thin layer of bone.

The **arteries** supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The **nerves** are chiefly derived from the auriculotemporal branch of the mandibular nerve and the auricular branch of the vagus.

The *Tragicus* is a short, flattened vertical band on the lateral surface of the tragus.

The *Antitragicus* arises from the outer part of the antitragus, and is inserted into the cauda helix and antihelix.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the eminentia conchæ to the prominence corresponding with the scapha.

The *Obliquus auriculæ*, also on the cranial surface, consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

Nerves.—The Auriculares anterior and superior and the intrinsic muscles on the lateral surface are supplied by the temporal branch of the facial nerve, the Auricularis posterior and the intrinsic muscles on the cranial surface by the posterior auricular branch of the same nerve.

The *arteries of the auricula* are the posterior auricular from the external carotid, the anterior auricular from the superficial temporal, and a branch from the occipital artery.

The *veins* accompany the corresponding arteries.

The *sensory nerves* are: the great auricular, from the cervical plexus; the auricular branch of the vagus; the auriculotemporal branch of the mandibular nerve; and the lesser occipital from the cervical plexus.

Cartilages of auricula

<i>Cartilaginous part of ext. acoustic meatus</i>	<i>Bony part of ext. acoustic meatus</i>
---	--

FIG. 869. —External and middle ear, opened from the front. Right side.

The **External Acoustic Meatus** (*meatus acusticus externus*; *external auditory canal or meatus*) extends from the bottom of the concha to the tympanic membrane (Figs. 869, 870). It is about 4 cm. in length if measured from the tragus; from the bottom of the concha its length is about 2.5 cm. It forms an S-shaped curve, and is directed at first inward, forward, and slightly upward (*pars externa*); it then passes inward and backward (*pars media*), and lastly is carried inward, forward, and slightly downward (*pars interna*). It is an oval cylindrical canal, the greatest diameter being directed downward and backward at the external orifice, but nearly horizontally at the inner end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the *isthmus*, in the osseous portion, about 2 cm. from the bottom of the concha. The tympanic membrane, which closes the inner end of the meatus, is obliquely directed; in consequence of this the floor and anterior wall of the meatus are longer than the roof and posterior wall.

The external acoustic meatus is formed partly by cartilage and membrane, and partly by bone, and is lined by skin.

The **cartilaginous portion** (*meatus acusticus externus cartilagineus*) is about 8 mm. in length; it is continuous with the cartilage of the auricula, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at the upper and back part of the meatus, its place being supplied by fibrous membrane; two or three deep fissures are present in the anterior part of the cartilage.

The **osseous portion** (*meatus acusticus externus osseus*) is about 16 mm. in length, and is narrower than the cartilaginous portion. It is directed inward and a little forward, forming in its course a slight curve the convexity of which is upward and backward. Its inner end is smaller than the outer, and sloped, the anterior wall

FIG. 870.—Horizontal section through left ear; upper half of section.

projecting beyond the posterior for about 4 mm.; it is marked, except at its upper part, by a narrow groove, the **tympanic sulcus**, in which the circumference of the tympanic membrane is attached. Its outer end is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the auricula. The front and lower parts of the osseous portion are formed by a curved plate of bone, the tympanic part of the temporal, which, in the fetus, exists as a separate ring (**annulus tympanicus**), incomplete at its upper part (page 245).

The **skin** lining the meatus is very thin; adheres closely to the cartilaginous and osseous portions of the tube, and covers the outer surface of the tympanic membrane. After maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which secrete the ear-wax; their structure resembles that of the sudoriferous glands.

Relations of the Meatus.—In front of the osseous part is the condyle of the mandible, which however, is frequently separated from the cartilaginous part by a portion of the parotid gland. The movements of the jaw influence to some extent the lumen of this latter portion. Behind the osseous part are the mastoid air cells, separated from the meatus by a thin layer of bone.

The **arteries** supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The **nerves** are chiefly derived from the auriculotemporal branch of the mandibular nerve and the auricular branch of the vagus.

These are cavities hollowed out of the substance of the bone, and lined by periosteum; they contain a clear fluid, the perilymph, in which the membranous labyrinth is situated.

The Vestibule (*vestibulum*).—The vestibule is the central part of the osseous labyrinth, and is situated medial to the tympanic cavity, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoid in shape, but flattened transversely; it measures about 5 mm. from before backward, the same from above downward, and about 3 mm. across. In its *lateral* or *tympanic wall* is the **fenestra vestibuli**, closed, in the recent state, by the base of the stapes and annular ligament. On its *medial wall*, at the forepart, is a small circular depression, the **recessus sphaericus**, which is perforated, at its anterior and inferior part, by several minute holes (**macula cribrosa media**) for the passage of filaments of the acoustic nerve to the sacculæ; and behind this depression is an oblique ridge, the **crista vestibuli**, the anterior end of which is named the **pyramid of the vestibule**. This ridge bifurcates below to enclose a small depression, the **fossa cochlearis**, which is perforated by a number of holes for the passage of filaments of the acoustic nerve which supply the vestibular end of the ductus cochlearis. As the hinder part of the medial wall

x10

Cochlear fenestra

FIG. 878.—Interior of right osseous labyrinth.

is the orifice of the **aqueductus vestibuli**, which extends to the posterior surface of the petrous portion of the temporal bone. It transmits a small vein, and contains a tubular prolongation of the membranous labyrinth, the **ductus endolymphaticus**, which ends in a cul-de-sac between the layers of the dura mater within the cranial cavity. On the *upper wall* or *roof* is a transversely oval depression, the **recessus ellipticus**, separated from the recessus sphaericus by the crista vestibuli already mentioned. The pyramid and adjoining part of the recessus ellipticus are perforated by a number of holes (**macula cribrosa superior**). The apertures in the pyramid transmit the nerves to the utricle; those in the recessus ellipticus the nerves to the ampullæ of the superior and lateral semicircular ducts. *Behind* are the five orifices of the semicircular canals. In *front* is an elliptical opening, which communicates with the scala vestibuli of the cochlea.

The Bony Semicircular Canals (*canales semicirculares ossei*).—The bony semicircular canals are three in number, **superior**, **posterior**, and **lateral**, and are situated above and behind the vestibule. They are unequal in length, compressed from side to side, and each describes the greater part of a circle. Each measures about 0.8 mm. in diameter, and presents a dilatation at one end, called the **ampulla**, which

measures more than twice the diameter of the tube. They open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The **superior semicircular canal** (*canalis semicircularis superior*), 15 to 20 mm. in length, is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which its arch forms a round projection. It describes about two-thirds of a circle. Its lateral extremity is ampullated, and opens into the upper part of the vestibule; the opposite end joins with the upper part of the posterior canal to form the **crus commune**, which opens into the upper and medial part of the vestibule.

The **posterior semicircular canal** (*canalis semicircularis posterior*), also vertical, is directed backward, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three, measuring from 18 to 22 mm.; its lower or ampullated end opens into the lower and back part of the vestibule, its upper into the crus commune already mentioned.

FIG. 879.—The cochlea and vestibule, viewed from above. (Testut.) All the hard parts which form the roof of the internal ear have been removed with the saw. A Cochlea. B, Vestibule. C Internal acoustic meatus. D, Tympanic cavity. 1 Lower border of vestibular fenestra. 2 Fissura vestibuli. 3. Recessus sphaericus. 4 Recessus ellipticus. 5. Fossa cochlearis. 6. Orifice of the aquaeductus vestibuli. 7. Inferior opening of the posterior semicircular canal. 8. Non-ampullated end of lateral semicircular canal. 9. Scala tympani of the cochlea. 10. Scala vestibuli. 11. Cupula. 12. Lamina spiralis ossea, with 12', its vestibular origin; 12'', its external border. 13. Helicotrema. 14. Bony wall of cochlea.

The **lateral or horizontal canal** (*canalis semicircularis lateralis*; *external semicircular canal*) is the shortest of the three. It measures from 12 to 15 mm., and its arch is directed horizontally backward and lateralward; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and lateral angle of the vestibule, just above the fenestra vestibuli, where it opens close to the ampullated end of the superior canal; its opposite end opens at the upper and back part of the vestibule. The lateral canal of one ear is very nearly in the same plane as that of the other; while the superior canal of one ear is nearly parallel to the posterior canal of the other.

The **Cochlea** (Figs. 878, 879).—The cochlea bears some resemblance to a common snail-shell; it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its **apex** (*cupula*) is directed forward and lateralward, with a slight inclination downward, toward the upper and front

part of the labyrinthic wall of the tympanic cavity; its **base** corresponds with the bottom of the internal acoustic meatus, and is perforated by numerous apertures for the passage of the cochlear division of the acoustic nerve. It measures about 5 mm. from base to apex, and its breadth across the base is about 9 mm. It consists of a conical shaped central axis, the **modiolus**; of a canal, the inner wall of which is formed by the central axis, wound spirally around it for two turns and three-quarters, from the base to the apex; and of a delicate lamina, the **osseous spiral lamina**, which projects from the modiolus, and, following the windings of the canal, partially subdivides it into two. In the recent state a membrane, the **basilar membrane**, stretches from the free border of this lamina to the outer wall of the bony cochlea and completely separates the canal into two passages, which, however, communicate with each other at the apex of the modiolus by a small opening, named the **helicotrema**.

The **modiolus** is the conical central axis or pillar of the cochlea. Its base is broad, and appears at the bottom of the internal acoustic meatus, where it corresponds with the area cochleae; it is perforated by numerous orifices, which transmit filaments of the cochlear division of the acoustic nerve; the nerves for the first turn and a half pass through the foramina of the tractus spiralis foraminosus; those for the apical turn, through the foramen centrale. The canals of the tractus spiralis foraminosus pass up through the modiolus and successively bend outward to reach the attached margin of the lamina spiralis ossea. Here they become enlarged, and by their apposition form the **spiral canal of the modiolus**, which follows the course of the attached margin of the osseous spiral lamina and lodges the **spiral ganglion** (*ganglion of Corti*). The foramen centrale is continued into a canal which runs up the middle of the modiolus to its apex. The modiolus diminishes rapidly in size in the second and succeeding coil.

The bony canal of the cochlea takes two turns and three-quarters around the modiolus. It is about 30 mm. in length, and diminishes gradually in diameter from the base to the summit, where it terminates in the **cupula**, which forms the apex of the cochlea. The beginning of this canal is about 3 mm. in diameter; it diverges from the modiolus toward the tympanic cavity and vestibule, and presents three openings. One, the **fenestra cochleae**, communicates with the tympanic cavity—in the recent state this aperture is closed by the **secondary tympanic membrane**; another, of an elliptical form, opens into the vestibule. The third is the aperture of the aquaeductus cochleae, leading to a minute funnel-shaped canal, which opens on the inferior surface of the petrous part of the temporal bone and transmits a small vein, and also forms a communication between the subarachnoid cavity and the scala tympani.

The **osseous spiral lamina** (*lamina spiralis ossea*) is a bony shelf or ledge which projects from the modiolus into the interior of the canal, and, like the canal, takes two- and three-quarter turns around the modiolus. It reaches about half-way toward the outer wall of the tube, and partially divides its cavity into two passages or *scalæ*, of which the upper is named the **scala vestibuli**, while the lower is termed the **scala tympani**. Near the summit of the cochlea the lamina ends in a hook-shaped process, the **hamulus laminae spiralis**; this assists in forming the boundary of a small opening, the **helicotrema**, through which the two *scalæ* communicate with each other. From the spiral canal of the modiolus numerous canals pass outward through the osseous spiral lamina as far as its free edge. In the lower part of the first turn a second bony lamina, the **secondary spiral lamina**, projects inward from the outer wall of the bony tube; it does not, however, reach the primary osseous spiral lamina, so that if viewed from the vestibule a narrow fissure, the **vestibule fissure**, is seen between them.

The *osseous labyrinth* is lined by an exceedingly thin fibro-serous membrane; its attached surface is rough and fibrous, and closely adherent to the bone; its

free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the **perilymph**. A delicate tubular process of this membrane is prolonged along the aqueduct of the vestibule to the inner surface of the dura mater.

FIG. 880.—The membranous labyrinth. (Enlarged.)

The Membranous Labyrinth (*labyrinthus membranaceus*) (Figs. 880, 881, 882).—The membranous labyrinth is lodged within the bony cavities just described, and has the same general form as these; it is, however, considerably smaller, and

3 4 5 6 7 8 9 11 10 12
1 1 1 1 1 1 1 1 1

is partly separated from the bony walls by a quantity of fluid, the **perilymph**. In certain places it is fixed to the walls of the cavity. The membranous labyrinth contains fluid, the **endolymph**, and on its walls the ramifications of the acoustic nerve are distributed.

Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but consists of two membranous sacs, the **utricle**, and the **sacculus**.

The Utricle (*utriculus*).—The utricle, the larger of the two, is of an oblong form, compressed transversely, and occupies the upper and back part of the vestibule, lying in contact with the recessus ellipticus and the part below it. That portion which is lodged in the recess forms a sort of pouch or cul-de-sac, the floor and anterior wall of which are thickened, and form the **macula acustica utriculi**, which receives the utricular filaments of the acoustic nerve. The cavity of the utricle communicates behind with the semicircular ducts by five orifices. From its anterior wall is given off the **ductus utriculosaccularis**, which opens into the ductus endolymphaticus.

The Sacculus (*sacculus*).—The sacculus is the smaller of the two vestibular sacs; it is globular in form, and lies in the recessus sphaericus near the opening of the scala vestibuli of the cochlea. Its anterior part exhibits an oval thickening, the **macula acustica sacculi**, to which are distributed the saccular filaments of the acoustic nerve. Its cavity does not directly communicate with that of the utricle. From the posterior wall a canal, the **ductus endolymphaticus**, is given off; this duct is joined by the ductus utriculosaccularis, and then passes along the aquaeductus vestibuli and ends in a blind pouch (**sacculus endolymphaticus**) on the posterior surface of the petrous portion of the temporal bone, where it is in contact with the dura mater. From the lower part of the sacculus a short tube, the **canalis reuniens of Hensen**, passes downward and opens into the ductus cochlearis near its vestibular extremity (Fig. 880).

The Semicircular Ducts (*ductus semicirculares*; *membranous semicircular canals*), (Figs. 881, 882).—The semicircular ducts are about one-fourth of the diameter

of the osseous canals, but in number, shape, and general form they are precisely similar, and each presents at one end an ampulla. They open by five orifices into the utricle, one opening being common to the medial end of the superior and the upper end of the posterior duct. In the ampullæ the wall is thickened, and projects into the cavity as a fiddle-shaped, transversely placed elevation, the *septum transversum*, in which the nerves end.

The utricle, saccule, and semicircular ducts are held in position by numerous fibrous bands which stretch across the space between them and the bony walls.

Structure (Fig. 883).—The walls of the utricle, saccule, and semicircular ducts consist of three layers. The *outer layer* is a loose and flocculent structure, apparently composed of ordinary fibrous tissue containing bloodvessels and some pigment-cells. The *middle layer*, thicker and more transparent, forms a homogeneous *membrana propria*, and presents on its internal surface, especially in the semicircular ducts, numerous papilliform projections, which, on the addition of acetic acid, exhibit an appearance of longitudinal fibrillation. The *inner layer* is formed of polygonal nucleated epithelial cells. In the maculæ of the utricle and saccule, and in the transverse septa of the ampullæ of the semicircular ducts, the middle coat is thickened and the epithelium is columnar, and consists of *supporting cells* and *hair cells*. The former are fusiform, and their deep ends are attached to the *membrana propria*, while their free extremities are united to form a thin cuticle. The hair cells are flask-shaped, and their deep, rounded ends do not reach the *membrana propria*, but lie between the supporting cells. The deep part of each contains a large nucleus, while its more superficial part is granular and pigmented. The free end is surmounted by a long, tapering, hair-like filament, which projects into the cavity. The filaments of the acoustic nerve enter these parts, and having pierced the outer and middle layers, they lose their medullary sheaths, and their axis-cylinders ramify between the hair cells.

Two small rounded bodies termed *otoconia*, and consisting of a mass of minute crystalline grains of carbonate of lime, held together in a mesh of gelatinous tissue, are suspended in the endolymph in contact with the free ends of the hairs projecting from the maculæ. According to Bowman, a calcareous material is also sparingly scattered in the cells lining the ampullæ of the semicircular ducts.

The Ductus Cochlearis (*membranous cochlea; scala media*).—The ductus cochlearis consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall.

As already stated, the osseous spiral lamina extends only part of the distance between the modiolus and the outer wall of the cochlea, while the *basilar membrane* stretches from its free edge to the outer wall of the cochlea, and completes the roof of the *scala tympani*. A second and more delicate membrane, the *vestibular membrane* (*Reissneri*) extends from the thickened periosteum covering the osseous spiral lamina to the outer wall of the cochlea, where it is attached at some little distance above the outer edge of the basilar membrane. A canal is thus shut off between the *scala tympani* below and the *scala vestibuli* above; this is the *ductus*

5

2

cochlearis or **scala media** (Fig. 884). It is triangular on transverse section, its roof being formed by the vestibular membrane, its outer wall by the periosteum lining the bony canal, and its floor by the **membrana basilaris** and the outer part of the **lamina spiralis ossæ**. Its extremities are closed; the upper is termed the **lagena** and is attached to the cupula at the upper part of the **helicotrema**; the lower is lodged in the **recessus cochlearis** of the vestibule. Near the lower end the **ductus**

FIG. 884.—Diagrammatic longitudinal section of the cochlea.

cochlearis is brought into continuity with the saccule by a narrow, short canal, the **canalis reuniens of Hensen** (Fig. 880). On the **membrana basilaris** is situated the **spiral organ of Corti**. The vestibular membrane is thin and homogeneous, and is covered on its upper and under surfaces by a layer of epithelium. The periosteum, forming the outer wall of the **ductus cochlearis**, is greatly thickened and altered in character, and is called the **spiral ligament**. It projects inward below as a triangular prominence, the **basilar crest**, which gives attachment to the outer

FIG. 885.—Floor of ductus cochlearis.

edge of the **basilar membrane**; immediately above the crest is a concavity, the **sulcus spiralis externus**. The upper portion of the **spiral ligament** contains numerous capillary loops and small bloodvessels, and is termed the **stria vascularis**.

The **osseous spiral lamina** consists of two plates of bone, and between these are the canals for the transmission of the filaments of the **acoustic nerve**. On the upper plate of that part of the lamina which is outside the vestibular membrane, the perios-

teum is thickened to form the *limbus laminae spiralis* (Fig. 885), this ends externally in a concavity, the *sulcus spiralis internus*, which represents, on section, the form of the letter C; the upper part, formed by the overhanging extremity of the limbus, is named the *vestibular lip*; the lower part, prolonged and tapering, is called the *tympanic lip*, and is perforated by numerous foramina for the passage of the cochlear nerves. The upper surface of the vestibular lip is intersected at right angles by a number of furrows, between which are numerous elevations; these present the appearance of teeth along the free surface and margin of the lip, and have been named by Huschke the *auditory teeth* (Fig. 886). The limbus is covered by a layer of what appears to be squamous epithelium, but the deeper parts of the cells with their contained nuclei occupy the intervals between the elevations and between the auditory teeth. This layer of epithelium is continuous on the one hand with that lining the *sulcus spiralis internus*, and on the other with that covering the under surface of the vestibular membrane.

FIG. 886.—*Limbus laminae spiralis* and *membrana basilaris*. (Schematic.) (Testut.) 1, 1'. Foramina nervosa, giving passage to the nerves from the ganglion spirale or ganglion of Corti. 5. *Vas spirale*. 6. *Zona arcuata*, and 6', *zona pectinata* of the basilar membrane, with *a*, its hyaline layer, *β*, its connective-tissue layer. 7. Arch of spiral organ, with 7', its inner rod, and 7'', its outer rod. 8. Feet of the internal rods, from which the cells are removed. 9. Feet of the external rods. 10. Vestibular membrane, at its origin.

Basilar Membrane.—The basilar membrane stretches from the tympanic lip of the osseous spiral lamina to the basilar crest and consists of two parts, an inner and an outer. The inner is thin, and is named the *zona arcuata*: it supports the spiral organ of Corti. The outer is thicker and striated, and is termed the *zona pectinata*. The under surface of the membrane is covered by a layer of vascular connective tissue; one of the vessels in this tissue is somewhat larger than the rest, and is named the *vas spirale*; it lies below Corti's tunnel.

The *spiral organ of Corti* (*organon spirale* [Corti]; *organ of Corti*) (Figs. 887, 888) is composed of a series of epithelial structures placed upon the inner part of the basilar membrane. The more central of these structures are two rows of rod-like bodies, the *inner and outer rods* or *pillars of Corti*. The bases of the rods are supported on the basilar membrane, those of the inner row at some distance from those of the outer; the two rows incline toward each other and, coming into contact above, enclose between them and the basilar membrane a triangular tunnel, the *tunnel of Corti*. On the inner side of the inner rods is a single row of hair cells, and on the outer side of the outer rods three or four rows of similar cells, together with certain

supporting cells termed the cells of Deiters and Hensen. The free ends of the outer hair cells occupy a series of apertures in a net-like membrane, the **reticular membrane**, and the entire organ is covered by the tectorial membrane.

FIG. 887.—Section through the spiral organ of Corti. Magnified. (G. Retzius.)

RODS OF CORTI.—Each of these consists of a base or foot-plate, and elongated part or body, and an upper end or head; the body of each rod is finely striated, but in the head there is an oval non-striated portion which stains deeply with carmine.

FIG. 888.—The lamina reticularis and subjacent structures. (Schematic) (Testut.) *A.* Internal rod of Corti, with *a*, its plate. *B.* External rod (in yellow). *C.* Tunnel of Corti. *D.* Membrana basilaris. *E.* Inner hair cells. 1, 1' Internal and external borders of the membrana reticularis. 2, 2', 2". The three rows of circular holes (in blue). 3. First row of phalanges (in yellow). 4, 4', 4". Second, third, and fourth rows of phalanges (in red). 5, 5', 5". The three rows of outer hair cells (in blue). 7, 7', 7". Cells of Deiters. 8. Cells of Hensen and Claudius.

Occupying the angles between the rods and the basilar membrane are nucleated cells which partly envelop the rods and extend on to the floor of Corti's tunnel; these may be looked upon as the undifferentiated parts of the cells from which the rods have been formed.

The **inner rods** number nearly 6000, and their bases rest on the basilar membrane close to the tympanic lip of the sulcus spiralis internus. The shaft or body of each is sinously curved and forms an angle of about 60 degrees with the basilar membrane. The head resembles the proximal end of the ulna and presents a deep concavity which accommodates a convexity on the head of the outer rod. The head-plate, or portion overhanging the concavity, overlaps the head-plate of the outer rod.

The **outer rods**, nearly 4000 in number, are longer and more obliquely set than the inner, forming with the basilar membrane an angle of about 40 degrees. Their heads are convex internally; they fit into the concavities on the heads of the inner rods and are continued outward as thin flattened plates, termed **phalangeal processes**, which unite with the phalangeal processes of Deiters' cells to form the reticular membrane.

Hair Cells.—The hair cells are short columnar cells; their free ends are on a level with the heads of Corti's rods, and each is surmounted by about twenty hair-like processes arranged in the form of a crescent with its concavity directed inward. The deep ends of the cells reach about half-way along Corti's rods, and each contains a large nucleus; in contact with the deep ends of the hair cells are the terminal filaments of the cochlear division of the acoustic nerve. The *inner* hair cells are arranged in a single row on the medial side of the inner rods, and their diameters being greater than those of the rods it follows that each hair cell is supported by more than one rod. The free ends of the inner hair cells are encircled by a cuticular membrane which is fixed to the heads of the inner rods. Adjoining the inner hair cells are one or two rows of columnar supporting cells, which, in turn, are continuous with the cubical cells lining the sulcus spiralis internus. The *outer* hair cells number about 12,000, and are nearly twice as long as the inner. In the basal coil of the cochlea they are arranged in three regular rows; in the apical coil, in four, somewhat irregular, rows.

Between the rows of the outer hair cells are rows of supporting cells, called the **cells of Deiters**; their expanded bases are planted on the basilar membrane, while the opposite end of each presents a clubbed extremity or **phalangeal process**. Immediately to the outer side of Deiters' cells are five or six rows of columnar cells, the **supporting cells of Hensen**. Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen's cells are termed the **cells of Claudius**. A space exists between the outer rods of Corti and the adjacent hair cells; this is called the **space of Nuel**.

The **reticular lamina** (Fig. 888) is a delicate frame-work perforated by rounded holes which are occupied by the free ends of the outer hair cells. It extends from the heads of the outer rods of Corti to the external row of the outer hair cells, and is formed by several rows of "minute fiddle-shaped cuticular structures," called **phalanges**, between which are circular apertures containing the free ends of the hair cells. The inner most row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters' cells.

Covering the sulcus spiralis internus and the spiral organ of Corti is the **tectorial membrane**, which is attached to the limbus laminae spiralis close to the inner edge of the vestibular membrane. Its inner part is thin and overlies the auditory teeth of Huschke; its outer part is thick, and along its lower edge, opposite the inner hair cells, is a clear band, named **Hensen's stripe**. The lateral margin of the membrane is much thinner, and is attached to the outer row of Deiters' cells (Retzius).

The **acoustic nerve** (*n. acusticus*; *auditory nerve* or *nerve of hearing*) divides near the bottom of the internal acoustic meatus into an anterior or cochlear and a posterior or vestibular branch.

The **vestibular nerve** (*n. vestibularis*) supplies the utricle, the saccule, and the ampullæ of the semicircular ducts. On the trunk of the nerve, within the internal acoustic meatus, is a ganglion, the **vestibular ganglion** (*ganglion of Scarpa*); the fibres of the nerve arise from the cells of this ganglion. On the distal side of the ganglion the nerve splits into a superior, an inferior, and a posterior branch.¹ The filaments of the *superior branch* are transmitted through the foramina in the area vestibularis superior, and end in the macula of the utricle and in the ampullæ of the superior and lateral semicircular ducts; those of the *inferior branch* traverse the foramina in the area vestibularis inferior, and end in the macula of the saccule. The *posterior branch* runs through the foramen singulare at the postero-inferior part of the bottom of the meatus and divides into filaments for the supply of the ampulla of the posterior semicircular duct.

The **cochlear nerve** (*n. cochlearis*) divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the

Ganglion Spiral Nerve-fibres passing out
spirale fibres between the two layers of
the lamina spiralis ossea

tractus spiralis foraminosis, those for the apical coil through the canalis centralis, and the nerves bend outward to pass between the lamellæ of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the **spiral ganglion of the cochlea** (*ganglion of Corti*) (Fig. 889), consisting of bipolar nerve cells, which constitute the cells of origin of this nerve. Reaching the outer edge of the osseous spiral lamina, the fibres of the nerve pass through the foramina in the tympanic lip; some end by arborizing around the bases of the inner hair cells, while others pass

FIG. 889.—Part of the cochlear division of the acoustic nerve, highly magnified. (Henle.)

between Corti's rods and across the tunnel, to end in a similar manner in relation to the outer hair cells. The cochlear nerve gives off a vestibular branch to supply the vestibular end of the ductus cochlearis; the filaments of this branch pass through the foramina in the fossa cochlearis (page 1058).

Vessels. The **arteries of the labyrinth** are the internal auditory, from the basilar, and the stylomastoid, from the posterior auricular. The internal auditory artery divides at the bottom of the internal acoustic meatus into two branches: cochlear and vestibular. The cochlear branch subdivides into twelve or fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary net-work, in the lamina spiralis and basilar membrane. The vestibular branches are distributed to the utricle, saccule, and semicircular ducts.

The **veins** of the vestibule and semicircular canals accompany the arteries, and, receiving those of the cochlea at the base of the modiolus, unite to form the internal auditory veins which end in the posterior part of the superior petrosal sinus or in the transverse sinus.

Applied Anatomy.—The diseased conditions which may be found in the internal ear usually result from the spread of a suppurative process from the middle ear—thus in chronic suppuration of the latter, destruction of the internal ear may take place, with necrosis of parts of the cochlea or vestibule. Such cases will be associated with "nerve deafness," and the disease may spread by means of the sheaths of the facial and acoustic nerves into the posterior fossa of the skull.

Hemorrhage occasionally occurs into the labyrinth in certain blood disorders, resulting in complete nerve deafness, and such conditions may be associated with symptoms known as *Ménière's disease*, vertigo, giddiness, and tinnitus. Nerve deafness is diagnosticated when all "bone-conduction" of sound is lost, and is most commonly seen in patients suffering from congenital syphilis, many deaf-mutes being the subjects of this condition.

¹ The nerve sometimes splits on the proximal side of the ganglion, and the latter is then divided into three parts, one on each branch of the nerve.

PERIPHERAL TERMINATIONS OF NERVES OF GENERAL SENSATIONS.

The peripheral terminations of the nerves associated with general sensations, i. e., the muscular sense and the senses of heat, cold, pain, and pressure, are widely distributed throughout the body. These nerves may end *free* among the tissue elements, or in *special end-organs* where the terminal nerve filaments are enclosed in capsules.

Free nerve-endings occur chiefly in the epidermis and in the epithelium covering certain mucous membranes; they are well seen also in the stratified squamous epithelium of the cornea, and are also found in the root-sheaths and papillæ of the hairs, and around the bodies of the sudoriferous glands. When the nerve fibre approaches its termination, the medullary sheath suddenly disappears, leaving only the axis-cylinder surrounded by the neurolemma. After a time the fibre loses its neurolemma, and consists only of an axis-cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrillæ. Finally, the axis-cylinder breaks up into its constituent fibrillæ which often present regular varicosities and anastomoses with one another, and end in small knobs or disks between the epithelial cells.

Under this heading may be classed the **tactile disks** described by Merkel as occurring in the epidermis of the pig's snout, where the fibrillæ of the axis-cylinder end in cup-shaped disks in apposition with large epithelial cells.

The **special end-organs** exhibit great variety in size and shape, but have one feature in common—viz., the terminal nerve fibrillæ are enveloped by a capsule. Included in this group are the end-bulbs of Krause, the corpuscles of Grandry, of Pacini, of Golgi and Mazzoni, of Wagner and Meissner, and the neurotendinous and neuromuscular spindles.

The **end-bulbs of Krause** (Fig. 890) are minute cylindrical or oval bodies, consisting of a capsule formed by the expansion of the connective-tissue sheath of a medullated fibre, and containing a soft semifluid core in which the axis-cylinder terminates either in a bulbous extremity or in a coiled-up plexiform mass. End-bulbs are found in the conjunctiva of the eye (where they are spheroidal in shape in man, but cylindrical in most other animals), in the mucous membrane of the lips and tongue, and in the epineurium of nerve trunks. They are also found in the penis and the clitoris, and have received the name of **genital corpuscles**; in these situations they have a mulberry-like appearance, being constricted by connective-tissue septa into from two to six knob-like masses. In the synovial membranes of certain joints, e. g., those of the fingers, rounded or oval end-bulbs occur, and are designated **articular end-bulbs**.

The **tactile corpuscles of Grandry** occur in the papillæ of the beak and tongue of birds. Each consists of a capsule composed of a very delicate, nucleated membrane, and contains two or more granular, somewhat flattened cells; between these cells the axis-cylinder ends in flattened disks.

The **Pacinian corpuscles** (Fig. 891) are found in the subcutaneous tissue on the nerves of the palm of the hand and sole of the foot and in the genital organs of both sexes; they also occur in connection with the nerves of the joints, and in some other situations, as in the mesentery and pancreas of the cat and along the tibia of the rabbit. Each of these corpuscles is attached to and encloses the termination of a single nerve fibre. The corpuscle, which is perfectly visible to the naked eye (and which can be most easily demonstrated in the mesentery of a cat), consists of a number of lamellæ or capsules arranged more or less concentrically around a central clear space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective-tissue fibres, and is lined on its inner surface by a single layer of flattened epithelioid cells. The central clear space, which is elongated or cylindrical in shape, is filled with a transparent core, in the middle of which the axis-cylinder traverses the space to near its distal extremity, where it ends in one or more small knobs. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space.

Herbst has described a nerve-ending somewhat similar to the Pacinian corpuscle, in the mucous membrane of the tongue of the duck, and in some other situations. It differs, however, from the Pacinian corpuscle, in being smaller, its capsules being more closely approximated, and especially in the fact that the axis cylinder in the central clear space is coated with a continuous row of nuclei. These bodies are known as the **corpuscles of Herbst**.

The **corpuscles of Golgi and Mazzoni** are found in the subcutaneous tissue of the pulp of the fingers. They differ from Pacinian corpuscles in that their capsules are thinner, their contained cores thicker, and in the latter the axis-cylinders ramify more extensively and end in flat expansions.

FIG. 890. — End-bulb of Krause. a. Medullated nerve fibre. b. Capsule of corpuscle. (Klein.)

The tactile corpuscles of Wagner and Meissner (Fig. 892) are oval-shaped bodies. Each is enveloped by a connective-tissue capsule, and imperfect membranous septa derived from this penetrate the interior. The axis-cylinder passes through the capsule, and after making several spiral turns around the body of the corpuscle ends in small globular or pyriform enlargements. These tactile corpuscles occur in the papillae of the corium of the hand and foot, the front of the forearm, the skin of the lips, the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the mammary papilla.

Corpuscles of Ruffini.—Ruffini described a special variety of nerve-ending in the subcuta-

FIG. 891. Pacinian corpuscle, with its system of capsules and central cavity. *a*. neous tissue of the human finger (Fig. 893); they are principally situated at the junction of the corium with the subcutaneous tissue. They are oval in shape, and consist of strong connective-tissue sheaths, inside which the nerve-fibres divide into numerous branches, which show varicosities and end in small free knobs.

FIG. 893.—Nerve ending of Ruffini. (After A. Ruffini.)

The **neurotendinous spindles** (*organs of Golgi*) are chiefly found near the junctions of tendons and muscles. Each is enclosed in a capsule which contains a number of enlarged tendon fasciculi (*intrafusal fasciculi*). One or more nerve fibres perforate the side of the capsule and lose their medullary sheaths; the axis-cylinders subdivide and end between the tendon fibres in irregular disks or varicosities (Fig. 894).

The **neuromuscular spindles** are present in the majority of voluntary muscles, and consist of small bundles of peculiar muscular fibres (*intrafusal fibres*), embryonic in type, invested by capsules, within which nerve fibres, experimentally shown to be sensory in origin, terminate.

Muscular fibres

FIG. 894.—Organ of Golgi (neurotendinous spindle) from the human tendo calcaneus. (After Ciacio.)

These neuromuscular spindles vary in length from 0.8 mm. to 5 mm., and have a distinctly fusiform appearance. The large medullated nerve fibres passing to the end-organ are from one to three or four in number; entering the fibrous capsule, they divide several times, and,

FIG. 895.—Middle third of a terminal plaque in the muscle spindle of an adult cat. (After Ruffini.)

losing their medullary sheaths, ultimately end in naked axis-cylinders encircling the intrafusal fibres by flattened expansions, or irregular ovoid or rounded disks (Fig. 895). Neuromuscular spindles have not yet been demonstrated in the tongue muscles, and only a few exist in the ocular muscles.

THE COMMON INTEGUMENT (INTEGUMENTUM COMMUNE; SKIN).

The **integument** (Fig. 896) covers the body and protects the deeper tissues; it contains the peripheral endings of many of the sensory nerves; it plays an important part in the regulation of the body temperature, and has also limited excretory and absorbing powers. It consists principally of a layer of vascular connective tissue, named the **corium** or **cutis vera**, and an external covering of epithelium, termed the **epidermis** or **cuticle**. On the surface of the former layer are sensitive and **vascular papillæ** within, or beneath it, are certain organs with special functions: namely, the **sudoriferous** and **sebaceous glands**, and the **hair follicles**.

The **epidermis**, **cuticle**, or **scarf skin** is non-vascular, and consists of stratified epithelium (Fig. 897), and is accurately moulded on the papillary layer of the corium. It varies in thickness in different parts. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. This may be in

a measure due to the fact that these parts are exposed to intermittent pressure, but that this is not the only cause is proved by the fact that the condition exists to a very considerable extent at birth. The more superficial layers of cells, called the **horny layer** (*stratum corneum*), may be separated by maceration from a deeper stratum, which is called the *stratum mucosum*, and which consists of several layers of differently shaped cells. The free surface of the epidermis is marked by a net-work of linear furrows of variable size, dividing the surface into a number of polygonal or lozenge-shaped areas. Some of these furrows are large, as opposite the flexures of the joints, and correspond to the folds in the corium produced by move-

FIG. 896.—A diagrammatic sectional view of the skin (magnified).

ments. In other situations, as upon the back of the hand, they are exceedingly fine, and intersect one another at various angles. Upon the palmar surfaces of the hands and fingers, and upon the soles of the feet, these lines are very distinct, and are disposed in curves; they depend upon the large size and peculiar arrangements of the papillæ upon which the epidermis is placed. In each individual the lines on the tips of the fingers and thumbs form distinct patterns unlike those of any other person. A method of determining the identity of a criminal is based on this fact, impressions "finger-prints" of these lines being made on paper covered with soot, or on white paper after first covering the fingers with ink. The deep

surface of the epidermis is accurately moulded upon the papillary layer of the corium, the papillæ being covered by a basement membrane; so that when the epidermis is removed by maceration, it presents on its under surface a number of pits or depressions corresponding to the papillæ, and ridges corresponding to the intervals between them. Fine tubular prolongations are continued from this layer into the ducts of the sudoriferous and sebaceous glands.

FIG. 897.—Section of epidermis. (Ranvier.)

The epidermis consists of stratified epithelium which is arranged in four layers from within outward as follows: (a) *stratum mucosum*, (b) *stratum granulosum*, (c) *stratum lucidum*, and (d) *stratum corneum*.

The *stratum mucosum* (*mucous layer*) is composed of several layers of cells; those of the deepest layer are columnar in shape and placed perpendicularly on the surface of the basement membrane, to which they are attached by toothed extremities; this deepest layer is sometimes termed the *stratum germinativum*; the succeeding strata consist of cells of a more rounded or polyhedral form, the contents of which are soft, opaque, granular, and soluble in acetic acid. These are known as prickly cells because of the bridges by which they are connected to one another (see page 38). They contain fine fibrils which are continuous across the connecting processes with corresponding fibrils in adjacent cells. Between the bridges are fine intercellular clefts serving for the passage of lymph, and in these, lymph corpuscles or pigment granules may be found.

The *stratum granulosum* comprises two or three layers of flattened cells which contain granules of *eleidin*, a substance readily stained by hematoxylin or carmine, and probably an intermediate substance in the formation of keratin. They are supposed to be cells in a transitional stage between the protoplasmic cells of the *stratum mucosum* and the horny cells of the superficial layers.

The *stratum lucidum* appears in section as a homogeneous or dimly striated membrane, composed of closely packed cells in which traces of flattened nuclei may be found, and in which minute granules of a substance named *keratohyalin* are present.

The *stratum corneum* (*horny layer*) consists of several layers of horny epithelial

scales in which no nuclei are discernible, and which are unaffected by acetic acid, the protoplasm having become changed into horny material or *keratin*. According to Ranvier they contain granules of a material which has the characteristics of beeswax.

The black color of the skin in the negro, and the tawny color among some of the white races, is due to the presence of pigment in the cells of the epidermis. This pigment is more especially distinct in the cells of the stratum mucosum, and is similar to that found in the cells of the pigmentary layer of the retina. As the cells approach the surface and desiccate, the color becomes partially lost; the disappearance of the pigment from the superficial layers of the epidermis is, however, difficult to explain.

The **Corium, Cutis Vera, Dermis, or True Skin** is tough, flexible, and highly elastic. It varies in thickness in different parts of the body. Thus it is very thick in the palms of the hands and soles of the feet; thicker on the posterior aspect of the body than on the front, and on the lateral than on the medial sides of the limbs. In the eyelids, scrotum, and penis it is exceedingly thin and delicate.

It consists of felted connective tissue, with a varying amount of elastic fibres and numerous bloodvessels, lymphatics, and nerves. The connective tissue is arranged in two layers: a deeper or **reticular**, and a superficial or **papillary**. Unstriped muscular fibres are found in the superficial layers of the corium, wherever hairs are present, and in the subcutaneous areolar tissue of the scrotum, penis, labia majora, and nipples. In the nipples the fibres are disposed in bands, closely reticulated and arranged in superimposed laminæ.

The **reticular layer** (*stratum reticulare; deep layer*) consists of strong interlacing bands, composed chiefly of white fibrous tissue, but containing some fibres of yellow elastic tissue, which vary in number in different parts; and connective-tissue corpuscles, which are often to be found flattened against the white fibrous tissue bundles. Toward the attached surface the fasciculi are large and coarse, and the areolæ left by their interlacement are large, and occupied by adipose tissue and sweat glands. Below the reticular layer is the subcutaneous areolar tissue, which, except in a few situations, contains fat.

The **papillary layer** (*stratum papillare; superficial layer; corpus papillare of the corium*) consists of numerous small, highly sensitive, and vascular eminences, the **papillæ**, which rise perpendicularly from its surface. The papillæ are minute conical eminences, having rounded or blunted extremities, occasionally divided into two or more parts, and are received into corresponding pits on the under surface of the cuticle. On the general surface of the body, more especially in parts endowed with slight sensibility, they are few in number, and exceedingly minute; but in some situations, as upon the palmar surfaces of the hands and fingers, and upon the plantar surfaces of the feet and toes, they are long, of large size, closely aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. Each ridge contains two rows of papillæ, between which the ducts of the sudoriferous glands pass outward to open on the summit of the ridge. Each papilla consists of very small and closely interlacing bundles of finely fibrillated tissue, with a few elastic fibres; within this tissue is a capillary loop, and in some papillæ, especially in the palms of the hands and the fingers, there are tactile corpuscles.

The **arteries** supplying the skin form a net-work in the subcutaneous tissue, and from this net-work branches are given off to supply the sudoriferous glands, the hair follicles, and the fat. Other branches unite in a plexus immediately beneath the corium; from this plexus, fine capillary vessels pass into the papillæ, forming, in the smaller ones, a single capillary loop, but in the larger, a more or less convoluted vessel. The **lymphatic vessels** of the skin form two net-works, superficial and deep, which communicate with each other and with those of the subcutaneous tissue by oblique branches.

The **nerves** of the skin terminate partly in the epidermis and partly in the corium; their different modes of ending are described on pages 1069 to 1071.

THE APPENDAGES OF THE SKIN.

The appendages of the skin are the **nails**, the **hairs**, and the **sudoriferous** and **sebaceous glands** with their ducts.

The **Nails** (*ungues*) (Fig. 898) are flattened, elastic structures of a horny texture, placed upon the dorsal surfaces of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within, and is implanted by a portion, called the **root**, into a groove in the skin; the exposed portion is called the **body**, and the distal extremity the **free edge**. The nail is firmly adherent to the corium, being accurately moulded upon its surface; the part beneath the body and root of the nail is called the **nail matrix**, because from it the nail is produced. Under the greater part of the body of the nail, the matrix is thick, and raised into a series of longitudinal ridges which are very vascular, and the color is seen through the transparent tissue. Near the root of the nail, the papillæ are smaller, less vascular, and have no regular arrangement, and here the tissue of the nail is more opaque; hence this portion is of a whiter color, and is called the **lunula** on account of its shape.

FIG. 898.—Longitudinal section through nail and its nail groove (sulcus).

The cuticle as it passes forward on the dorsal surface of the finger or toe is attached to the surface of the nail a little in advance of its root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The superficial, horny part of the nail consists of a greatly thickened **stratum lucidum**, the **stratum corneum** forming merely the thin cuticular fold (**eponychium**) which overlaps the lunula; the deeper part consists of the **stratum mucosum**. The cells in contact with the papillæ of the matrix are columnar in form and arranged perpendicularly to the surface; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely packed as to make the limits of the cells very indistinct. The nails grow in length by the proliferation of the cells of the **stratum mucosum** at the root of the nail, and in thickness from that part of the **stratum mucosum** which underlies the lunula.

Hairs (*pili*) are found on nearly every part of the surface of the body, but are absent from the palms of the hands, the soles of the feet, the dorsal surfaces of the terminal phalanges, the glans penis, the inner surface of the prepuce, and the inner surfaces of the labia. They vary much in length, thickness, and color in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; again, in other parts, as the eyelashes, the hairs of the pubic region, and the whiskers and beard, they are remarkable for their thickness. Straight hairs are stronger than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flattened. A hair consists of a **root**, the part implanted in the skin; and a **shaft** or **scapus**, the portion projecting from the surface.

The **root of the hair** (*radix pili*) ends in an enlargement, the **hair bulb**, which is

whiter in color and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the **hair follicle** (Fig. 899). When the hair is of considerable length the follicle extends into the subcutaneous cellular tissue. The hair follicle commences on the surface of the skin with a funnel-shaped opening, and passes inward in an oblique or curved direction—the latter in curly hairs—to become dilated at its deep extremity, where it corresponds with the hair bulb. Opening into the follicle, near its free extremity, are the ducts of one or more sebaceous glands. At the bottom of each hair follicle is a small conical, vascular eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle, and is supplied with nerve fibrils. The hair follicle consists of two coats—an **outer or dermic**, and an **inner or epidermic**.

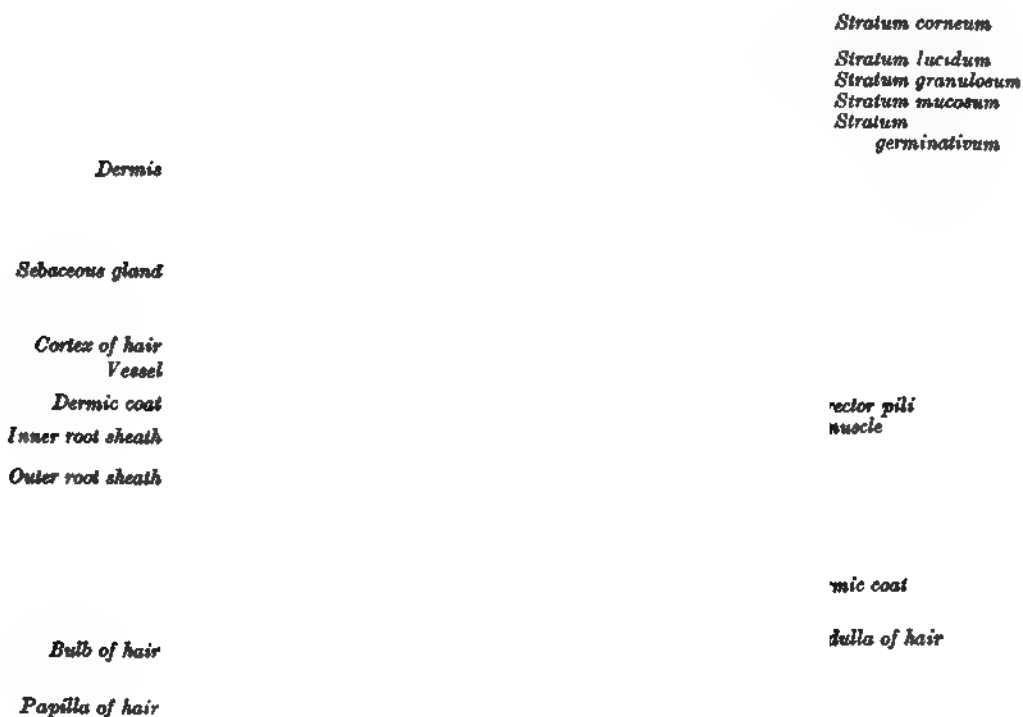

FIG. 899.—Section of skin, showing the epidermis and dermis, a hair in its follicle; the Arrector pili muscle, sebaceous glands.

The **outer or dermic coat** is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and supplied by numerous minute nervous filaments. It consists of three layers (Fig. 900). The most internal is a hyaline basement membrane, which is well-marked in the larger hair follicles, but is not very distinct in the follicles of minute hairs; it is limited to the deeper part of the follicle. Outside this is a compact layer of fibres and spindle-shaped cells arranged circularly around the follicle; this layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally is a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the corium; in this are contained the bloodvessels and nerves.

The **inner or epidermic coat** is closely adherent to the root of the hair, and consists of two strata named respectively the **outer and inner root sheaths**; the former of these corresponds with the stratum mucosum of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair follicle these cells become continuous with those of the root of the hair. The inner root sheath consists of (1) a delicate cuticle next the hair, composed of a single layer of imbricated scales with atrophied nuclei; (2) one or two layers of horny, flattened, nucleated cells, known as **Huxley's layer**; and (3) a single layer of cubical cells with clear flattened nuclei, called **Henle's layer**.

The hair bulb is moulded over the papilla and composed of polyhedral epithelial cells, which as they pass upward into the root of the hair become elongated and spindle-shaped, except some in the centre which remain polyhedral. Some of these latter cells contain pigment granules which give rise to the color of the hair. It occasionally happens that these pigment granules completely fill the cells in the centre of the bulb; this gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

The **shaft of the hair** (*scapus pili*) consists, from within outward, of three parts, the medulla, the cortex, and the cuticle. The **medulla** is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is more opaque and deeper colored than the cortex when viewed by transmitted light; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, containing granules of eleidin and frequently air spaces. The **cortex** constitutes the chief part of the shaft; its cells are elongated and united to form flattened fusiform fibres which contain pigment granules in dark hair, and air in white hair. The **cuticle** consists of a single layer of flat scales which overlap one another from below upward.

Connected with the hair follicles are minute bundles of involuntary muscular fibres, termed the **Arrectores pilorum**. They *arise* from the superficial layer of the corium, and are inserted into the hair follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side toward which the hair slopes, and by their action diminish the obliquity of the follicle and elevate the hair (Fig. 899).¹ The sebaceous gland is situated in the angle which the Arrector muscle forms with the superficial portion of the hair follicle, and contraction of the muscle thus tends to squeeze the sebaceous secretion out from the duct of the gland.

The **Sebaceous Glands** (*glandulae sebaceae*) are small, sacculated, glandular

FIG. 900.—Transverse section of hair follicle.

¹ Professor Arthur Thomson of Oxford suggests that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it, so that the hair, on emerging through the skin, will be curled. Curved hair follicles are characteristic of the scalp of the Bushman.

organs, lodged in the substance of the corium. They are found in most parts of the skin, but are especially abundant in the scalp and face; they are also very numerous around the apertures of the anus, nose, mouth, and external ear, but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which emerges from a cluster of oval or flask-shaped alveoli which vary from two to five in number, but in some instances there may be as many as twenty. Each alveolus is composed of a transparent basement membrane, enclosing a number of epithelial cells. The outer or marginal cells are small and polyhedral, and are continuous with the cells lining the duct. The remainder of the alveolus is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity filled with their debris and a mass of fatty matter, which constitutes the *sebum cutaneum*. The ducts open most frequently into the hair follicles, but occasionally upon the general surface, as in the labia minora and the free margin of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The tarsal glands of the eyelids are elongated sebaceous glands with numerous lateral diverticula.

The **Sudoriferous** or **Sweat Glands** (*glandulae sudoriferae*) are found in almost every part of the skin, and are situated in small pits on the under surface of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. Each consists of a single tube, the deep part of which is rolled into an oval or spherical ball, named the **body** of the gland, while the super-

ficial part, or **duct**, traverses the corium and cuticle and opens on the surface of the skin by a funnel-shaped aperture. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted; where the epidermis is thick, as in the palms of the hands and soles of the feet, the part of the duct which passes through it is spirally coiled. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillæ, where they form a thin, mammillated layer of a reddish color, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies.

They are very plentiful on the palms

FIG. 901.—Body of a sudoriferous-gland cut in various directions. *a*. Longitudinal section of the proximal part of the coiled tube. *b*. Transverse section of the same. *c*. Longitudinal section of the distal part of the coiled tube. *d*. Transverse section of the same. (Klein and Noble Smith.)

of the hands, and on the soles of the feet, where the orifices of the ducts are exceedingly regular, and open on the curved ridges; they are least numerous in the neck and back. The tube, both in the body of the gland and in the duct, consists of two layers—an outer, of fine **areolar tissue**, and an inner of **epithelium** (Fig. 901). The outer layer is thin and is continuous with the superficial stratum of the corium. In the body of the gland the epithelium consists of a single layer of cubical cells, between the deep ends of which and the basement membrane is a layer of longitudinally or obliquely arranged non-striped muscular fibres. The ducts are destitute of muscular fibres and are composed of a basement membrane lined by two or three layers of polyhedral cells; the lumen of the duct is coated by a thin cuticle. When the cuticle is carefully removed from the surface of the corium, the ducts may be drawn out in the form of short, thread-like processes on its under surface. The ceruminous glands of the external acoustic meatus, and the ciliary glands at the margins of the eyelids, are modified sudoriferous glands.

SPLANCHNOLOGY.

UNDER this heading are included the respiratory, digestive, and urogenital organs, and the ductless glands.

THE RESPIRATORY APPARATUS (APPARATUS RESPIRATORIUS; RESPIRATORY SYSTEM).

The respiratory apparatus consists of the larynx, trachea, bronchi, lungs, and pleura.

THE LARYNX.

The larynx or organ of voice is placed at the upper part of the air passage. It is situated between the trachea and the root of the tongue, at the upper and forepart of the neck, where it presents a considerable projection in the middle line. It forms the lower part of the anterior wall of the pharynx, and is covered behind by the mucous lining of that cavity; on either side of it lie the great vessels of the neck. Its vertical extent corresponds to the fourth, fifth, and sixth cervical vertebræ, but it is placed somewhat higher in the female and also during childhood. Symington found that in infants between six and twelve months of age the tip of the epiglottis was a little above the level of the fibrocartilage between the odontoid process and body of the axis, and that between infancy and adult life the larynx descends for a distance equal to two vertebral bodies and two inter-vertebral fibrocartilages. According to Sappey the average measurements of the adult larynx are as follows:

	In males.	In females.
Length	44 mm.	36 mm.
Transverse diameter	43 "	41 "
Antero-posterior diameter	36 "	26 "
Circumference	136 "	112 "

Until puberty the larynx of the male differs little in size from that of the female. In the female its increase after puberty is only slight; in the male it undergoes considerable increase; all the cartilages are enlarged and the thyroid cartilage becomes prominent in the middle line of the neck, while the length of the rima glottidis is nearly doubled.

The larynx is broad above, where it presents the form of a triangular box flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected together by ligaments and moved by numerous muscles. It is lined by mucous membrane continuous above with that of the pharynx and below with that of the trachea.

The **Cartilages of the Larynx** (*cartilagine laryngis*) (Fig. 902) are nine in number, three single and three paired, as follows:

Thyroid.	Two Corniculate.
Cricoid.	Two Cuneiform.
Two Arytenoid.	Epiglottis.

and medialward. They are situated in the posterior parts of the aryepiglottic folds of mucous membrane, and are sometimes fused with the arytenoid cartilages.

The **Cuneiform Cartilages** (*cartilaginee cuneiformes*; *cartilages of Wrisberg*) are two small, elongated pieces of yellow elastic cartilage, placed one on either side, in the aryepiglottic fold, where they give rise to small whitish elevations on the surface of the mucous membrane, just in front of the arytenoid cartilages.

The **Epiglottis** (*cartilago epiglottica*) is a thin lamella of fibrocartilage of a yellowish color, shaped like a leaf, and projecting obliquely upward behind the root of the tongue, in front of the entrance to the larynx. The free extremity is broad and rounded; the attached part or stem is long, narrow, and connected by the **thyroepiglottic ligament** to the angle formed by the two laminae of the thyroid cartilage, a short distance below the superior thyroid notch. The lower part of its anterior surface is connected to the upper border of the body of the hyoid bone by an elastic ligamentous band, the **hyoepiglottic ligament**.

The **anterior or lingual surface** is curved forward, and covered on its upper, free part by mucous membrane which is reflected on to the sides and root of the tongue, forming a median and two lateral **glossoepiglottic folds**; the lateral folds are partly attached to the wall of the pharynx. The depressions between the epiglottis and the root of the tongue, on either side of the median fold, are named the **valleculae**. The lower part of the anterior surface lies behind the hyoid bone, the hyothyroid membrane, and upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

The **posterior or laryngeal surface** is smooth, concave from side to side, concavo-convex from above downward; its lower part projects backward as an elevation, the **tubercle** or **cushion**. When the mucous membrane is removed, the surface of the cartilage is seen to be indented by a number of small pits, in which mucous glands are lodged. To its sides the aryepiglottic folds are attached.

Structure.—The corniculate and cuneiform cartilages, the epiglottis, and the apices of the arytenoids at first consist of hyaline cartilage, but later elastic fibres are deposited in the matrix, converting them into yellow fibrocartilage, which shows little tendency to calcification. The thyroid, cricoid, and the greater part of the arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, and somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone.

Ligaments.—The ligaments of the larynx (Figs. 903, 904) are **extrinsic**, *i. e.*, those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and **intrinsic**, those which connect the several cartilages of the larynx to each other.

Extrinsic Ligaments.—The ligaments connecting the thyroid cartilage with the hyoid bone are the hyothyroid membrane, and a middle and two lateral hyothyroid ligaments.

The **Hyothyroid Membrane** (*membrana hyothyreoidea*; *thyrohyoid membrane*) is a broad, fibro-elastic layer, attached below to the upper border of the thyroid cartilage and to the front of its superior cornu, and above to the upper margin of the posterior surface of the body and greater cornua of the hyoid bone, thus passing behind the posterior surface of the body of the hyoid, and being separated from it by a mucous bursa, which facilitates the upward movement of the larynx during deglutition. Its middle thicker part is termed the **middle hyothyroid ligament** (*ligamentum hyothyroideum medium*; *middle thyrohyoid ligament*), its lateral thinner portions are pierced by the superior laryngeal vessels and the internal branch of the superior laryngeal nerve. Its anterior surface is in relation with the Thyrohyoideus, Sternohyoideus, and Omohyoideus, and with the body of the hyoid bone.

The **Lateral Hyothyroid Ligament** (*ligamentum hyothyreoideum laterale*; *lateral thyrohyoid ligament*) is a round elastic cord, which forms the posterior border of the hyothyroid membrane and passes between the tip of the superior cornu of the thyroid cartilage and the extremity of the greater cornu of the hyoid bone. A small cartilaginous nodule (*cartilago triticea*), sometimes bony, is frequently found in it.

The **Epiglottis** is connected with the hyoid bone by an elastic band, the **hyoepiglottic ligament** (*ligamentum hyoepiglotticum*), which extends from the anterior surface of the epiglottis to the upper border of the body of the hyoid bone. The glossoepiglottic folds of mucous membrane (page 1082) may also be considered as extrinsic ligaments of the epiglottis.

FIG. 903.—The ligaments of the larynx. Antero-lateral view

The **Cricotracheal Ligament** (*ligamentum cricotracheale*) connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea to each other.

Intrinsic Ligaments.—Beneath the mucous membrane of the larynx is a broad sheet of fibrous tissue containing many elastic fibres, and termed the **elastic membrane of the larynx**. It is subdivided on either side by the interval between the ventricular and vocal ligaments, the upper portion extends between the arytenoid cartilage and the epiglottis and is often poorly defined; the lower part is a well-marked membrane forming, with its fellow of the opposite side, the **conus elasticus** which connects the thyroid, cricoid, and arytenoid cartilages to one another. In addition the joints between the individual cartilages are provided with ligaments.

The **Conus Elasticus** (*cricothyroid membrane*) is composed mainly of yellow elastic tissue. It consists of an anterior and two lateral portions. The **anterior part** or **middle cricothyroid ligament** (*ligamentum cricothyreoideum medium*; *central part* of

cricothyroid membrane) is thick and strong, narrow above and broad below. It connects together the front parts of the contiguous margins of the thyroid and cricoid cartilages. It is overlapped on either side by the Cricothyreoides, but between these is subcutaneous; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two cricothyroid arteries, branches of which pierce it. The lateral portions are thinner and lie close under the mucous membrane of the larynx; they extend from the superior border of the cricoid cartilage to the inferior margin of the vocal ligaments, with which they are continuous. These ligaments may therefore be regarded as the free borders of the lateral portions of the conus elasticus, and extend from the vocal processes of the arytenoid cartilages to the angle of the thyroid cartilage about midway between its upper and lower borders. The lateral portions are lined medially by mucous membrane, and covered by the Cricoarytaenoideus lateralis and Thyreoarytaenoideus.

Arytenoid

*Posterior crico-arytenoid
ligament*

*Cricothyroid
articulation*

FIG. 904.—Ligaments of the larynx. Posterior view.

An **articular capsule**, strengthened posteriorly by a well-marked fibrous band, encloses the articulation of the inferior cornu of the thyroid with the cricoid cartilage on either side.

Each arytenoid cartilage is connected to the cricoid by a capsule and a posterior cricoarytenoid ligament. The **capsule** (*capsula articularis cricoarytenoidea*) is thin and loose, and is attached to the margins of the articular surfaces. The **posterior cricoarytenoid ligament** (*ligamentum cricoarytenoideum posterius*) extends from the cricoid to the medial and back part of the base of the arytenoid.

The **thyroepiglottic ligament** (*ligamentum thyroepiglotticum*) is a long, slender, elastic cord which connects the stem of the epiglottis with the angle of the thyroid

cartilage, immediately beneath the superior thyroid notch, above the attachment of the ventricular ligaments.

Movements.—The articulation between the inferior cornu of the thyroid cartilage and the cricoid cartilage on either side is a diarthrodial one, and permits of rotatory and gliding movements. The rotatory movement is one in which the cricoid cartilage rotates upon the inferior cornua of the thyroid cartilage around an axis passing transversely through both joints. The gliding movement consists in a limited shifting of the cricoid on the thyroid in different directions.

The articulation between the arytenoid cartilages and the cricoid is also a diarthrodial one, and permits of two varieties of movement: one is a rotation of the arytenoid on a vertical axis, whereby the vocal process is moved lateralward or medialward, and the rima glottidis increased or diminished; the other is a gliding movement, and allows the arytenoid cartilages to approach or recede from each other; from the direction and slope of the articular surfaces lateral gliding is accompanied by a forward and downward movement. The two movements of gliding and rotation are associated, the medial gliding being connected with medialward rotation, and the lateral gliding with lateralward rotation. The posterior cricoarytenoid ligaments limit the forward movement of the arytenoid cartilages on the cricoid.

Interior of the Larynx (Figs. 905, 907).—The **cavity of the larynx** (*cavum laryngis*) extends from the laryngeal entrance to the lower border of the cricoid cartilage where it is continuous with that of the trachea. It is divided into two parts by the projection of the vocal folds, between which is a narrow triangular fissure or chink, the **rima glottidis**. The portion of the cavity of the larynx above the vocal folds is called the **vestibule**; it is wide and triangular in shape, its base or anterior wall presenting, however, about its centre the backward projection of the tubercle of the epiglottis. It contains the ventricular folds, and between these and the vocal folds are the **ventricles of the larynx**. The portion below the vocal folds is at first of an elliptical form, but lower down it widens out, assumes a circular form, and is continuous with the tube of the trachea.

The **entrance of the larynx** (Fig. 906) is a triangular opening, wide in front, narrow behind, and sloping obliquely downward and backward. It is bounded, in front, by the epiglottis; behind, by the apices of the arytenoid cartilages, the corniculate cartilages, and the interarytenoid notch; and on either side, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the side of the epiglottis and the apex of the arytenoid cartilage; this is the **aryepiglottic fold**, on the posterior part of the margin of which the cuneiform cartilage forms a more or less distinct whitish prominence, the **cuneiform tubercle**.

The **Ventricular Folds** (*plicae ventriculares*; *superior or false vocal cords*) are two thick folds of mucous membrane, each enclosing a narrow band of fibrous tissue, the **ventricular ligament** which is attached in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the antero-

FIG. 905.—Sagittal section of the larynx and upper part of the trachea.

cricothyroid membrane) is thick and strong, narrow above and broad below. It connects together the front parts of the contiguous margins of the thyroid and cricoid cartilages. It is overlapped on either side by the Cricothyreoides, but between these is subcutaneous; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two cricothyroid arteries, branches of which pierce it. The **lateral portions** are thinner and lie close under the mucous membrane of the larynx; they extend from the superior border of the cricoid cartilage to the inferior margin of the vocal ligaments, with which they are continuous. These ligaments may therefore be regarded as the free borders of the lateral portions of the conus elasticus, and extend from the vocal processes of the arytenoid cartilages to the angle of the thyroid cartilage about midway between its upper and lower borders. The lateral portions are lined medially by mucous membrane, and covered by the Cricoarytaenoideus lateralis and Thyreoarytaenoideus.

FIG. 904.—Ligaments of the larynx. Posterior view.

An **articular capsule**, strengthened posteriorly by a well-marked fibrous band, encloses the articulation of the inferior cornu of the thyroid with the cricoid cartilage on either side.

Each arytenoid cartilage is connected to the cricoid by a capsule and a posterior cricoarytenoid ligament. The **capsule** (*capsula articularis cricoarytenoidea*) is thin and loose, and is attached to the margins of the articular surfaces. The **posterior cricoarytenoid ligament** (*ligamentum cricoarytenoideum posterius*) extends from the cricoid to the medial and back part of the base of the arytenoid.

The **thyroepiglottic ligament** (*ligamentum thyroepiglotticum*) is a long, slender, elastic cord which connects the stem of the epiglottis with the angle of the thyroid

cartilage, immediately beneath the superior thyroid notch, above the attachment of the ventricular ligaments.

Movements.—The articulation between the inferior cornu of the thyroid cartilage and the cricoid cartilage on either side is a diarthrodial one, and permits of rotatory and gliding movements. The rotatory movement is one in which the cricoid cartilage rotates upon the inferior cornua of the thyroid cartilage around an axis passing transversely through both joints. The gliding movement consists in a limited shifting of the cricoid on the thyroid in different directions.

The articulation between the arytenoid cartilages and the cricoid is also a diarthrodial one, and permits of two varieties of movement: one is a rotation of the arytenoid on a vertical axis, whereby the vocal process is moved lateralward or medialward, and the rima glottidis increased or diminished; the other is a gliding movement, and allows the arytenoid cartilages to approach or recede from each other; from the direction and slope of the articular surfaces lateral gliding is accompanied by a forward and downward movement. The two movements of gliding and rotation are associated, the medial gliding being connected with medialward rotation, and the lateral gliding with lateralward rotation. The posterior cricoarytenoid ligaments limit the forward movement of the arytenoid cartilages on the cricoid.

Interior of the Larynx (Figs. 905, 907).—The cavity of the larynx (*cavum laryngis*) extends from the laryngeal entrance to the lower border of the cricoid cartilage where it is continuous with that of the trachea. It is divided into two parts by the projection of the vocal folds, between which is a narrow triangular fissure or chink, the *rima glottidis*. The portion of the cavity of the larynx above the vocal folds is called the **vestibule**; it is wide and triangular in shape, its base or anterior wall presenting, however, about its centre the backward projection of the tubercle of the epiglottis. It contains the ventricular folds, and between these and the vocal folds are the **ventricles of the larynx**. The portion below the vocal folds is at first of an elliptical form, but lower down it widens out, assumes a circular form, and is continuous with the tube of the trachea.

The **entrance of the larynx** (Fig. 906) is a triangular opening, wide in front, narrow behind, and sloping obliquely downward and backward. It is bounded, in front, by the epiglottis; behind, by the apices of the arytenoid cartilages, the corniculate cartilages, and the interarytenoid notch; and on either side, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the side of the epiglottis and the apex of the arytenoid cartilage; this is the **aryepiglottic fold**, on the posterior part of the margin of which the cuneiform cartilage forms a more or less distinct whitish prominence, the **cuneiform tubercle**.

The **Ventricular Folds** (*plicae ventriculares*; *superior or false vocal cords*) are two thick folds of mucous membrane, each enclosing a narrow band of fibrous tissue, the **ventricular ligament** which is attached in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the antero-

FIG. 905.—Sagittal section of the larynx and upper part of the trachea.

lateral surface of the arytenoid cartilage, a short distance above the vocal process. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx.

Sulcus terminalis

FIG. 906.—The entrance to the larynx, viewed from behind.

The **Vocal Folds** (*plicae vocales; inferior or true vocal cords*) are concerned in the production of sound, and enclose two strong bands, named the **vocal ligaments** (*ligamenta vocales; inferior thyroarytenoid*). Each ligament consists of a band of yellow elastic tissue, attached in front to the angle of the thyroid cartilage, and behind to the vocal process of the arytenoid. Its lower border is continuous with the thin lateral part of the conus elasticus. Its upper border forms the lower boundary of the ventricle of the larynx. Laterally, the Vocalis muscle lies parallel with it. It is covered medially by mucous membrane, which is extremely thin and closely adherent to its surface.

The **Ventricle of the Larynx** (*ventriculus laryngis* [Morgagnii]; *laryngeal sinus*) is a fusiform fossa, situated between the ventricular and vocal folds on either side, and extending nearly their entire length. The fossa is bounded, *above*, by the free crescentic edge of the ventricular fold; *below*, by the straight margin of the vocal fold; *laterally*, by the mucous membrane covering the corresponding Thyroarytaenoides. The anterior part of the ventricle leads up by a narrow opening into a cecal pouch of mucous membrane of variable size called the **appendix**.

The **appendix of the laryngeal ventricle** (*appendix ventriculi laryngis; laryngeal saccule*) is a membranous sac, placed between the ventricular fold and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border or even higher; it is conical in form, and curved slightly backward. On the surface

of its mucous membrane are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the ventricular ligament. Its medial surface is covered by a few delicate muscular fasciculi, which arise from the apex of the arytenoid cartilage and become lost in the aryepiglottic fold of mucous membrane; laterally it is separated from the thyroid cartilage by the Thyreoepiglotticus. These muscles compress the sac, and express the secretion it contains upon the vocal folds to lubricate their surfaces.

The **Rima Glottidis** (Fig. 908) is the elongated fissure or chink between the vocal folds in front, and the bases and vocal processes of the arytenoid cartilages behind. It is therefore subdivided into a larger anterior intramembranous part (*glottis vocalis*), which measures about three-fifths of the length of the entire aperture, and a posterior intercartilaginous part (*glottis respiratoria*). Posteriorly it is limited by the mucous membrane passing between the arytenoid cartilages. The rima glottidis is the narrowest part of the cavity of the larynx, and its level corresponds with the bases of the arytenoid cartilages. Its length, in the male, is about 23 mm.; in the female from 17 to 18 mm. The width and shape of the rima glottidis vary with the movements of the vocal folds and arytenoid cartilages during respiration and phonation. In the condition of rest, i. e., when these structures are uninfluenced by muscular action, as in

quiet respiration, the intramembranous part is triangular, with its apex in front and its base behind—the latter being represented by a line, about 8 mm. long, connecting the anterior ends of the vocal processes, while the medial surfaces of

the arytenoids are parallel to each other, and hence the intercartilaginous part is rectangular. During extreme adduction of the vocal folds, as in the emission of a high note, the intramembranous part is reduced to a linear slit by the apposition of the vocal folds, while the intercartilaginous part is triangular, its apex corresponding to the anterior ends of the vocal processes of the arytenoids, which are approximated by the medial rotation of the cartilages. Conversely in extreme abduction of the vocal folds, as in forced inspiration, the arytenoids and their vocal processes are rotated lateralward, and the intercartilaginous part is triangular in shape but with its apex directed backward. In this condition the entire glottis is somewhat lozenge-shaped, the sides of the intramembranous part diverging from before backward, those of the intercartilaginous part diverging from behind forward—the widest part of the aperture corresponding with the attachments of the vocal folds to the vocal processes.

Muscles.—The muscles of the larynx are *extrinsic*, passing between the larynx and parts around—these have been described in the section on Myology; and *intrinsic*, confined entirely to the larynx.

The intrinsic muscles are:

Cricothyreoides.

Cricoarytaenoideus posterior.

Cricoarytaenoideus lateralis.

Arytaenoideus.

Thyroarytaenoideus.

The **Cricothyreoides** (*Cricothyroid*) (Fig. 909), triangular in form, *arises* from the front and lateral part of the cricoid cartilage; its fibres diverge, and are arranged in two groups. The lower fibres constitute a *pars obliqua* and slant backward and lateralward to the anterior border of the inferior cornu; the anterior fibres, forming a *pars recta*, run upward, backward, and lateralward to the posterior part of the lower border of the lamina of the thyroid cartilage.

The medial borders of the two muscles are separated by a triangular interval, occupied by the middle cricothyroid ligament.

The **Cricoarytaenoideus posterior** (*posterior cricoarytenoid*) (Fig. 910) *arises* from the broad depression on the corresponding half of the posterior surface of the lamina of the cricoid cartilage; its fibres run upward and lateralward, and converge to be *inserted* into the back of the muscular process of the arytenoid cartilage. The uppermost fibres are nearly horizontal, the middle oblique, and the lowest almost vertical.

The **Cricoarytaenoideus lateralis** (*lateral cricoarytenoid*) (Fig. 911) is smaller than the preceding, and of an oblong form. It *arises* from the upper border of the arch of the cricoid cartilage, and, passing obliquely up-

FIG. 909.—Side view of the larynx, showing muscular attachments.

ward and backward, is inserted into the front of the muscular process of the arytenoid cartilage.

The **Arytaenoideus** (Fig. 910) is a single muscle, filling up the posterior concave surfaces of the arytenoid cartilages. It *arises* from the posterior surface and lateral border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of oblique and transverse parts. The **Arytae-**

noldeus obliquus, the more superficial, forms two fasciculi, which pass from the base of one cartilage to the apex of the opposite one, and therefore cross each other

FIG. 910.—Muscles of larynx. Posterior view.

FIG. 911.—Muscles of larynx. Side view. Right lamina of thyroid cartilage removed.

like the limbs of the letter X; a few fibres are continued around the lateral margin of the cartilage, and are prolonged into the aryepiglottic fold; they are sometimes described as a separate muscle, the **Aryepiglotticus**. The **Arytaenoid transversus** crosses transversely between the two cartilages.

The **Thyroarytaenoides** (*Thyroarytenoid*) (Figs. 911, 912) is a broad, thin, muscle which lies parallel with and lateral to the vocal fold, and supports the wall of the ventricle and its appendix. It arises in front from the lower half of the angle of the thyroid cartilage, and from the middle cricothyroid ligament. Its fibres pass backward and lateralward, to be inserted into the base and anterior surface of the arytenoid cartilage. The lower and deeper fibres of the muscle can be differentiated as a triangular band which is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its anterior surface; it is termed the **Vocalis**, and lies parallel with the vocal ligament, to which it is adherent.

FIG. 912.—Muscles of the larynx, seen from above (Enlarged.)

A considerable number of the fibres of the *Thyreothyrotaenoideus* are prolonged into the aryepiglottic fold, where some of them become lost, while others are continued to the margin of the epiglottis. They have received a distinctive name, *Thyreopiglotticus*, and are sometimes described as a separate muscle.

Actions.—In considering the actions of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal folds.

1. The muscles which open the glottis are the *Cricothyrotaenoidei posteriores*; and those which close it are the *Cricothyrotaenoidei laterales* and the *Arytaenoideus*. 2. The muscles which regulate the tension of the vocal folds are the *Cricothyrotaenoidei*, which elongate and render them tense; and the *Thyreothyrotaenoidei*, which relax and shorten them.

The *Cricothyrotaenoidei posteriores* separate the vocal folds, and, consequently, open the glottis, by rotating the arytenoid cartilages outward around a vertical axis passing through the crico-arytenoid joints; so that their vocal processes and the vocal folds attached to them become widely separated.

The *Cricothyrotaenoidei laterales* close the glottis by rotating the arytenoid cartilages inward, so as to approximate their vocal processes.

The *Arytaenoideus* approximates the arytenoid cartilages, and thus closes the opening of the glottis, especially at its back part.

The *Cricothyrotaenoidei* produce tension and elongation of the vocal folds by drawing up the arch of the cricoid cartilage and tilting back the upper border of its lamina; the distance between the vocal processes and the angle of the thyroid is thus increased, and the folds are consequently elongated.

The *Thyreothyrotaenoidei*, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forward toward the thyroid, and thus shorten and relax the vocal folds. But, owing to the connection of the deeper portion with the vocal fold, this part, if acting separately, is supposed to modify its elasticity and tension, while the lateral portion rotates the arytenoid cartilage inward, and thus narrows the rima glottidis by bringing the two vocal folds together.

The manner in which the entrance of the larynx is closed during deglutition is referred to on page 1114.

Mucous Membrane.—The mucous membrane of the larynx is continuous above with that lining the mouth and pharynx, and is prolonged through the trachea and bronchi into the lungs. It lines the posterior surface and the upper part of the anterior surface of the epiglottis, to which it is closely adherent, and forms the aryepiglottic folds which bound the entrance of the larynx. It lines the whole of the cavity of the larynx; forms, by its reduplication, the chief part of the ventricular fold, and, from the ventricle, is continued into the ventricular appendix. It is then reflected over the vocal ligament, where it is thin, and very intimately adherent; covers the inner surface of the conus elasticus and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. The anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the aryepiglottic folds and the vocal folds are covered by stratified squamous epithelium; all the rest of the laryngeal mucous membrane is covered by columnar ciliated cells, but patches of stratified squamous epithelium are found in the mucous membrane above the glottis.

Glands.—The mucous membrane of the larynx is furnished with numerous mucous secreting glands, the orifices of which are found in nearly every part; they are very plentiful upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the margin of the aryepiglottic fold, in front of the arytenoid cartilages, where they are termed the *arytenoid glands*. They exist also in large numbers in the ventricular appendages. None are found on the free edges of the vocal folds.

Vessels and Nerves.—The chief arteries of the larynx are the laryngeal branches derived from the superior and inferior thyroid. The veins accompany the arteries; those accompanying the superior laryngeal artery join the superior thyroid vein which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the innominate vein. The lymphatic vessels consist of two sets, superior and inferior. The former accompany the superior laryngeal artery and pierce the hyothyroid membrane, to end in the glands situated near the bifurcation of the common carotid artery. Of the latter, some pass through the middle cricothyroid ligament and open into a gland lying in front of that ligament or in front of the upper part of the trachea, while others pass to the deep cervical glands and to the glands accompanying the inferior thyroid artery. The nerves are derived from the internal and external branches of the superior laryngeal nerve; from the recurrent nerve, and from the sympathetic. The internal laryngeal branch is almost entirely sensory, but some motor filaments are said to be carried by it to the *Arytaenoideus*. It enters the larynx by piercing the posterior part of the hyothyroid membrane above the superior

laryngeal vessels, and divides into a branch which is distributed to both surfaces of the epiglottis, a second to the aryepiglottic fold, and a third, the largest, which supplies the mucous membrane over the back of the larynx and communicates with the recurrent nerve. The external laryngeal branch supplies the Cricothyreoides. The recurrent nerve passes upward beneath the lower border of the Constrictor pharyngis inferior immediately behind the cricothyroid joint. It supplies all the muscles of the larynx except the Cricothyreoides, and perhaps a part of the Arytaenoideus. The sensory branches of the laryngeal nerves form subepithelial plexuses, from which fibres pass to end between the cells covering the mucous membrane.

Over the posterior surface of the epiglottis, in the aryepiglottic folds, and less regularly in some other parts, taste-buds, similar to those in the tongue, are found.

THE TRACHEA AND BRONCHI (Fig. 913).

The **trachea** or **windpipe** is a cartilaginous and membranous tube, extending from the lower part of the larynx, on a level with the sixth cervical vertebra, to the

FIG. 913.—Front view of cartilages of larynx, trachea, and bronchi

upper border of the fifth thoracic vertebra, where it divides into the two bronchi, one for each lung. The trachea is nearly but not quite cylindrical, being flattened posteriorly; it measures about 11 cm. in length; its diameter, from side to side,

is from 2 to 2.5 cm., being always greater in the male than in the female. In the child the trachea is smaller, more deeply placed, and more movable than in the adult.

Relations.—The *anterior surface* of the trachea is convex, and covered, in the neck, from above downward, by the isthmus of the thyroid gland, the inferior thyroid veins, the *arteria thyroidea ima* (when that vessel exists), the *Sternothyroideus* and *Sternohyoideus* muscles, the cervical fascia, and, more superficially, by the anastomosing branches between the anterior jugular veins; in the thorax, it is covered from before backward by the manubrium sterni, the remains of the thymus, the left innominate vein, the aortic arch, the innominate and left common carotid arteries, and the deep cardiac plexus. Posteriorly it is in contact with the oesophagus. *Laterally, in the neck*, it is in relation with the common carotid arteries, the right and left lobes of the thyroid gland, the inferior thyroid arteries, and the recurrent nerves; in the thorax, it lies in the superior mediastinal cavity, and is in relation on the right side with the pleura and right vagus, and near the root of the neck with the innominate artery; on its left side are the left recurrent nerve, the aortic arch, and the left common carotid and subclavian arteries.

The **right bronchus** (*bronchus dexter*), wider, shorter, and more vertical in direction than the left, is about 2.5 cm. long, and enters the right lung nearly opposite the fifth thoracic vertebra. The azygos vein arches over it from behind; and the right pulmonary artery lies at first below and then in front of it. About 2 cm. from its commencement it gives off a branch to the upper lobe of the right lung. This is termed the **oparterial branch** of the bronchus, because it arises above the right pulmonary artery. The bronchus now passes below the artery, and is known as the **hyparterial branch**; it divides into two branches for the middle and lower lobes.

The **left bronchus** (*bronchus sinister*) is smaller in calibre but longer than the right, being nearly 5 cm. long. It enters the root of the left lung opposite the sixth thoracic vertebra. It passes beneath the aortic arch, crosses in front of the oesophagus, the thoracic duct, and the descending aorta, and has the left pulmonary artery lying at first above, and then in front of it. The left bronchus has no oparterial branch, and therefore it has been supposed by some that there is no

upper lobe to the left lung, but that the so-called upper lobe corresponds to the middle lobe of the right lung.

The further subdivisions of the bronchi will be considered with the anatomy of the lung.

If a transverse section be made across the trachea a short distance above its point of bifurcation, and a bird's-eye view taken of its interior (Fig. 914), the septum placed at the bottom of the trachea and separating the two bronchi will be seen

FIG. 914.—Transverse section of the trachea, just above its bifurcation, with a bird's-eye view of the interior.

to occupy the left of the median line, and the right bronchus appears to be a more direct continuation of the trachea than the left, so that any solid body dropping into the trachea would naturally be directed toward the right bronchus. This tendency is aided by the larger diameter of the right tube as compared with its fellow. This fact serves to explain why a foreign body in the trachea more frequently falls into the right bronchus.¹

Structure (Fig. 915).—The trachea and extrapulmonary bronchi are composed of imperfect rings of hyaline cartilage, fibrous tissue, muscular fibres, mucous membrane, and glands.

The cartilages of the trachea vary from sixteen to twenty in number: each forms an imperfect ring, which occupies the anterior two-thirds or so of the circumference of the trachea, being deficient behind, where the tube is completed by fibrous tissue and unstriped muscular fibres. The cartilages are placed horizontally above each other, separated by narrow intervals. They measure about 4 mm. in depth and 1 mm. in thickness. Their outer surfaces are flattened in a vertical direction, but the internal are convex, the cartilages being thicker in the middle than

¹ Reigel asserts that the entry of a foreign body into the left bronchus is by no means so infrequent as is generally supposed. See also *Med.-Chil. Trans.*, lxxi, 121.

at the margins. Two or more of the cartilages often unite, partially or completely, and they are sometimes bifurcated at their extremities. They are highly elastic, but may become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea, but have the same shape and arrangement. The peculiar tracheal cartilages are the first and the last (Fig. 913).

The *first cartilage* is broader than the rest, and often divided at one end; it is connected by the cricotracheal ligament with the lower border of the cricoid cartilage, with which, or with the succeeding cartilage, it is sometimes blended.

The *last cartilage* is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process, which curves downward and backward between the two bronchi. It ends on each side in an imperfect ring, which encloses the commencement of the bronchus. The cartilage above the last is somewhat broader than the others at its centre.

The Fibrous Membrane. The cartilages are enclosed in an elastic fibrous membrane, which consists of two layers; one, the thicker, passing over the outer surface of the ring, the other over the inner surface: at the upper and lower margins of the cartilages the two layers blend together to form a single membrane, which connects the rings one with another. They are thus invested by the membrane. In the space behind, between the ends of the rings, the membrane forms a single layer.

The **muscular tissue** consists of two layers of non-striated muscle, longitudinal and transverse. The **longitudinal fibres** are external, and consist of a few scattered bundles. The **transverse fibres** (*Trachealis muscle*) are internal, and form a thin layer which extends transversely between the ends of the cartilages.

Mucous Membrane.—The mucous membrane is continuous above with that of the larynx, and below with that of the bronchi. It consists of areolar and lymphoid tissue, and presents a well-marked basement membrane, supporting a stratified epithelium, the surface layer of which is columnar and ciliated, while the deeper layers are composed of oval or rounded cells. Beneath the basement membrane there is a distinct layer of longitudinal elastic fibres with a small amount of intervening areolar tissue. The submucous layer is composed of a loose mesh-work of connective tissue, containing large bloodvessels, nerves, and mucous glands; the ducts of the latter pierce the overlying layers and open on the surface (Fig. 915).

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid arteries. The veins end in the thyroid venous plexus. The nerves are derived from the vagus and the recurrent nerves, and from the sympathetic; they are distributed to the Trachealis muscles and between the epithelial cells.

Applied Anatomy.—*Foreign bodies* often find their way into the air passages. These may consist of large soft substances, as pieces of meat, which may become lodged in the entrance of the larynx, or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air passages below, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry or plum stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx, they may produce very few symptoms, beyond sudden loss of voice or alteration in the voice sounds immediately after the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against

the vocal folds during expiratory efforts, and produce attacks of dyspnoea from spasm of the glottis. When lodged in the bronchus, they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, and may subsequently lead to purulent bronchitis and gangrene of the lung. Foreign bodies in the air passages should always be removed as soon as possible.

Beneath the mucous membrane of the upper part of the air passages there is a considerable amount of submucous tissue, which is liable to become much swollen from effusion in inflammatory affections, constituting the condition known as *œdema of the glottis*. This effusion does not extend below the level of the vocal folds, on account of the fact that the mucous membrane is closely adherent to these structures without the intervention of any submucous tissue. So that, in cases of œdema of the glottis, in which it is necessary to open the air passages to prevent suffocation, the operation of laryngotomy is sufficient. Laryngeal or glottidean œdema may be secondary to some local inflammatory affection, such as acute septic laryngitis, syphilitic laryngeal perichondritis, or to malignant disease. Or the œdema may be passive (non-inflammatory), consequent upon renal or cardiac mischief, angioneurotic œdema; or, in unusually susceptible persons, the administration of potassium iodide.

Chronic laryngitis is an inflammation of the mucous glands of the larynx, which occurs in those who speak much in public, and is known as *clergyman's sore throat*. It is due to the dryness induced by the large amount of cold air drawn into the air passages during prolonged speaking, which excites increased activity of the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis, either as a superficial ulceration, or from the softening of a gumma; from tuberculous disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air passages may be opened in three different situations: by a vertical incision through the centre of the thyroid cartilage (*thyrotomy*); through the middle cricothyroid ligament (*laryngotomy*), or in some part of the trachea (*tracheotomy*).

Thyrotomy is usually performed for the purpose of removing growths from the vocal folds or for extracting foreign bodies from the ventricle of the larynx. A median incision is made from the upper border of the body of the hyoid bone to the lower border of the cricoid cartilage, and is carried through the subcutaneous tissues and deep fascia between the margins of the Sternohyoidei. An incision is then made in the middle cricothyroid ligament, and one blade of a stout, sharp-pointed pair of scissors is introduced beneath the lower border of the thyroid cartilage, and this structure is divided from below upward. Great care must be taken to cut exactly in the middle line to avoid wounding the vocal folds. If the two halves of the cartilage are now drawn apart, a very good view of the interior of the larynx will be obtained.

Laryngotomy is anatomically a simple operation: it can readily be performed, and should be employed in those cases where the air passages require opening in an emergency for the relief of some sudden obstruction to respiration. The middle cricothyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia, and the deep fascia. On either side of the middle line it is also covered by the Sternohyoideus and Sternothyroideus, which diverge from each other at their upper parts, leaving a slight interval between them. On these muscles rest the anterior jugular veins. The only vessel of any importance in connection with this operation is the cricothyroid artery, which crosses the middle cricothyroid ligament, and may be wounded, but rarely gives rise to any trouble. The operation is performed thus: the head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the cricothyroid depression felt for. A vertical incision is then made through the skin in the middle line over this spot, and carried down through the fascia until the middle cricothyroid ligament is exposed. A cross-cut is then made through the ligament close to the upper border of the cricoid cartilage, so as to avoid, if possible, the cricothyroid artery, and a laryngotomy tube inserted. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut through the superficial structures, and thus to open at once the air passages. It will be seen, however, that in operating in this way the anterior jugular veins are in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid gland, or this structure may be divided and the trachea opened behind it.

From the relations already described, it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid gland.

Tracheotomy above the isthmus is performed thus: the patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon standing on the right side of his patient makes an incision from 4 to 5 cm. long in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line so as to avoid the anterior jugular veins, and after the superficial structures have been divided, the interval between the Sternohyoidei must be found, the raphé divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed

from this point downward in the middle line. Bose has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downward with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed and is saved from all danger of being wounded, and the trachea cleanly exposed. The trachea is now trans-fixed with a sharp hook and drawn forward in order to steady it, and is then opened by inserting the knife into it and dividing the upper two or three rings by cutting upward. If the trachea is to be opened beneath the isthmus, the incision must be made from a little below the cricoid cartilage to the top of the sternum.

A portion of the larynx or the whole of it may be removed for malignant disease. The results which have been obtained from the removal of the whole of it have not been very satisfactory, and the cases in which the operation is justifiable are very few. It may be removed by a median incision through the soft parts, freeing the cartilages from the muscles and other structures in front, separating the larynx from the trachea below, and dissecting off the deeper structure from below upward.

THE PLEURÆ.

Each lung is invested by an exceedingly delicate serous membrane, the **pleura**, which is arranged in the form of a closed invaginated sac. A portion of the serous membrane covers the surface of the lung and dips into the fissures between its lobes; it is called the **pulmonary pleura**. The rest of the membrane lines the inner surface of the chest wall, covers the Diaphragma, and is reflected over the structures occupying the middle of the thorax; this portion is termed the **parietal pleura**. The two layers are continuous with one another around and below the root of the lung; in health they are in actual contact with one another, but the potential space between them is known as the **pleural cavity**. When the lung collapses or when air or fluid collects between the two layers the cavity becomes apparent. The right and left pleural sacs are entirely separate from one another; between them are all the thoracic viscera except the lungs, and they only touch each other for a short distance in front; opposite the second and third pieces of the sternum the interval between the two sacs is termed the mediastinal cavity.

Different portions of the parietal pleura have received special names which indicate their position: thus, that portion which lines the inner surfaces of the ribs and Intercostales is the **costal pleura**; that clothing the convex surface of the Diaphragma is the **diaphragmatic pleura**; that which rises into the neck, over the summit of the lung, is the **cupula of the pleura** (*cervical pleura*); and that which is applied to the other thoracic viscera is the **mediastinal pleura**.

Reflections of the Pleura (Figs. 916, 917).—Commencing at the sternum, the pleura passes lateralward, lines the inner surfaces of the costal cartilages, ribs, and Intercostales, and at the back part of the thorax passes over the sympathetic trunk and its branches, and is reflected upon the sides of the bodies of the vertebræ, where it is separated by a narrow interval, the **posterior mediastinal cavity**, from the opposite pleura. From the vertebral column the pleura passes to the side of the pericardium, which it covers to a slight extent; it then covers the back part of the root of the lung, from the lower border of which a triangular sheet descends vertically toward the Diaphragma. This sheet is the posterior layer of a wide fold, known as the **pulmonary ligament**. From the back of the lung root, the pleura may be traced over the costal surface of the lung, the apex and base, and also over the sides of the fissures between the lobes, on to its mediastinal surface and the front part of its root. It is continued from the lower margin of the root as the anterior layer of the pulmonary ligament, and from this it is reflected on to the pericardium (**pericardial pleura**), and from it to the back of the sternum. Above the level of the root of the lung, however, the mediastinal pleura passes uninterruptedly from the vertebral column to the sternum over the structures in the superior mediastinal cavity. *Below*, it covers the upper surface of the Diaphragma and extends, in front, as low as the costal cartilage of the seventh rib; at the side of the chest,

to the lower border of the tenth rib on the left side and to the upper border of the same rib on the right side; and *behind*, it reaches as low as the twelfth rib, and sometimes even to the transverse process of the first lumbar vertebra. *Above*, its cupula projects through the superior opening of the thorax into the neck, extending from 2.5 to 5 cm. above the sternal end of the first rib; this portion of the sac is strengthened by a dome-like expansion of fascia (*Sibson's fascia*), attached in front to the inner border of the first rib, and behind to the anterior border of the transverse process of the seventh cervical vertebra. This is covered and strengthened by a few spreading muscular fibres derived from the *Scaleni*.

Lower margin of pleura

FIG. 916.—Front view of thorax, showing the relations of the pleurae and lungs to the chest wall.
Pleura in blue; lungs in purple.

In the front of the chest, where the parietal pleura is reflected backward to the pericardium, the two pleural sacs are in contact for a short distance. At the upper part of the chest, behind the manubrium, they are separated by an angular interval; the line of reflection being represented by a line drawn from the sternoclavicular articulation to the mid-point of the junction of the manubrium with the body of the sternum. From this point the two pleurae descend in close contact to the level of the fourth costal cartilages, and the line of reflection on the right side is continued downward in nearly a straight line to the xiphoid process, and then turns lateralward, while on the left side the line of reflection diverges lateralward and is continued downward, close to the left border of the sternum, as far as the sixth costal cartilage. The inferior limit of the pleura is on a considerably lower level than the corresponding limit of the lung, but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the chest wall on to the Diaphragm the latter is in direct contact with the rib cartilages

and the Intercostales interni. Moreover, in ordinary inspiration the thin inferior margin of the lung does not extend as low as the line of the pleural reflection, with the result that the costal and diaphragmatic pleuræ are here in contact, the intervening narrow slit being termed the **phrenicocostal sinus**. A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms what is called the **costomediastinal sinus**.

The line along which the right pleura is reflected from the chest-wall to the Diaphragma starts in front, immediately below the seventh sternocostal joint, and runs downward and backward behind the seventh costal cartilage so as to cross the tenth rib in the mid-axillary line, from which it is prolonged to the spinous process of the twelfth thoracic vertebra. The reflection of the left pleura follows at first the ascending part of the sixth costal cartilage, and in the rest of its course is slightly lower than that of the right side.

The free surface of the pleura is smooth, polished, and moistened by a serous fluid; its attached surface is intimately adherent to the lung, and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragma: throughout the rest of its extent it is easily separable from the adjacent parts.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Pulmonary Ligament (*ligamentum pulmonale; ligamentum latum pulmonis*).—From the above description it will be seen that the root of the lung is covered in front, above, and behind by pleura, and that at its lower border the investing layers come into contact. Here they form a sort of mesenteric fold, the pulmonary ligament, which extends between the lower part of the mediastinal surface of the lung and the pericardium. Just above the Diaphragma the ligament ends in a free falciform border. It serves to retain the lower part of the lung in position.

Structure of Pleura.—Like other serous membranes, the pleura is covered by a single layer of flattened, nucleated cells, united at their edges by cement substance. These cells are modified connective-tissue corpuscles, and rest on a basement membrane. Beneath the basement membrane there are net-works of yellow elastic and white fibres, imbedded in ground substance which also contains connective-tissue cells. Bloodvessels, lymphatics, and nerves are distributed in the substance of the pleura, and the lymphatics communicate with the pleural cavity by means of stomata or openings between the cells of the superficial layer.

Vessels and Nerves.—The arteries of the pleura are derived from the intercostal, internal mammary, musculophrenic, thymic, pericardiac, and bronchial vessels. The veins correspond

an art.
vein

of lung

Fig. 917.—Lateral view of thorax, showing the relations of the pleuræ and lungs to the chest wall. Pleura in blue; lungs in purple.

to the arteries. The **lymphatics** are described on page 800. The **nerves** are derived from the phrenic and sympathetic (Luschka). Kölliker states that nerves accompany the ramifications of the bronchial arteries in the pulmonary pleura.

Applied Anatomy.—Acute inflammation of the pleura or *pleurisy* may be either dry or wet, and, if wet, either serous or purulent. *Dry pleurisy* is common in pneumonia, and is often an early manifestation of tuberculosis. It gives rise to much pain, and to friction sounds due to the scraping to and fro over one another of the inflamed and roughened parietal and pulmonary pleuræ. *Wet pleurisy* occurs if the inflammation causes the effusion of serum into the pleural cavity. The two pleural layers are now separated by the fluid effusion, so the friction sounds are no longer produced. Room is found for the fluid by shrinkage of the supernatant lung due to the retraction of its elastic tissue, and later, when the quantity of serum exceeds about 1.5 litre, by shifting over of the heart and unaffected lung toward the sound side. This shifting may be so extensive that the apex beat of the heart comes to lie under the right mammary papilla. Any pleural effusion that is large enough to embarrass respiration seriously, or has remained unabsorbed for two or three weeks, should be removed by tapping (*paracentesis thoracis*). The trocar is pushed through the chest wall into the fluid, in the sixth or seventh intercostal space in the mid-axillary line, or in the eighth or ninth space just outside the angle of the scapula. Aspiration is then performed, and as much fluid as possible drawn off; it must be stopped, however, if the patient shows signs of collapse, or if fits of coughing occur and threaten to wound the expanding lung against the sharp end of the trocar. Non-inflammatory or passive effusion into the pleura, called *hydrothorax*, is often seen in the later stages of chronic renal or cardiac disease, and demands treatment on lines similar to the above.

Purulent pleural effusion, or *empyema*, often occurs after such diseases as pneumonia or measles. This condition requires drainage of the cavity, which usually necessitates excision of a portion of the rib. An incision is made down to the seventh or eighth rib in the mid- or posterior axillary line and the periosteum is incised, and separated from the shaft of the rib, carrying with it the structures in the costal groove. With bone-cutting forceps about 4 or 5 cm. of the rib are separated and removed, and the underlying pleura is incised. The pus having been evacuated, a large drainage-tube is inserted into the cavity. The pleura should never be irrigated, as sudden death has followed this proceeding, and great care should be taken to prevent the tube from slipping into the cavity, an occurrence which is far from uncommon.

Pneumothorax, or the presence of gas in the pleural cavity, is a common terminal event in tuberculosis of the lungs; less often it is due to trauma—rupture of the lung, for example, when the chest is crushed; or tearing of the lung tissue by the sharp projecting end of a broken rib. Air escapes from the lung into the pleural cavity; the elastic tissue of the lung at once contracts, and finally that organ shrinks away to a dark rounded mass the size of a fist, lying close against the vertebral column. The symptoms of pneumothorax are often very severe; cyanosis, intense dyspnoea, great pain on the affected side, and cardiac failure. Their severity is increased by the fact that the bloodvessels of the collapsed lung offer less resistance to the circulation of the blood than do those of the other lung. Not only, therefore, does the sound lung suddenly have to take over the work—the aëration of the blood—normally performed by both lungs, but it has to do so at the moment when the circulation of blood through it is partially short-circuited by the collapsed lung. If the patient survives for a few days, empyema often complicates the pneumothorax, setting up the condition called *pyopneumothorax*.

In operations upon the kidney, it must be borne in mind that the pleura usually extends below the level of the medial portion of the last rib, and may therefore be opened in these operations, especially when the last rib is removed in order to give more room.

THE MEDIASTINAL CAVITY (INTERPLEURAL SPACE).

The **mediastinal cavity** is the space between the right and left pleuræ in and near the median sagittal plane of the chest. It extends from the sternum in front to the vertebral column behind, and contains all the thoracic viscera excepting the lungs. The cavity may be divided for purposes of description into two parts: an upper portion, above the upper level of the pericardium, which is named the **superior mediastinal cavity**; and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three parts, viz., that in front of the pericardium, the **anterior mediastinal cavity**; that containing the pericardium and its contents, the **middle mediastinal cavity**; and that behind the pericardium, the **posterior mediastinal cavity**.

The **superior mediastinal cavity** (Fig. 918) is that portion of the interpleural space which lies between the manubrium sterni in front, and the upper thoracic

vertebræ behind. It is bounded below by a slightly oblique plane passing backward from the junction of the manubrium and body of the sternum to the lower part

FIG. 918.—Transverse section through the upper margin of the second thoracic vertebra. (Braune.)

Transversum thoracis

Thoracic duct

Vagus nerves

FIG. 919.—A transverse section of the thorax, showing the contents of the middle and posterior mediastinal cavities.

of the body of the fourth thoracic vertebra, and laterally by the pleuræ. It contains the origins of the Sternohyoidei and Sternothyreoidei and the lower ends of the Longi colli; the aortic arch; the innominate artery and the thoracic portions of the left common carotid and the left subclavian arteries; the innominate veins and the upper half of the superior vena cava; the left highest intercostal vein; the vagus, cardiac, phrenic, and left recurrent nerves; the trachea, œsophagus, and thoracic duct; the remains of the thymus, and some lymph glands. .

des
n

FIG. 920. —The middle and posterior mediastina. Left side.

The **anterior mediastinal cavity** (Fig. 919) exists only on the left side where the left pleura diverges from the mid-sternal line. It is bounded in front by the sternum, laterally by the pleuræ, and behind by the pericardium. It is narrow, above, but widens out a little below. Its anterior wall is formed by the left Transversus thoracis and the fifth, sixth, and seventh left costal cartilages. It contains

a quantity of loose areolar tissue, some lymphatic vessels which ascend from the convex surface of the liver, two or three anterior mediastinal lymph glands, and the small mediastinal branches of the internal mammary artery.

The **middle mediastinal cavity** (Fig. 919) is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava with the azygos vein opening into it, the bifurcation of the trachea and the two bronchi, the pulmonary artery dividing into its two branches, the right and left pulmonary veins, the phrenic nerves, and some bronchial lymph glands.

The **posterior mediastinal cavity** (Figs. 919, 920) is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium above, and by the posterior surface of the Diaphragma below, behind by the vertebral column from the lower border of the fourth to the twelfth thoracic vertebra, and on either side by the mediastinal pleura. It contains the thoracic part of the descending aorta, the azygos and the two hemiazygos veins, the vagus and splanchnic nerves, the œsophagus, the thoracic duct, and some lymph glands.

Applied Anatomy.—*Primary tumors* of the mediastinum are usually lymphoma or lymphosarcoma arising from the thymus or from the bronchial or posterior mediastinal lymph glands sarcomata, dermoid cysts, and embryomata occur more rarely. These tumors give rise to pain, deformity of the chest, and symptoms of pressure on the various nerves, bloodvessels, air passages, lymphatics, and on the œsophagus, as these various structures pass through the thorax. They may produce physical signs very much like those of an aortic aneurism, so that diagnosis between the two is often difficult. The prognosis is bad, the condition usually proving fatal within a few months or a year of the onset of the symptoms.

Inflammation of the mediastinum due to wounds, or to the spread of inflammation from adjacent parts, *e. g.*, the œsophagus, the pericardium, is sometimes acute, leading to abscess formation. A more chronic form associated with adhesions and inflammation of the pericardium—the so-called chronic adhesive mediastinopericarditis—gives rise to obscure symptoms suggesting gradual heart-failure, and leads to death slowly but surely.

THE LUNGS (PULMONES).

The **lungs** are the essential organs of respiration; they are two in number, placed one on either side within the thorax, and separated from each other by the heart and other contents of the mediastinal cavity (Fig. 921). The substance of the lung is of a light, porous, spongy texture; it floats in water, and crepitates when handled, owing to the presence of air in the alveoli; it is also highly elastic; hence the retracted state of these organs when they are removed from the closed cavity of the thorax. The surface is smooth, shining, and marked out into numerous polyhedral areas, indicating the lobules of the organ: each of these areas is crossed by numerous lighter lines.

At birth the lungs are pinkish white in color; in adult life the color is a dark slaty gray, mottled in patches; and as age advances, this mottling assumes a black color. The coloring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. As a rule, the posterior border of the lung is darker than the anterior.

The right lung usually weighs about 625 gm., the left 567 gm., but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female, their proportion to the body being, in the former, as 1 to 37, in the latter as 1 to 43.

Each lung is conical in shape, and presents for examination an **apex**, a **base**, three **borders**, and two **surfaces**.

The **apex** (*apex pulmonis*) is rounded, and extends into the root of the neck, reaching from 2.5 to 4 cm. above the level of the sternal end of the first rib. A

sulcus produced by the subclavian artery as it curves in front of the pleura runs upward and lateralward immediately below the apex.

The **base** (*basis pulmonis*) is broad, concave, and rests upon the convex surface of the Diaphragma, which separates the right lung from the right lobe of the liver, and the left lung from the left lobe of the liver, the stomach, and the spleen. Since the Diaphragma extends higher on the right than on the left side, the concavity on the base of the right lung is deeper than that on the left. Laterally and behind, the base is bounded by a thin, sharp margin which projects for some distance into the phrenicocostal sinus of the pleura, between the lower ribs and the costal attachment of the Diaphragma. The base of the lung descends during inspiration and ascends during expiration.

79

FIG. 921.—Front view of heart and lungs

Surfaces.—The **costal surface** (*facies costalis; external or thoracic surface*) is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front. It is in contact with the costal pleura, and presents, in specimens which have been hardened *in situ*, slight grooves corresponding with the overlying ribs.

The **mediastinal surface** (*facies mediastinalis; inner surface*) is in contact with the mediastinal pleura. It presents a deep concavity, the **cardiac impression**, which accommodates the pericardium; this is larger and deeper on the left than on the right lung, on account of the heart projecting farther to the left than to the right side of the median plane. Above and behind this concavity is a triangular depression named the **hilus**, where the structures which form the root of the lung enter and leave the viscus. These structures are invested by pleura, which, below

the hilus and behind the pericardial impression, forms the pulmonary ligament. On the *right* lung (Fig. 922), immediately above the hilus, is an arched furrow which accommodates the azygos vein; while running upward, and then arching lateralward some little distance below the apex, is a wide groove for the superior vena cava and right innominate vein; behind this, and nearer the apex, is a furrow for the innominate artery. Behind the hilus and the attachment of the pulmonary ligament is a vertical groove for the œsophagus; this groove becomes less distinct below, owing to the inclination of the lower part of the œsophagus to the left of the middle line. In front and to the right of the lower part of the œsophageal groove is a deep concavity for the extrapericardiac portion of the thoracic part of the inferior vena cava. On the *left* lung (Fig. 923), immediately above the hilus, is a well-marked curved furrow produced by the aortic arch, and running upward

FIG. 922.—Mediastinal surface of right lung.

from this toward the apex is a groove accommodating the left subclavian artery; a slight impression in front of the latter and close to the margin of the lung lodges the left innominate vein. Behind the hilus and pulmonary ligament is a vertical furrow produced by the descending aorta, and in front of this, near the base of the lung, the lower part of the œsophagus causes a shallow impression.

Borders.—The *inferior border* (*margo inferior*) is thin and sharp where it separates the base from the costal surface and extends into the phrenicocostal sinus; medially where it divides the base from the mediastinal surface it is blunt and rounded.

The *posterior border* (*margo posterior*) is broad and rounded, and is received into the deep concavity on either side of the vertebral column. It is much longer than the anterior border, and projects, below, into the phrenicocostal sinus.

The **anterior border** (*margo anterior*) is thin and sharp, and overlaps the front of the pericardium. The anterior border of the *right* lung is almost vertical, and projects into the costomediastinal sinus; that of the *left* presents, below, an angular notch, the **cardiac notch**, in which the pericardium is exposed. Opposite this notch the anterior margin of the left lung is situated some little distance lateral to the line of reflection of the corresponding part of the pleura.

FIG. 923.—Mediastinal surface of left lung.

Fissures and Lobes of the Lungs.—The **left lung** is divided into two lobes, an upper and a lower, by an interlobular fissure, which extends from the costal to the mediastinal surface of the lung both above and below the hilus. As seen on the surface, this fissure begins on the mediastinal surface of the lung at the upper and posterior part of the hilus, and runs backward and upward to the posterior border, which it crosses at a point about 6 cm. below the apex. It then extends downward and forward over the costal surface, and reaches the lower border a little behind its anterior extremity, and its further course can be followed upward and backward across the mediastinal surface as far as the lower part of the hilus. The **superior lobe** lies above and in front of this fissure, and includes the apex, the anterior border, and a considerable part of the costal surface and the greater part of the mediastinal surface of the lung. The **inferior lobe**, the larger of the two, is situated below and behind the fissure, and comprises almost the whole of the base, a large portion of the costal surface, and the greater part of the posterior border.

The **right lung** is divided into three lobes, superior, middle, and inferior, by two interlobular fissures. One of these separates the inferior from the middle and superior lobes, and corresponds closely with the fissure in the left lung. Its

direction is, however, more vertical, and it cuts the lower border about 7.5 cm. behind its anterior extremity. The other fissure separates the superior from the middle lobe. It begins in the previous fissure near the posterior border of the lung, and, running horizontally forward, cuts the anterior border on a level with the sternal end of the fourth costal cartilage; on the mediastinal surface it may be traced backward to the hilus. The **middle lobe**, the smallest lobe of the right lung, is wedge-shaped, and includes the lower part of the anterior border and the anterior part of the base of the lung.

The right lung, although shorter by 2.5 cm. than the left, in consequence of the Diaphragma rising higher on the right side to accommodate the liver, is broader, owing to the inclination of the heart to the left side; its total capacity is greater and it weighs more than the left lung.

The Root of the Lung (*radix pulmonis*).—A little above the middle of the mediastinal surface of each lung, and nearer its posterior than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchus, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexuses of nerves, lymphatic vessels, bronchial lymph glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the superior vena cava and part of the right atrium, and below the azygos vein. That of the left lung passes beneath the aortic arch and in front of the descending aorta; the phrenic nerve, the pericardiophrenic artery and vein, and the anterior pulmonary plexus, lie in front of each, and the vagus and posterior pulmonary plexus behind each; below each is the pulmonary ligament.

The chief structures composing the root of each lung are arranged in a similar manner from before backward on both sides, viz., the upper of the two pulmonary veins in front; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downward, on the two sides, their arrangement differs, thus:

On the right side their position is—eparterial bronchus, pulmonary artery, hyparterial bronchus, pulmonary veins, but on the left side their position is—pulmonary artery, bronchus, pulmonary veins. The lower of the two pulmonary veins, is situated below the bronchus, at the apex or lowest part of the hilus (Figs. 922, 923).

Divisions of the Bronchi.—Just as the lungs differ from each other in the number of their lobes, so the bronchi differ in their mode of subdivision.

The **right bronchus** gives off, about 2.5 cm. from the bifurcation of the trachea, a branch for the superior lobe. This branch arises above the level of the pulmonary artery, and is therefore named the **eparterial bronchus**. All the other divisions of the main stem come off below the pulmonary artery, and consequently are termed **hyparterial bronchi**. The first of these is distributed to the middle lobe, and the main tube then passes downward and backward into the inferior lobe, giving off in its course a series of large ventral and small dorsal branches. The ventral and dorsal branches arise alternately, and are usually eight in number—four of each kind. The branch to the middle lobe is regarded as the first of the ventral series.

The **left bronchus** passes below the level of the pulmonary artery before it divides, and hence all its branches are hyparterial; it may therefore be looked upon as equivalent to that portion of the right bronchus which lies on the distal side of its eparterial branch. The first branch of the left bronchus arises about 5 cm. from the bifurcation of the trachea, and is distributed to the superior lobe. The main stem then enters the inferior lobe, where it divides into ventral and dorsal branches similar to those in the right lung. The branch to the superior lobe of the left lung is regarded as the first of the ventral series.

Structure.—The lungs are composed of an external serous coat, a subserous areolar tissue, and the pulmonary substance or parenchyma.

The **serous coat** is the pulmonary pleura (page 1097); it is thin, transparent, and invests the entire organ as far as the root.

The **subserous areolar tissue** contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inward between the lobules.

The **parenchyma** is composed of lobules which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the fetus. The lobules vary in size; those on the surface are large, of pyramidal form, the base turned toward the surface; those in the interior smaller, and of various forms. Each lobule is composed of a lobular bronchiole and its terminal air cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves; all of these structures being connected together by areolar tissue.

The **intrapulmonary bronchi** divide and subdivide throughout the entire organ, the smallest subdivisions constituting the lobular bronchioles. The *larger divisions* consist of: (1) an outer coat of fibrous tissue in which are found at intervals irregular plates of hyaline cartilage, most developed at the points of division; (2) internal to the fibrous coat, a layer of circularly disposed smooth muscle fibres, the bronchial muscle; and (3) most internally, the mucous membrane, lined by columnar ciliated epithelium resting on a basement membrane. The corium of the mucous membrane contains numerous elastic fibres running longitudinally, and a certain amount of lymphoid tissue; it also contains the ducts of mucous glands, the acini of which lie in the fibrous coat. The **lobular bronchioles** differ from the larger tubes in containing no cartilage and in the fact that the ciliated epithelial cells are cubical in shape. The lobular bronchioles are about 0.2 mm. in diameter.

Cartilage plates

FIG. 924.—Section of lung of cat, showing termination of bronchus. $\times 50$.

Each bronchiole terminates at a point called the **vestibule** by dividing into from three to six wider irregular passages called **atria**. These are lined by flattened non-ciliated epithelium; at the vestibule the bronchial muscle forms a definite circular band. From each atrium arise two or more **infundibula**, elongated, blind passages, lined by simple squamous epithelium, and beset on all sides by hemispherical alveoli or air cells (Fig. 924).

The **alveoli** are lined by a delicate layer of simple squamous epithelium, the cells of which are united at their edges by cement substance. Between the squames are here and there smaller, polygonal, nucleated cells. Outside the epithelial lining is a little delicate connective tissue, containing numerous elastic fibres and a close net-work of blood capillaries, and forming a common wall to adjacent alveoli (Fig. 925).

The fetal lung resembles a gland in that the alveoli have a small lumen and are lined by cubical epithelium (Fig. 926). After the first respiration the alveoli become distended, and the epithelium takes on the characters described above.

Vessels and Nerves.—The **pulmonary artery** conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes and end in a dense capillary net-work in

FIG. 925.—Section of lung tissue.

the walls of the alveoli. In the lung the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below.

a

FIG. 926.—Section of lung of pig embryo, 13 cm. long, showing the glandular character of the developing alveoli. (J. M. Flint.) X 70. a. Interstitial connective tissue. b. A bronchial tube. c. An Alveolus. l. lymphatic clefts. p. Pleura.

The **pulmonary capillaries** form plexuses which lie immediately beneath the lining epithelium, in the walls and septa of the alveoli and of the infundibula. In the septa between the

alveoli the capillary net-work forms a single layer. The capillaries form a very minute net-work, the meshes of which are smaller than the vessels themselves; their walls are also exceedingly thin. The arteries of neighboring lobules are independent of each other, but the veins freely anastomose.

The **pulmonary veins** commence in the pulmonary capillaries, the radicles coalescing into larger branches which run through the substance of the lung, independently of the pulmonary arteries and bronchi. After freely communicating with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilus of the organ. Finally they open into the left atrium of the heart, conveying oxygenated blood to be distributed to all parts of the body by the aorta.

The **bronchial arteries** supply blood for the nutrition of the lung; they are derived from the thoracic aorta or from the upper aortic intercostal arteries, and, accompanying the bronchial tubes, are distributed to the bronchial glands and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat; this plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary veins. Others are distributed in the interlobular areolar tissue, and end partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung, beneath the pleura, where they form a capillary network.

The **bronchial vein** is formed at the root of the lung, receiving superficial and deep veins corresponding to branches of the bronchial artery. It does not, however, receive all the blood supplied by the artery, as some of it passes into the pulmonary veins. It ends on the right side in the azygos vein, and on the left side in the highest intercostal or in the accessory hemiazygos vein.

The **lymphatics** are described on page 799.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and vagus. The filaments from these plexuses accompany the bronchial tubes, supplying efferent fibres to the bronchial muscle and afferent fibres to the bronchial mucous membrane and to the alveoli of the lung. Small ganglia are found upon these nerves.

Applied Anatomy.—The lungs may be wounded or torn in three ways: (1) by compression of the chest, without any injury to the ribs; (2) by a fractured rib penetrating the lung; (3) by stabs, gunshot wounds, etc.

The first form, where the lung is ruptured by external compression without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung, *i. e.*, the most fixed part, and thus, implicating the great vessels, is frequently fatal. It would seem *a priori* a most unusual injury, and its exact mode of causation is difficult to interpret.

In the second variety, when the wound in the lung is produced by the penetration of a broken rib, both the costal pleura and pulmonary pleura must necessarily be injured, and consequently the air taken into the wounded alveoli may find its way through these wounds into the cellular tissue of the parietes of the chest, producing *surgical emphysema*. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air passes straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes therefore the most important sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries of the third variety—that is to say, from external wounds, from stabs, gunshot injuries, and such like—in which case air passes either from the wound of the lung or from the external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air is drawn into the wound during inspiration, and then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally in wounds of the parietes of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This takes place where the wound is large, and constitutes one form of *hernia* of the lung. Another form of hernia of the lung occurs, though very rarely, after wounds of the chest wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls in during inspiration, and disappears on holding the breath.

An incision into the lung is occasionally required in cases of abscess the result of pneumonia or the presence of a foreign body, and from an abscess in the liver which has made its way through the Diaphragm into the lung substance, and also in cases of hydatid disease. In these cases there is always risk of hemorrhage, and it has been recommended that the lung tissue should be penetrated by the actual cautery, rather than with the knife. Unless adhesions have formed between the two layers of the pleura, the pleural cavity must necessarily be opened, and there is the further risk of pneumothorax, and possibly of septic infection. It is therefore advisable to suture the lung to the opening in the thoracic wall, and wait for adhesions to form before perforating the lung.

The routine methods of physical examination—inspection, palpation, percussion, and auscultation—are nowhere more important than they are in the diagnosis of diseases of the lungs. It is essential, too, that in every case the two sides of the chest should be compared with one another, and that the wide variations that may be met with under normal conditions in different persons and at different ages should be kept in mind when the chest is being examined. On *inspection* the thorax will be seen to be enlarged and barrel-shaped in emphysema, in which the volume of the lungs is increased by dilatation of their alveoli, or in an acute attack of asthma, or when a large pleural effusion or mediastinal tumor is present. The chest wall will be flattened or sunken, on the other hand, over an area of lung that has collapsed or become fibrosed, as often happens in chronic pulmonary tuberculosis. The respiratory movements of the chest wall will be lessened, or even absent, over a part of the whole of the affected side in such acute disorders as pleurisy, pneumonia, or pleural effusion, or in more chronic diseases where the underlying lung is fibrosed, or is crushed to one side by a mediastinal tumor; and by the use of the x-rays a corresponding loss of movement or displacement of the Diaphragma on the affected side can often be observed. Under normal conditions the intercostal spaces are a little depressed; but they may be obliterated or even bulging on that side when a large effusion or new growth fills up one of the pleural cavities.

On *palpation* the hand can be used to verify the eye's impressions as to the degree of movement on respiration of any part of the chest wall. The facility with which the vibrations produced by the voice are conducted from the larynx by the underlying lung to the hand (in the form of *vocal fremitus*) can also be tested. The vocal fremitus is commonly much increased over the consolidated area in pneumonia or in fibrosis of the lung, and much diminished over a pleural effusion when the lung is pushed up by the fluid toward the top of the pleural cavity. It is also diminished, but to a less extent, in emphysema, and in bronchitis when the bronchi are blocked by secretion. In bronchitis the bubbling of the secretion in the tubes can often be felt by a hand placed on the chest wall as the patient breathes; and in chronic pleurisy the friction of the two roughened pleural surfaces against one another can sometimes be felt in the same way.

On *percussion*, the normal resonance of the pulmonary tissue is found to be increased in emphysema, and in pneumothorax (page 1098) this hyperresonance may be still further increased. The resonance is lessened in any condition causing collapse or solidification of the lung tissue, or when its place is taken by fluid (pleural effusion) or some solid growth (mediastinal tumor). Thus dullness on percussion at the bases of the lungs is common in the hypostatic congestion of the bases seen in heart failure; dullness at the right base is often due to compression of the lung by enlargement of the liver; some dullness at the apex of a lung is frequently met with in tuberculosis of the part, before the disease has progressed very far. Complete dullness over one side of the chest, back and front alike, except at the apex, is common when a large pleural effusion has taken the lung's place. Von Korányi, Grocco, and others have drawn attention to a triangular patch of dullness along the vertebral column (the paravertebral triangle of dullness) on the unaffected side in pleural effusion; this triangle of dullness is said to be absent in other conditions, causing loss of pulmonary resonance on percussion, and is due to shifting over of the contents of the posterior mediastinal cavity toward the sound side. The apex of this triangle is in the middle line at the upper level of the fluid effusion; its base, some 5 to 10 cm. in length, runs horizontally outward from the middle line at the level where the pulmonary resonance normally comes to an end.

On *auscultation* of the lungs, both in health and disease, the variety of sounds to be heard is very great. It is impossible to give adequate consideration to them here, and for further information reference should be made to text-books dealing with the subject.¹

THE DIGESTIVE APPARATUS (APPARATUS DIGESTORIUS; ORGANS OF DIGESTION).

The apparatus for the digestion of the food consists of the **digestive tube** and of certain **accessory organs**.

The **Digestive Tube** (*alimentary canal*) is a musculomembranous tube, about 9 metres long, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course: at its commencement is the **mouth**, where provision is made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); beyond this are the organs of deglutition, the **pharynx** and the **œsophagus**, which convey the food into the **stomach**, in which it is stored for a time and in which also the first stages of the

¹ See especially *Auscultation and Percussion*, by Austin Flint, M.D., 6th ed., 1912.

digestive process take place; the stomach is followed by the **small intestine**, which is divided for purposes of description into three parts, the **duodenum**, the **jejunum**, and **ileum**. In the small intestine the process of digestion is completed and the resulting products are absorbed into the blood and lacteal vessels. Finally the small intestine ends in the **large intestine**, which is made up of **cecum**, **colon**, **rectum**, and **anal canal**, the last terminating on the surface of the body at the **anus**.

The accessory organs are the **teeth**, for purposes of mastication; the three pairs of **salivary glands**—the **parotid**, **submaxillary**, and **sublingual**—the secretion from which mixes with the food in the mouth and converts it into a bolus and acts chemically on one of its constituents; the **liver** and **pancreas**, two large glands in the abdomen, the secretions of which, in addition to that of numerous minute glands in the walls of the alimentary canal, assist in the process of digestion.

THE MOUTH (CAVUM ORIS; ORAL OR BUCCAL CAVITY).

The **cavity of the mouth** is placed at the commencement of the digestive tube (Fig. 927); it is a nearly oval-shaped cavity which consists of two parts: an outer, smaller portion, the **vestibule**, and an inner, larger part, the **mouth cavity proper**.

The **Vestibule** (*vestibulum oris*) is a slit-like space, bounded externally by the lips and cheeks; internally by the gums and teeth. It communicates with the surface of the body by the **rima** or **orifice of the mouth**. Above and below, it is limited by the reflection of the mucous membrane from the lips and cheeks to the gum covering the upper and lower alveolar arch respectively. It receives the secretion from the parotid salivary glands, and communicates, when the jaws are closed, with the mouth cavity proper by an aperture on either side behind the wisdom teeth, and by narrow clefts between opposing teeth.

The **Mouth Cavity Proper** (*cavum oris proprium*) (Fig. 943) is bounded laterally and in front by the alveolar arches with their contained teeth; behind, it communicates with the pharynx by a constricted aperture termed the **isthmus faucium**. It is roofed in by the hard and soft plates, while the greater part of the floor is formed by the tongue, the remainder by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner aspect of the mandible. It receives the secretion from the submaxillary and sublingual salivary glands.

Structure.—The **mucous membrane** lining the mouth is continuous with the integument at the free margin of the lips, and with the mucous lining of the pharynx behind; it is of a rose-pink tinge during life, and very thick where it overlies the hard parts bounding the cavity. It is covered by stratified squamous epithelium.

The **Lips** (*labia oris*), the two fleshy folds which surround the rima or orifice of the mouth, are formed externally of integument and internally of mucous membrane, between which are found the Orbicularis oris muscle, the labial vessels, some nerves, areolar tissue, and fat, and numerous small labial glands. The inner surface of each lip is connected in the middle line to the corresponding gum by a fold of mucous membrane, the **frenulum**—the upper being the larger.

The **Labial Glands** (*glandulae labiales*) are situated between the mucous membrane and the Orbicularis oris, around the orifice of the mouth. They are circular in form, and about the size of small peas; their ducts open by minute orifices upon the mucous membrane. In structure they resemble the salivary glands.

The **Cheeks** (*buccae*) form the sides of the face, and are continuous in front with the lips. They are composed externally of integument; internally of mucous membrane; and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

Structure.—The **mucous membrane** lining the cheek is reflected above and below upon the gums, and is continuous behind with the lining membrane of the soft palate. Opposite the

second molar tooth of the maxilla is a papilla, on the summit of which is the aperture of the parotid duct. The principal muscle of the cheek is the Buccinator; but other muscles enter into its formation, viz., the Zygomaticus, Risorius, and Platysma.

The *buccal glands* are placed between the mucous membrane and Buccinator muscle: they are similar in structure to the labial glands, but smaller. About five, of a larger size than the rest, are placed between the Masseter and Buccinator muscles around the distal extremity of the parotid duct; their ducts open in the mouth opposite the last molar tooth. They are called *molar glands*.

FIG. 927. —Sagittal section of nose, mouth, pharynx, and larynx.

The **Gums** (*gingivæ*) are composed of dense fibrous tissue, closely connected to the periosteum of the alveolar processes, and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this membrane

presents numerous fine papillæ, and is reflected into the alveoli, where it is continuous with the periosteal membrane lining these cavities.

Applied Anatomy.—The gums are occasionally the seat of considerable hypertrophy, forming a lobulated vascular fold growing up in front of and behind the teeth, so as almost to bury them. They may also become swollen and congested, bleeding freely, and often becoming ulcerated. The condition is known as *spongy gums*, and may occur in scurvy, in stomatitis and dyspepsia, in ill-fed tuberculous children, and from the administration of mercury; the gums are very tender, mastication is painful, and there is often considerable fetor. The margin of the gum presents an interrupted blue line in cases of lead poisoning. The collection of tartar, which consists of the secretion from the gums, mixed with fragments of food and salivary salts, may give rise to a condition known as *pyorrhæa alveolaris*, which is an inflammatory condition of the gums, followed by the gradual absorption of the alveolus and the falling out of the teeth. Fibrous tumors (*epulis*), myeloid growths, and epitheliomata are met with in the gums.

The **Palate** (*palatum*) forms the roof of the mouth; it consists of two portions, the **hard palate** in front, the **soft palate** behind.

The **Hard Palate** (*palatum durum*) (Fig. 943) is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate: It is covered by a dense structure, formed by the periosteum and mucous membrane of the mouth, which are intimately adherent. Along the middle line is a linear raphé, which ends anteriorly in a small papilla corresponding with the incisive canal. On either side and in front of the raphé the mucous membrane is thick, pale in color, and corrugated; behind, it is thin, smooth, and of a deeper color; it is covered with stratified squamous epithelium, and furnished with numerous palatal glands, which lie between the mucous membrane and the surface of the bone.

The **Soft Palate** (*palatum molle*) (Fig. 943) is a movable fold, suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position, *i. e.*, relaxed and pendent, its anterior surface is concave, continuous with the roof of the mouth, and marked by a median raphé. Its posterior surface is convex, and continuous with the mucous membrane covering the floor of the nasal cavities. Its upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its lower border is free. Its lower portion, which hangs like a curtain between the mouth and pharynx is termed the **palatine velum**.

Hanging from the middle of its lower border is a small, conical, pendulous process, the **palatine uvula**; and arching lateralward and downward from the base of the uvula on either side are two curved folds of mucous membrane, containing muscular fibres, called the **arches or pillars of the fauces**.

The **glossopalatine arch** (*arcus glossopalatinus*; *anterior pillar of fauces*) on either side runs downward, lateralward, and forward to the side of the base of the tongue, and is formed by the projection of the Glossopalatinus with its covering mucous membrane.

The **pharyngopalatine arch** (*arcus pharyngopalatinus*; *posterior pillar of fauces*) is larger and projects farther toward the middle line than the anterior; it runs downward, lateralward, and backward to the side of the pharynx, and is formed by the projection of the Pharyngopalatinus, covered by mucous membrane. On either side the two arches are separated below by a triangular interval, in which the palatine tonsil is lodged.

The aperture by which the mouth communicates with the pharynx is called the **isthmus faucium**. It is bounded, above, by the soft palate; below, by the dorsum of the tongue; and on either side, by the glossopalatine arch.

Palatine Aponeurosis.—Attached to the posterior border of the hard palate is a thin, firm fibrous lamella which supports the muscles and gives strength to the

soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally it is continuous with the pharyngeal aponeurosis.

Muscles of the Palate.—The muscles of the palate (Fig. 928) are:

Levator veli palatini.

Glossopalatinus.

Tensor veli palatini.

Pharyngopalatinus.

Musculus uvulae.

218

76218

FIG. 928.—Dissection of the muscles of the palate from behind

The **Levator veli palatini** (*Levator palati*) is a thick, rounded muscle situated lateral to the choanæ. It *arises* from the under surface of the apex of the petrous part of the temporal bone and from the medial lamina of the cartilage of the auditory tube. After passing above the upper concave margin of the Constrictor pharyngis superior it spreads out in the palatine velum, its fibres extending obliquely downward and medialward to the middle line, where they blend with those of the opposite side.

The **Tensor veli palatini** (*Tensor palati*) is a broad, thin, riband-like muscle placed lateral to the Levator veli palatini. It *arises* by a flat lamella from the scaphoid fossa at the base of the medial pterygoid plate, from the spina angularis of the sphenoid and from the lateral wall of the cartilage of the auditory tube. Descending vertically between the medial pterygoid plate and the Pterygoideus internus it ends in a tendon which winds around the pterygoid hamulus, being retained in this situation by some of the fibres of origin of the Pterygoideus internus.

Between the tendon and the hamulus is a small bursa. The tendon then passes medialward and is *inserted* into the palatine aponeurosis and into the surface behind the transverse ridge on the horizontal part of the palatine bone.

The **Musculus uvulae** (*Azygos uvulae*) *arises* from the posterior nasal spine of the palatine bones and from the palatine aponeurosis; it descends to be inserted into the uvula.

The **Glossopalatinus** (*Palatoglossus*) is a small fleshy fasciculus, narrower in the middle than at either end, forming, with the mucous membrane covering its surface, the glossopalatine arch. It *arises* from the anterior surface of the soft palate, where it is continuous with the muscle of the opposite side, and passing downward, forward, and lateralward in front of the palatine tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the Transversus linguae.

The **Pharyngopalatinus** (*Palatopharyngeus*) is a long, fleshy fasciculus narrower in the middle than at either end, forming, with the mucous membrane covering its surface, the pharyngopalatine arch. It is separated from the Glossopalatinus by an angular interval, in which the palatine tonsil is lodged. It *arises* from the soft palate, where it is divided into two fasciculi by the Levator veli palatini and Musculus uvulae. The **posterior fasciculus** lies in contact with the mucous membrane, and joins with that of the opposite muscle in the middle line; the **anterior fasciculus**, the thicker, lies in the soft palate between the Levator and Tensor, and joins in the middle line the corresponding part of the opposite muscle. Passing lateralward and downward behind the palatine tonsil, the Pharyngopalatinus joins the Stylopharyngeus, and is inserted with that muscle into the posterior border of the thyroid cartilage, some of its fibres being lost on the side of the pharynx and others passing across the middle line posteriorly, to decussate with the muscle of the opposite side.

Dissection.—In a dissection of the soft palate from its posterior or pharyngeal surface to its anterior or oral surface, the muscles would be exposed in the following order: viz., the posterior fasciculus of the Pharyngopalatinus, covered by a continuation of the mucous membrane of the floor of the nasal cavities; the Musculus uvulae; the Levator veli palatini; the anterior fasciculus of the Pharyngopalatinus; the aponeurosis of the Tensor veli palatini, and the Glossopalatinus covered by a continuation of the oral mucous membrane.

Nerves.—The Tensor veli palatini is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the accessory nerve through the pharyngeal plexus.¹

Actions.—During the *first stage* of deglutition, the bolus of food is driven back into the fauces by the pressure of the tongue against the hard palate, the base of the tongue being, at the same time, retracted, and the larynx raised with the pharynx. During the second stage the entrance to the larynx is closed by the drawing forward of the arytenoid cartilages toward the cushion of the epiglottis—a movement produced by the contraction of the Thyreoarytaenoidei, the Arytaenoidei, and the Arytaenoepiglottidei.

After leaving the tongue the bolus passes on to the posterior or laryngeal surface of the epiglottis, and glides along this for a certain distance; then the Glossopalatini, the constrictors of the fauces, contract behind it; the palatine velum is slightly raised by the Levator veli palatini, and made tense by the Tensor veli palatini; and the Pharyngopalatini, by their contraction, pull the pharynx upward over the bolus, and come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented from passing into the nasal part of the pharynx; at the same time, the Pharyngopalatini form an inclined plane, directed obliquely downward and backward along the under surface of which the bolus descends into, the lower part of the pharynx. The Salpingopharyngei raise the upper and lateral parts of the pharynx—i. e., those parts which are above the points where the Stylopharyngei are attached to the pharynx.

Mucous Membrane.—The *mucous membrane of the soft palate* is thin, and covered with stratified squamous epithelium on both surfaces, excepting near the pharyngeal ostium of the auditory tube, where it is columnar and ciliated. According to Klein, the mucous membrane on the

¹ "The Innervation of the Soft Palate," by Aldren Turner, *Journal of Anatomy and Physiology*, xxiii, 523.

nasal surface of the soft palate in the fetus is covered throughout by columnar ciliated epithelium, which subsequently becomes squamous; some anatomists state that it is covered with columnar ciliated epithelium, except at its free margin, throughout life. Beneath the mucous membrane on the oral surface of the soft plate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on its posterior surface and around the uvula.

Vessels and Nerves. The **arteries** supplying the palate are the descending palatine branch of the internal maxillary, the ascending palatine branch of the external maxillary, and the palatine branch of the ascending pharyngeal. The **veins** end chiefly in the pterygoid and tonsillar plexuses. The **lymphatic vessels** pass to the deep cervical glands. The **sensory nerves** are derived from the palatine and nasopalatine nerves and from the glossopharyngeal.

Applied Anatomy.—The occurrence of a congenital cleft in the palate has been already referred to as a defect in development (page 299). After the operation for the closure of a cleft in the palate, the palatine muscles, especially the Tensor and Levator veli palatini, have a tendency to retard the healing process by active traction upon the line of suture. To obviate this, it is necessary to divide them. This is best done by making longitudinal incisions, on either side, parallel to the cleft and just medial to the pterygoid hamulus, in such a position as to avoid the descending palatine artery. Acquired perforations of the palate are almost invariably the result of the breaking down of syphilitic gummata. The ensuing ulceration may continue until practically the whole palate, both hard and soft, has been destroyed. Tumors of the palate, both innocent and malignant, are occasionally seen.

Paralysis of the soft palate often occurs after diphtheria. It gives rise to a change in the voice, which becomes nasal, and to the regurgitation of fluids down the nose when their swallowing is attempted. On inspection, the palate is seen to hang flaccid and motionless when phonation or deglutition are attempted; it is also anesthetic.

FIG. 929.—Side view of the teeth and jaws.

The Teeth (*dentes*) (Figs. 929 to 931).—Man is provided with two sets of teeth, which make their appearance at different periods of life. Those of the first set appear in childhood, and are called the **deciduous** or **milk teeth**. Those of the second set, which also appear at an early period, may continue until old age, and are named **permanent**.

The **deciduous teeth** are twenty in number: four incisors, two canines, and four molars, in each jaw.

The **permanent teeth** are thirty-two in number: four incisors, two canines, four premolars, and six molars, in each jaw.

The dental formulæ may be represented as follows:

Deciduous Teeth.

	mol.	can.	in.	in.	can.	mol.	
Upper jaw	2	1	2	2	1	2	} Total 20
Lower jaw	2	1	2	2	1	2

Upper jaw	3	2	1	2	2	1	2	3	} Total 32
Lower jaw	3	2	1	2	2	1	2	3	

General Characteristics.—Each tooth consists of three portions: the **crown**, projecting above the gum; the **root**, imbedded in the alveolus; and the **neck**, the constricted portion between the crown and root.

FIG. 930.—Permanent teeth of upper dental arch, seen from below.

FIG. 931.—Permanent teeth of right half of lower dental arch, seen from above

The roots of the teeth are firmly implanted in depressions within the alveoli; these depressions are lined with periosteum which invests the tooth as far as the neck. At the margins of the alveoli, the periosteum is continuous with the fibrous structure of the gums.

In consequence of the curve of the dental arch, terms such as anterior and posterior, as applied to the teeth, are misleading and confusing. Special terms are therefore used to indicate the different surfaces of a tooth: the surface directed toward the lips or cheek is known as the **labial** or **buccal surface**; that directed toward the tongue is described as the **lingual surface**; those surfaces which touch

neighboring teeth are termed **surfaces of contact**. In the case of the incisor and canine teeth the surfaces of contact are medial and lateral; in the premolar and molar teeth they are anterior and posterior.

The superior dental arch is larger than the inferior, so that in the normal condition the teeth in the maxillæ slightly overlap those of the mandible both in front and at the sides. Since the upper central incisors are wider than the lower, the other teeth in the upper arch are thrown somewhat distally, and the two sets do not quite correspond to each other when the mouth is closed: thus the upper canine tooth rests partly on the lower canine and partly on the first premolar, and the cusps of the upper molar teeth lie behind the corresponding cusps of the lower molar teeth. The two series, however, end at nearly the same point behind; this is mainly because the molars in the upper arch are the smaller.

The Permanent Teeth (*dentes permanentes*) (Fig. 932). -The **Incisors** (*dentes incisivi*; *incisive* or *cutting teeth*) are so named from their presenting a sharp cutting edge, adapted for biting the food. They are eight in number, and form the four front teeth in each dental arch.

FIG. 932.—Permanent teeth. Right side. (Burchard)

The **crown** is directed vertically, and is chisel-shaped, being bevelled at the expense of its lingual surface, so as to present a sharp horizontal cutting edge, which, before being subjected to attrition, presents three small prominent points separated by two slight notches. It is convex, smooth, and highly polished on its labial surface; concave on its lingual surface, where, in the teeth of the upper arch, it is frequently marked by an inverted V-shaped eminence, situated near the gum. This is known as the **basal ridge** or **cingulum**. The **neck** is constricted. The **root** is long, single, conical, transversely flattened, thicker in front than behind, and slightly grooved on either side in the longitudinal direction.

The **upper incisors** are larger and stronger than the lower, and are directed obliquely downward and forward. The central ones are larger than the lateral, and their roots are more rounded.

The **lower incisors** are smaller than the upper: the central ones are smaller than the lateral, and are the smallest of all the incisors. They are placed vertically and are somewhat bevelled in front, where they have been worn down by contact with the overlapping edge of the upper teeth. The cingulum is absent.

The **Canine Teeth** (*dentes canini*) are four in number, two in the upper, and two in the lower arch, one being placed laterally to each lateral incisor. They are larger and stronger than the incisors, and their roots sink deeply into the bones, and cause well-marked prominences upon the surface.

The **crown** is large and conical, very convex on its labial surface, a little hollowed and uneven on its lingual surface, and tapering to a blunted point or cusp, which projects beyond the level of the other teeth. The **root** is single, but longer and thicker than that of the incisors, conical in form, compressed laterally, and marked by a slight groove on each side.

The **upper canine teeth** (popularly called *eye teeth*) are larger and longer than the lower, and usually present a distinct basal ridge.

The **lower canine teeth** (popularly called *stomach teeth*) are placed nearer the middle line than the upper, so that their summits correspond to the intervals between the upper canines and the lateral incisors.

The **Premolars** or **Bicuspid teeth** (*dentes praemolares*) are eight in number, four in each arch. They are situated lateral to and behind the canine teeth, and are smaller and shorter than them.

The **crown** is compressed antero-posteriorly, and surmounted by two pyramidal eminences or cusps, a labial and a lingual, separated by a groove; hence their name **bicuspid**. Of the two cusps the labial is the larger and more prominent. The **neck** is oval. The **root** is generally single, compressed, and presents in front and behind a deep groove, which indicates a tendency in the root to become double. The apex is generally bifid.

The **upper premolars** are larger, and present a greater tendency to the division of their roots than the lower; this is especially the case in the first upper premolar.

The **Molar Teeth** (*dentes molares*) are the largest of the permanent set, and their broad crowns are adapted for grinding and pounding the food. They are twelve in number; six in each arch, three being placed posterior to each of the second premolars.

The **crown** of each is nearly cubical in form, convex on its buccal and lingual surfaces, flattened on its surfaces of contact; it is surmounted by four or five tubercles, or cusps, separated from each other by a crucial depression; hence the molars are sometimes termed **multicuspids**. The **neck** is distinct, large, and rounded.

Upper Molars.—As a rule the first is the largest, and the third the smallest of the upper molars. The crown of the first has usually four tubercles; that of the second, three or four; that of the third, three. Each upper molar has three roots, and of these two are buccal and nearly parallel to one another; the third is lingual and diverges from the others as it runs upward. The roots of the third molar (*dens serotinus* or *wisdom-tooth*) are more or less fused together.

Lower Molars.—The lower molars are larger than the upper. On the crown of the first there are usually five tubercles; on those of the second and third, four

or five. Each lower molar has two roots, an anterior, nearly vertical, and a posterior, directed obliquely backward; both roots are grooved longitudinally, indicating a tendency to division. The two roots of the third molar (*dens serotinus* or *wisdom tooth*) are more or less united.

The Deciduous Teeth (*dentes decidui*; *temporary or milk teeth*) (Fig. 933).—The deciduous are smaller than, but, generally speaking, resemble in form, the teeth which bear the same names in the permanent set. The hinder of the two molars is the largest of all the deciduous teeth, and is succeeded by the

FIG. 933.—Deciduous teeth Left side.

second premolar. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The roots of the deciduous molars are

smaller and more divergent than those of the permanent molars, but in other respects bear a strong resemblance to them.

Structure of the Teeth.—On making a vertical section of a tooth (Fig. 934), a cavity will be found in the interior of the crown and the centre of each root; it opens by a minute orifice at the extremity of the latter. This is called the **pulp cavity**, and contains the **dental pulp**, a loose connective tissue richly supplied with vessels and nerves, which enter the cavity through the small aperture at the point of each root. Some of the cells of the pulp are arranged as a layer on the wall of the pulp cavity; they are named the **odontoblasts of Waldeyer**, and during the development of the tooth, are columnar in shape, but later on, after the dentin is fully formed, they become flattened and resemble osteoblasts. Each has two fine processes, the outer one passing into a dental canaliculus, the inner being continuous with the processes of the connective-tissue cells of the pulp matrix.

FIG. 936.—Vertical section of a premolar tooth. (Magnified.)

The solid portion of the tooth consists of (1) the **ivory** or **dentin**, which forms the bulk of the tooth; (2) the **enamel**, which covers the exposed part of the crown; and (3) a thin layer of bone, the **cement** or **crusta petrosa**, which is disposed on the surface of the root.

The **dentin** (*substantia eburnea, ivory*) (Fig. 936) forms the principal mass of a tooth. It is a modification of osseous tissue, from which it differs, however, in structure. On microscopic examination it is seen to consist of a number of minute wavy and branching tubes, the **dental canaliculi**, imbedded in a dense homogeneous substance, the **matrix**.

The **dental canaliculi** (*dental tubules*) (Fig. 937) are placed parallel with one another, and open at their inner ends into the pulp cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. These canaliculi vary in direction: thus in a tooth of the mandible they are vertical in the upper portion of the crown, becoming oblique and then horizontal in the neck and upper part of the root, while toward the lower part of the root they are inclined downward. In their course they divide and subdivide dichotomously, and, especially in the root, give off minute branches, which join together in loops in the matrix, or end blindly. Near the periphery of the dentin, the finer ramifications of the canaliculi terminate imperceptibly by free ends. The dental canaliculi have definite walls, consisting of an elastic homogeneous membrane, the **dental sheath of Neumann**, which resists the action of acids; they contain slender cylindrical prolongations of the odontoblasts, first described by Tomes, and named **Tomes' fibres** or **dental fibres**.

The **matrix** (*intertubular dentin*) is translucent, and contains the chief part of the earthy matter of the dentin. In it are a number of fine fibrils, which are continuous with the fibrils

Cement.

Interglobular
spaces

Dentin

of the dental pulp. After the earthy matter has been removed by steeping a tooth in weak acid, the animal basis remaining may be torn into laminae which run parallel with the pulp cavity, across the direction of the tubes. A section of dry dentin often displays a series of somewhat parallel lines—the **incremental lines of Salter**. These lines are composed of imperfectly calcified dentin arranged in layers. In consequence of the imperfection in the calcifying process, little irregular cavities are left, termed **interglobular spaces** (Fig. 937). Normally a series of these spaces is found toward the outer surface of the dentin, where they form a layer which is sometimes known as the **granular layer**. They have received their name from the fact that they are surrounded by minute nodules or globules of dentin. Other curved lines may be seen parallel to the surface. These are the **lines of Schreger**, and are due to the optical effect of simultaneous curvature of the dental fibres.

Chemical Composition.—According to Berzelius and von Bibra, dentin consists of 28 parts of animal and 72 parts of earthy matter. The animal matter is converted by boiling into gelatin. The earthy matter consists of phosphate of lime, carbonate of lime, a trace of fluoride of calcium, phosphate of magnesium, and other salts.

The **enamel** (*substantia adamantina*) is the hardest and most compact part of the tooth, and forms a thin crust over the exposed part of the crown, as far as the commencement of the root. It is thickest on the grinding surface of the crown, until worn away by attrition, and becomes thinner toward the neck. It consists of minute hexagonal rods or columns

FIG. 937. —Transverse section of a portion of the root of a canine tooth. $\times 300$.

termed **enamel fibres** or **enamel prisms** (*prismata adamantina*). They lie parallel with one another, resting by one extremity upon the dentin, which presents a number of minute depressions for their reception; and forming the free surface of the crown by the other extremity. The columns are directed vertically on the summit of the crown, horizontally at the sides; they are about 4μ in diameter, and pursue a more or less wavy course. Each column is a six-sided prism and presents numerous dark transverse shadings; these shadings are probably due to the manner in which the columns are developed in successive stages, producing shallow constrictions, as will be subsequently explained. Another series of lines, having a brown appearance, the **parallel striae** or **colored lines of Retzius**, is seen on section. According to Ebner, they are produced by air in the interprismatic spaces; others believe that they are the result of true pigmentation.

Numerous minute interstices intervene between the enamel fibres near their dental ends, a provision calculated to allow of the permeation of fluids from the dental canaliculi into the substance of the enamel.

Chemical Composition.—According to von Bibra, enamel consists of 96.5 per cent. of earthy matter, and 3.5 per cent. of animal matter. The earthy matter consists of phosphate of lime, with traces of fluoride of calcium, carbonate of lime, phosphate of magnesium, and other salts. According to Tomes, the enamel contains the merest trace of organic matter.

The *crusta petrosa* or *cement* (*substantia ossea*) is disposed as a thin layer on the roots of the teeth, from the termination of the enamel to the apex of each root, where it is usually very thick. In structure and chemical composition it resembles bone. It contains, sparingly, the lacunæ and canaliculi which characterize true bone; the lacunæ placed near the surface receive the canaliculi radiating from the side of the lacunæ toward the periodontal membrane; and those more deeply placed join with the adjacent dental canaliculi. In the thicker portions of the *crusta petrosa*, the lamellæ and Haversian canals peculiar to bone are also found.

P.p.

FIG. 938.—Sagittal section through the first lower deciduous molar of a human embryo 30 mm long. (R6æ.) $\times 100$. *L.E.L.* Labiodental lamina, here separated from the dental lamina. *Z.L.* Placed over the shallow dental furrow, points to the dental lamina, which is spread out below to form the enamel germ of the future tooth. *P.p.* Bicuspidate papilla, capped by the enamel germ. *Z.S.* Condensed tissue forming dental sac. *M.E.* Mouth epithelium.

As age advances, the cement increases in thickness, and gives rise to those bony growths or exostoses so common in the teeth of the aged; the pulp cavity also becomes partially filled up by a hard substance, intermediate in structure between dentin and bone (*osteodentin*, Owen; *secondary dentin*, Tomes). It appears to be formed by a slow conversion of the dental pulp, which shrinks, or even disappears.

Development of the Teeth (Figs. 938 to 941).—In describing the development of the teeth, the mode of formation of the deciduous teeth must first be considered, and then that of the permanent series.

FIG. 939.—Similar section through the canine tooth of an embryo 40 mm long. (R6æ.) $\times 100$. *L.F.* Labiodental furrow. The other lettering as in Fig. 938.

Development of the Deciduous Teeth.—The development of the deciduous teeth begins about the sixth week of fetal life as a thickening of the epithelium along the line of the future jaw, the thickening being due to a rapid multiplication of the more deeply situated epithelial cells. As the cells multiply they extend into the subjacent mesoderm, and thus form a ridge or strand of cells imbedded in mesoderm. About the seventh week a longitudinal splitting or cleavage of this strand of cells takes place, and it becomes divided into two strands; the separation begins in front and extends laterally, the process occupying four or five weeks. Of the two strands thus formed, the labial forms the labiodental lamina; while the other, the lingual, is the ridge of cells in connection with which the teeth, both deciduous and permanent, are developed. Hence it is known as the dental lamina or common dental germ. It forms a flat

band of cells, which grows into the substance of the embryonic jaw, at first horizontally inward, and then, as the teeth develop, vertically, i. e., upward in the upper jaw, and downward in the lower jaw. While still maintaining a horizontal direction it has two edges

—an *attached edge*, continuous with the epithelium lining the mouth, and a *free edge*, projecting inward, and imbedded in the mesodermal tissue of the embryonic jaw. Along its line of attachment to the buccal epithelium is a shallow groove, the **dental furrow**.

About the ninth week the dental lamina begins to develop enlargements along its free border. These are ten in number in each jaw, and each corresponds to a future deciduous tooth. They consist of masses of epithelial cells; and the cells of the deeper part—that is, the part farthest from the margin of the jaw—increase rapidly and spread out in all directions. Each mass thus comes to assume a club shape, connected with the general epithelial lining of the mouth by a narrow neck, embraced by mesoderm. They are now known as **special dental germs**. After a time the lower expanded portion inclines outward, so as to form an angle with the superficial constricted portion, which is sometimes known as the neck of the special dental germ. About the tenth week the mesodermal tissue beneath these special dental germs becomes differentiated into papillæ; these grow upward, and come in contact with the epithelial cells of the special dental germs, which become folded over them like a hood or cap. There is, then, at this stage a papilla (or papillæ) which has already begun to assume somewhat the shape of the crown of the future tooth, and from which the dentin and pulp of the tooth are formed, surmounted by a dome or cap of epithelial cells from which the enamel is derived.

FIG. 941.—Longitudinal section of the lower part of a growing tooth, showing the extension of the layer of adamantoblasts beyond the crown to mark off the limit of formation of the dentin of the root. (Röse.) *ad.* Adamantoblasts, continuous below with *ep. sch.*, the epithelial sheath of Hertwig. *d.* Dentin. *en.* Enamel. *od.* Odontoblasts. *p.* Pulp.

of a papilla in the mesodermal tissue for the same tooth. This is followed, about the sixth month after birth, by a further extension backward of the dental lamina, with the formation

In the meantime, while these changes have been going on, the dental lamina has been extending backward behind the special dental germ corresponding to the second deciduous molar tooth, and at about the seventeenth week it presents an enlargement, the special dental germ, for the first permanent molar, soon followed by the formation

of another enlargement and its corresponding papilla for the second molar. And finally the process is repeated for the third molar, its papilla appearing about the fifth year of life.

After the formation of the special dental germs, the dental lamina undergoes atrophic changes and becomes cribriform, except on the lingual and lateral aspects of each of the special germs of the temporary teeth, where it undergoes a local thickening forming the special dental germ of each of the successional permanent teeth—i. e., the ten anterior ones in each jaw. Here the same process goes on as has been described in connection with those of the deciduous teeth: that is, they recede into the substance of the gum behind the germs of the deciduous teeth. As they recede they become club-shaped, form expansions at their distal extremities, and finally meet papillæ, which have been formed in the mesoderm, just in the same manner as was the case in the deciduous teeth. The apex of each papilla indents the dental germ, which encloses it, and, forming a cap for it, becomes converted into the enamel, while the papilla forms the dentin and pulp of the permanent tooth.

The special dental germs consist at first of rounded or polyhedral epithelial cells; after the formation of the papillæ, these cells undergo a differentiation into three layers. Those which are in immediate contact with the papilla become elongated, and form a layer of well-marked columnar epithelium coating the papilla. They are the cells which form the enamel fibres, and are therefore termed **enamel cells** or **adamantoblasts**. The cells of the outer layer of the special dental germ, which are in contact with the inner surface of the dental sac, presently to be described, are much shorter, cubical in form, and are named the **external enamel epithelium**. All the intermediate round cells of the dental germ between these two layers undergo a peculiar change. They become stellate in shape and develop processes, which unite to form a net-work into which fluid is secreted; this has the appearance of a jelly, and to it the name of **enamel pulp** is given. This transformed special dental germ is now known under the name of **enamel organ** (Fig. 940).

While these changes are going on, a sac is formed around each enamel organ from the surrounding mesodermal tissue. This is known as the **dental sac**, and is a vascular membrane of connective tissue. It grows up from below, and thus encloses the whole tooth germ; as it grows it causes the neck of the enamel organ to atrophy and disappear; so that all communication between the enamel organ and the superficial epithelium is cut off. At this stage there are vascular papillæ surmounted by caps of epithelial cells, the whole being surrounded by by membranous sacs.

Formation of the Enamel.—The enamel is formed exclusively from the enamel cells or adamantoblasts of the special dental germ, either by direct calcification of the columnar cells, which become elongated into the hexagonal rods of the enamel; or, as is more generally believed, as a secretion from the adamantoblasts, within which calcareous matter is subsequently deposited.

The process begins at the apex of each cusp, at the ends of the enamel cells in contact with the dental papilla. Here a fine globular deposit takes place, being apparently shed from the end of the adamantoblasts. It is known by the name of the **enamel droplet**, and resembles keratin in its resistance to the action of mineral acids. This droplet then becomes fibrous and calcifies and forms the first layer of the enamel; a second droplet now appears and calcifies, and so on; successive droplets of keratin-like material are shed from the adamantoblasts and form successive layers of enamel, the adamantoblasts gradually receding as each layer is produced, until at the termination of the process they have almost disappeared. The intermediate cells of the enamel pulp atrophy and disappear, so that the newly formed calcified material and the external enamel epithelium come into apposition. This latter layer, however, soon disappears on the emergence of the tooth beyond the gum. After its disappearance the crown of the tooth is still covered by a distinct membrane, which persists for some time. This is known as the **cuticula dentis**, or **Nasmyth's membrane**, and is believed to be the last-formed layer of enamel derived from the adamantoblasts, which has not become calcified. It forms a horny layer, which may be separated from the subjacent calcified mass by the action of strong acids. It is marked by the hexagonal impressions of the enamel prisms, and, when stained by nitrate of silver, shows the characteristic appearance of epithelium.

Formation of the Dentin.—While these changes are taking place in the epithelium to form the enamel, contemporaneous changes occurring in the differentiated mesoderm of the dental papillæ result in the formation of the dentin. As before stated, the first germs of the dentin are the papillæ, corresponding in number to the teeth, formed from the soft mesodermal tissue which bounds the depressions containing the special enamel germs. The papillæ grow upward into the enamel germs and become covered by them, both being enclosed in a vascular connective tissue, the **dental sac**, in the manner above described. Each papilla then constitutes the formative pulp from which the dentin and permanent pulp are developed; it consists of rounded cells and is very vascular, and soon begins to assume the shape of the future tooth. The next step is the appearance of the **odontoblasts**, which have a relation to the development of the teeth similar to that of the osteoblasts to the formation of bone. They are formed from the cells of the periphery of the papilla—that is to say, from the cells in immediate contact with the adamantoblasts of the special dental germ. These cells become elongated, one end of the

elongated cell resting against the epithelium of the special dental germs, the other being tapered and often branched. By the direct transformation of the peripheral ends of these cells, or by a secretion from them, a layer of uncalcified matrix (**pro dentin**) is formed which caps the cusp or cusps, if there are more than one, of the papillæ. This matrix becomes fibrillated, and in it islets of calcification make their appearance, and coalescing give rise to a continuous layer of calcified material which covers each cusp and constitutes the first layer of dentin. The odontoblasts, having thus formed the first layer, retire toward the centre of the papilla, and, as they do so, produce successive layers of dentin from their peripheral extremities—that is to say, they form the dental matrix in which calcification subsequently takes place. As they thus recede from the periphery of the papilla, they leave behind them filamentous processes of cell protoplasm, provided with finer side processes; these are surrounded by calcified material, and thus form the dental canaliculi, and, by their side branches, the anastomosing canaliculi: the processes of protoplasm contained within them constitute the **dental fibres** (*Tomes' fibres*). In this way the entire thickness of the dentin is developed, each canaliculus being completed throughout its whole length by a single odontoblast. The central part of the papilla does not undergo calcification, but persists as the pulp of the tooth. In this process of formation of dentin it has been shown that an uncalcified matrix is first developed, and that in this matrix islets of calcification appear which subsequently blend together to form a cap to each cusp: in like manner successive layers are produced, which ultimately become blended with each other. In certain places this blending is not complete, portions of the matrix remaining uncalcified between the successive layers; this gives rise to little spaces, which are the interglobular spaces alluded to above.

Formation of the Cement.—The root of the tooth begins to be formed shortly before the crown emerges through the gum, but is not completed until some time afterward. It is produced by a downgrowth of the epithelium of the dental germ, which extends almost as far as the situation of the apex of the future root, and determines the form of this portion of the tooth. This fold of epithelium is known as the **epithelial sheath**, and on its papillary surface odontoblasts appear, which in turn form dentin, so that the dentin formation is identical in the crown and root of the tooth. After the dentin of the root has been developed, the vascular tissues of the dental sac begin to break through the epithelial sheath, and spread over the surface of the root as a layer of bone-forming material. In this osteoblasts make their appearance, and the process of ossification goes on in identically the same manner as in the ordinary intramembranous ossification of bone. In this way the cement is formed, and consists of ordinary bone containing canaliculi and lacunæ.

Formation of the Alveoli.—About the fourteenth week of embryonic life the dental lamina becomes enclosed in a trough or groove of mesodermal tissue, which at first is common to all the dental germs, but subsequently becomes divided by bony septa into loculi, each loculus containing the special dental germ of a deciduous tooth and its corresponding permanent tooth. After birth each cavity becomes subdivided, so as to form separate loculi (the future alveoli) for the deciduous tooth and its corresponding permanent tooth. Although at one time the whole of the growing tooth is contained in the cavity of the alveolus, the latter never completely encloses it, since there is always an aperture over the top of the crown filled by soft tissue, by which the dental sac is connected with the surface of the gum, and which in the permanent teeth is called the **gubernaculum dentis**.

Development of the Permanent Teeth.—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the deciduous teeth, and which, like them, are ten in number in each jaw: these are the **successional permanent teeth**; and (2) those which have no deciduous predecessors, but are superadded distal to the temporary dental series. These are three in number on either side in each jaw, and are termed **superadded permanent teeth**. They are the three molars of the permanent set, the molars of the deciduous set being replaced by the premolars of the permanent set. The development of the successional permanent teeth—the ten anterior ones in either jaw—has already been indicated. During their development the permanent teeth, enclosed in their sacs, come to be placed on the lingual side of the deciduous teeth and more distant from the margin of the future gum, and, as already stated, are separated from them by bony partitions. As the crown of the permanent tooth grows, absorption of these bony partitions and of the root of the deciduous tooth takes place, through the agency of **osteoclasts**, which appear at this time, and finally nothing but the crown of the deciduous tooth remains. This is shed or removed, and the permanent tooth takes its place.

The superadded permanent teeth are developed in the manner already described, by extensions backward of the posterior part of the dental lamina in each jaw.

Eruption of the Teeth.—When the calcification of the different tissues of the tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterward subjected, eruption takes place, the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is

itself pressed up by the increasing size of the root. At the same time the septa between the dental sacs ossify, and constitute the alveoli; these firmly embrace the necks of the teeth, and afford them a solid basis of support.

The eruption of the deciduous teeth commences about the seventh month after birth, and is completed about the end of the second year, the teeth of the lower jaw preceding those of the upper.

The following, according to C. S. Tomes, are the most usual times of eruption:

Lower central incisors	6 to 9 months.
Upper incisors	8 to 10 months.
Lower lateral incisors and first molars	15 to 21 months.
Canines	16 to 20 months.
Second molars	20 to 24 months.

There are, however, considerable variations in these times; thus, according to Holt:

At the age of 1 year a child should have	6 teeth.
“ “ 1½ years “ “	12 “
“ “ 2 “ “	16 “
“ “ 2½ “ “	20 “

Calcification of the permanent teeth proceeds in the following order in the lower jaw (in the upper jaw it takes place a little later): the first molar, soon after birth; the central and lateral incisors, and the canine, about six months after birth; the premolars, at the second year, or a little later; the second molar, about the end of the second year; the third molar, about the twelfth year.

The eruption of the permanent teeth takes place at the following periods, the teeth of the lower jaw preceding those of the upper by short intervals:

First molars	6th year.
Two central incisors	7th year.
Two lateral incisors	8th year.
First premolars	9th year.
Second premolars	10th year.
Canines	11th to 12th year.
Second molars	12th to 13th year.
Third molars	17th to 25th year.

Toward the sixth year, before the shedding of the deciduous teeth begins, there are twenty-four teeth in each jaw, viz., the ten deciduous teeth and the crowns of all the permanent teeth except the third molars.

Applied Anatomy.—As a consequence of local irritation or of chronic digestive disturbances occurring during their eruption, both the deciduous and the permanent teeth may show defective development or irregular transverse furrowing and erosions; this is particularly the case with the incisors. Quite distinct from and much less common than this is a characteristic malformation of the two upper central permanent incisors seen in patients with inherited syphilis, and first described by Hutchinson. Here there is a crescentic notch in the anterior surface and at the cutting edge of the tooth, which is peg-shaped, stunted, and often also set obliquely in the gum, pointing either inward or outward. Numerous forms of innocent *tumor* arising from the teeth, or from their constituent layers, have been described under the general name of *odontoma*. Infection of the pulp of a tooth by bacteria gaining access thereto in consequence of dental caries gives rise to the common and very painful *alveolar abscess*; starting in the apical space between the root of the tooth and its alveolar socket, the pus from such an abscess may make its way into the maxillary antrum, or burst through the hard palate or cheek. A more superficial abscess forming between the root of a tooth and the gum is known as a *gum-boil*.

The Tongue (*lingua*).—The tongue is the principal organ of the sense of taste, and an important organ of speech; it also assists in the mastication and deglutition

of the food. It is situated in the floor of the mouth, within the curve of the body of the mandible.

Its **Root** (*radix linguae; base*) (Fig. 906) is directed backward, and connected with the hyoid bone by the Hyoglossi and Genioglossi muscles and the hyoglossal membrane; with the epiglottis by three folds (*glossoepiglottic*) of mucous membrane; with the soft palate by the glossopalatine arches; and with the pharynx by the Constrictores pharyngis superiores and the mucous membrane.

Its **Apex** (*apex linguae; tip*), thin and narrow, is directed forward against the lingual surfaces of the lower incisor teeth.

FIG. 942.—The mouth cavity. The apex of the tongue is turned upward, and on the right side a superficial dissection of its under surface has been made.

Its **Inferior Surface** (*facies inferior linguae; under surface*) (Fig. 942) is connected with the mandible by the Genioglossi; the mucous membrane is reflected from it to the lingual surface of the gum and on to the floor of the mouth, where, in the middle line, it is elevated into a distinct vertical fold, the **frenulum linguae**. On either side lateral to the frenulum is a slight fold of the mucous membrane, the **plica fimbriata**, the free edge of which occasionally exhibits a series of fringe-like processes.

The apex of the tongue, part of the inferior surface, the sides, and dorsum are free.

The **Dorsum of the Tongue** (*dorsum linguae*) (Fig. 943) is convex and marked by a **median sulcus**, which divides it into symmetrical halves; this sulcus ends behind, about 2.5 cm. from the root of the organ, in a depression, the **foramen cecum**, from which a shallow groove, the **sulcus terminalis**, runs lateralward and forward on either side to the margin of the tongue. The part of the dorsum of the tongue

in front of this groove, forming about two-thirds of its surface, looks upward, and is rough and covered with papillæ; the posterior third looks backward, and is smoother, and contains numerous muciparous glands and lymph follicles (*lingual tonsil*). The foramen cecum is the remains of the upper part of the **thyroglossal duct** or diverticulum from which the thyroid gland is developed; the pyramidal lobe of the thyroid gland indicates the position of the lower part of the duct.

The **Papillæ of the Tongue** (Fig. 943) are projections of the corium. They are thickly distributed over the anterior two-thirds of its dorsum, giving to this surface its characteristic roughness. The varieties of papillæ met with are the **papillæ vallatæ**, **papillæ fungiformes**, **papillæ filiformes**, and **papillæ simplices**.

The **papillæ vallatæ** (*circumvallate papillæ*) (Fig. 944) are of large size, and vary from eight to twelve in number. They are situated on the dorsum of the tongue immediately in front of the foramen cecum and sulcus terminalis, forming a row on either side; the two rows run backward and medialward, and meet in the middle line, like the limbs of the letter V inverted. Each papilla consists of a projection of mucous membrane from 1 to 2 mm. wide, attached to the bottom of a circular depression of the mucous membrane; the margin of the depression is elevated to form a wall (*vallum*), and between this and the papilla is a circular sulcus termed

the fossa. The papilla is shaped like a truncated cone, the smaller end being directed downward and attached to the tongue, the broader part or base projecting a little above the surface of the tongue and being studded with numerous small secondary papillæ and covered by stratified squamous epithelium.

FIG. 944.—Vertical section of vallate papilla from the calf. (Engelmann.) A. The papilla. B. The surrounding wall. n. Nerves. d. Duct of a lingual gland.

FIG. 945.—A filiform papilla. Magnified

The **papillæ fungiformes** (*fungiform papillæ*) (Fig. 946), more numerous than the preceding, are found chiefly at the sides and apex, but are scattered irregularly and sparingly over the dorsum. They are easily recognized, among the other papillæ, by their large size, rounded eminences, and deep red color. They are narrow at their attachment to the tongue, but broad and rounded at their free extremities, and covered with secondary papillæ.

Secondary
papillæ

4

FIG. 946.—Section of a fungiform papilla. Magnified.

The **papillæ filiformes** (*filiform or conical papillæ*) (Fig. 945) cover the anterior two-thirds of the dorsum. They are very minute, filiform in shape, and arranged in lines parallel with the two rows of the papillæ vallatæ, excepting at the apex of the organ, where their direction is transverse. Projecting from their apices are numerous filamentous processes, or secondary papillæ; these are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillæ of mucous membrane generally. The larger and longer papillæ of this group are sometimes termed **papillæ conicæ**.

The **papillæ simplices** are similar to those of the skin, and cover the whole of the mucous membrane of the tongue, as well as the larger papillæ. They consist of closely set microscopic elevations of the corium, each containing a capillary loop, covered by a layer of epithelium.

Muscles of the Tongue.—The tongue is divided into lateral halves by a median fibrous septum which extends throughout its entire length and is fixed below to the hyoid bone. In either half there are two sets of muscles, extrinsic and intrinsic; the former have their origins outside the tongue, the latter are contained entirely within it.

The **extrinsic muscles** (Fig. 947) are:

Genioglossus.

Hyoglossus.

Chondroglossus.

Styloglossus.

Glossopalatinus.¹

—

FIG. 947.—Extrinsic muscles of the tongue. Left side.

The **Genioglossus** (*Geniohyoglossus*) is a flat triangular muscle close to and parallel with the median plane, its apex corresponding with its point of origin from the mandible, its base with its insertion into the tongue and hyoid bone. It *arises* by a short tendon from the superior mental spine on the inner surface of the symphysis menti, immediately above the Geniohyoideus, and from this point spreads out in a fan-like form. The inferior fibres extend downward, to be attached by a thin aponeurosis to the upper part of the body of the hyoid bone, a few passing between the Hyoglossus and Chondroglossus to blend with the Constrictores pharyngis; the middle fibres pass backward, and the superior ones upward and forward, to enter the whole length of the under surface of the tongue, from the root to the apex. The muscles of opposite sides are separated at their insertions by the median fibrous septum of the tongue; in front, they are more or less blended owing to the decussation of fasciculi in the median plane.

The **Hyoglossus**, thin and quadrilateral, *arises* from the side of the body and from the whole length of the greater cornu of the hyoid bone, and passes almost vertically upward to enter the side of the tongue, between the Styloglossus and Longitudinalis inferior. The fibres arising from the body of the hyoid bone overlap those from the greater cornu.

Relations.—The Hyoglossus is in relation by its *superficial surface* with the Digastricus, the Stylohyoideus, Styloglossus, and Mylohyoideus, the submaxillary ganglion, the lingual and

¹ The *Glossopalatinus* (*Palatoglossus*), although one of the muscles of the tongue, is more closely associated with the soft palate both in situation and function, it has consequently been described with the muscles of that structure (p. 1114).

hypoglossal nerves, the ranine vein, the sublingual gland, the deep portion of the submaxillary gland, and the submaxillary duct. By its *deep surface* it is in relation with the stylohyoid ligament, the Genioglossus, Longitudinalis inferior, and Constrictor pharyngis medius, the lingual vessels, and the glossopharyngeal nerve.

The **Chondroglossus** is sometimes described as a part of the Hyoglossus, but is separated from it by fibres of the Genioglossus, which pass to the side of the pharynx. It is about 2 cm. long, and *arises* from the medial side and base of the lesser cornu and contiguous portion of the body of the hyoid bone, and passes directly upward to blend with the intrinsic muscular fibres of the tongue, between the Hyoglossus and Genioglossus.

A small slip of muscular fibres is occasionally found, arising from the cartilago triticea in the lateral hyothyroid ligament and entering the tongue with the hindmost fibres of the Hyoglossus.

The **Styloglossus**, the shortest and smallest of the three styloid muscles, *arises* from the anterior and lateral surfaces of the styloid process, near its apex, and from the stylomandibular ligament. Passing downward and forward between the internal and external carotid arteries, it divides upon the side of the tongue into two portions: one, longitudinal, enters the side of the tongue near its dorsal surface, blending with the fibres of the Longitudinalis inferior in front of the Hyoglossus; the other, oblique, overlaps the Hyoglossus and decussates with its fibres.

The **intrinsic muscles** (Fig. 948) are:

Longitudinalis superior.

Transversus.

Longitudinalis inferior.

Verticalis.

The **Longitudinalis linguae superior** (*Superior lingualis*) is a thin stratum of oblique and longitudinal fibres immediately underlying the mucous membrane on the dorsum of the tongue. It *arises* from the submucous fibrous layer close to the epiglottis and from the median fibrous septum, and runs forward to the edges of the tongue.

The **Longitudinalis linguae inferior** (*Inferior lingualis*) is a narrow band situated on the under surface of the tongue between the Genioglossus and Hyoglossus. It extends from the root to the apex of the tongue: behind, some of its fibres are connected with the body of the hyoid bone; in front it blends with the fibres of the Styloglossus.

The **Transversus linguae** (*Transverse lingualis*) consists of fibres which *arise* from the median fibrous septum and pass lateralward to be inserted into the submucous fibrous tissue at the sides of the tongue.

The **Verticalis linguae** (*Vertical lingualis*) is found only at the borders of

the forepart of the tongue. Its fibres extend from the upper to the under surface of the organ.

Applied Anatomy.—The median fibrous septum of the tongue is very complete, so that the anastomosis between the two lingual arteries is not very free. This is a point of considerable

FIG. 948.—Coronal section of tongue, showing intrinsic muscles. (Altered from Krause.) a. Lingual artery. b. Longitudinalis inferior. c. Hyoglossus. d. Styloglossus. e. Insertion of Transversus. f. importance in connection with removal of one-half of the tongue for cancer, an operation frequently resorted to when the disease is strictly confined to one side of the organ. If the mucous membrane be divided exactly in the middle line, the tongue can be split into halves, without any appreciable hemorrhage, and the diseased half can then be removed.

Nerves.—The muscles of the tongue described above are supplied by the hypoglossal nerve.

Actions.—The movements of the tongue, although numerous and complicated, may be understood by carefully considering the direction of the fibres of its muscles. The Genioglossi, by means of their posterior fibres, draw the root of the tongue forward, and protrude the apex from the mouth. The anterior fibres draw the tongue back into the mouth. The two muscles acting in their entirety draw the tongue downward, so as to make its superior surface concave from side to side, forming a channel along which fluids may pass toward the pharynx, as in sucking. The Hyoglossi depress the tongue, and draw down its sides. The Styloglossi draw the tongue upward and backward. The Glossopalatini draw the root of the tongue upward. The intrinsic muscles are mainly concerned in altering the shape of the tongue, whereby it becomes shortened, narrowed, or curved in different directions; thus, the Longitudinalis superior and inferior tend to shorten the tongue, but the former, in addition, turn the tip and sides upward so as to render the dorsum concave, while the latter pull the tip downward and render the dorsum convex. The Transversus narrows and elongates the tongue, and the Verticalis flattens and broadens it. The complex arrangement of the muscular fibres of the tongue, and the various directions in which they run, give to this organ the power of assuming the forms necessary for the enunciation of the different consonantal sounds; and Macalister states "there is reason to believe that the musculature of the tongue varies in different races owing to the hereditary practice and habitual use of certain motions required for enunciating the several vernacular languages."

Structure of the Tongue.—The tongue is partly invested by mucous membrane and a sub-mucous fibrous layer.

The **mucous membrane** (*tunica mucosa linguae*) differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane of the dorsum of the tongue behind the foramen cecum and sulcus terminalis is thick and freely movable over the subjacent parts. It contains a large number of lymphoid follicles, which together constitute what is sometimes termed the **lingual tonsil**. Each follicle forms a rounded eminence, the centre of which is perforated by a minute orifice leading into a funnel-shaped cavity or recess; around this recess are grouped numerous oval or rounded nodules of lymphoid tissue, each enveloped by a capsule derived from the submucosa, while opening into the bottom of the recesses are also seen the ducts of mucous glands. The mucous membrane on the anterior part of the dorsum of the tongue is thin, intimately adherent to the muscular tissue, and presents numerous minute surface eminences, the **papillae** of the tongue. It consists of a layer of connective tissue, the **corium** or **mucosa**, covered with epithelium.

The epithelium is of the stratified squamous variety, similar to but much thinner than that of the skin; and each papilla has a separate investment from root to summit. The deepest cells may sometimes be detached as a separate layer, corresponding to the rete mucosum, but they never contain coloring matter.

The **corium** consists of a dense felt-work of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillae are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

Structure of the Papillae.—The papillae apparently resemble in structure those of the cutis, consisting of cone-shaped projections of connective tissue, covered with a thick layer of stratified squamous epithelium, and containing one or more capillary loops among which nerves are distributed in great abundance. If the epithelium be removed, it will be found that they are not simple elevations like the papillae of the skin, for the surface of each is studded with minute conical processes which form secondary papillae. In the papillae vallatae, the nerves are numerous and of large size; in the papillae fungiformes they are also numerous, and end in a plexiform net-work, from which brush-like branches proceed; in the papillae filiformes, their mode of termination is uncertain.

Glands of the Tongue.—The tongue is provided with mucous and serous glands.

The **mucous glands** are similar in structure to the labial and buccal glands. They are found especially at the back part behind the vallate papillae, but are also present at the apex and marginal parts. In this connection the anterior lingual glands (Blandin or Nuhn) require special notice. They are situated on the under surface of the apex of the tongue (Fig. 942), one on either side of the frenulum, where they are covered by a fasciculus of muscular fibres derived from the Styloglossus and Longitudinalis inferior. They are from 12 to 25 mm. long, and about 8 mm. broad, and each opens by three or four ducts on the under surface of the apex.

The **serous glands** occur only at the back of the tongue in the neighborhood of the taste-buds, their ducts opening for the most part into the fossae of the vallate papillae. These glands are racemose, the duct of each branching into several minute ducts, which end in alveoli, lined by

a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste area. (Ebner.)

The **septum** consists of a vertical layer of fibrous tissue, extending throughout the entire length of the median plane of the tongue, though not quite reaching the dorsum. It is thicker behind than in front, and occasionally contains a small fibrocartilage, about 6 mm. in length. It is well displayed by making a vertical section across the organ.

The **hyoglossal membrane** is a strong fibrous lamina, which connects the under surface of the root of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the fibres of the Genioglossi.

Taste-buds, the end-organs of the gustatory sense, are scattered over the mucous membrane of the mouth and tongue at irregular intervals. They occur especially in the sides of the vallate papillæ. In the rabbit there is a localized area at the side of the base of the tongue, the **papilla foliata**, in which they are especially abundant (Fig. 949). They are described under the organs of the senses (page 1007).

FIG. 949. Vertical section of papilla foliata of the rabbit, passing across the folia. (Ranvier.) *a*. Serous gland *g*. Gustatory calyculus. *n*. Nerve bundles. *p*. Central lamina of corium. *p'*. Lateral lamina. *s*. Section across a sinus-like vein, which traverses the whole length of the folium.

Vessels and Nerves. The main artery of the tongue is the lingual branch of the external carotid, but the external maxillary and ascending pharyngeal also give branches to it. The veins open into the internal jugular.

The lymphatics of the tongue have been described on page 778.

The **sensory nerves of the tongue** are: (1) the lingual branch of the mandibular, which is distributed to the papillæ at the forepart and sides of the tongue, and forms the nerve of ordinary sensibility for its anterior two-thirds; (2) the chorda tympani branch of the facial, which runs in the sheath of the lingual, and is generally regarded as the nerve of taste for the anterior two-thirds; this nerve is a continuation of the sensory root of the facial (*nervus intermedius*); (3) the lingual branch of the glossopharyngeal, which is distributed to the mucous membrane at the base and sides of the tongue, and to the papillæ vallatæ, and which supplies both gustatory filaments and fibres of general sensation to this region; (4) the superior laryngeal, which sends some fine branches to the root near the epiglottis.

Applied Anatomy.—The diseases to which the tongue is liable are numerous, and any or all of the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of vertical cleft have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of "tongue-tie," from shortness of the frenulum.

There is one condition which may be regarded as congenital, the so-called macroglossia, though sometimes it does not evidence itself until a year or two after birth. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph channels and a greatly increased development of the lymphatic tissue throughout the organ. This is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply placed sutures.

Acute inflammation of the tongue, which may be caused by injury and the introduction of some septic or irritating matter, is attended by great swelling from infiltration of its connective

tissue, which is in considerable quantity. This renders the patient incapable of swallowing or speaking, and may seriously impede respiration. It may run on to suppuration, and the formation of an acute abscess.

In all ages the mucous membrane of the tongue has received much sedulous consideration in disease, and it is certain that the amount and the distribution of the "fur" with which it may be covered often give valuable help in diagnosis. The fur consists of proliferating or desquamated epithelium, bound up with inspissated mucus, the debris of food, and bacteria of all sorts. The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in the various stages of the disease, to which the terms leucoplakia and psoriasis linguae have been given. They are usually the result of syphilis.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, tuberculosis, syphilis, and cancer. Of these the cancerous ulcer is the most important and also the most common. The variety is the squamous epithelioma, which soon develops into an ulcer with an indurated edge. It causes great pain, which speedily extends to all parts supplied with sensation by the trigeminal nerve, especially to the region of the ear (auriculotemporal nerve).

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the scissors; this is usually known as Whitehead's method. The mouth is widely opened with a gag, the tongue transfixed with a stout silk ligature, by which to hold and make traction on it; the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Genioglossus, are first divided with a pair of curved, blunt-pointed scissors. The Glossopalatinus is also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the main artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells' forceps, the tongue removed, and the vessel secured. In the event of the artery being accidentally injured, hemorrhage can be at once controlled by passing the forefinger over the tongue till it touches the epiglottis, and then turning it toward the side on which the artery is to be compressed, and pushing it forcibly against the jaw (Heath). In cases where the disease is confined to one side of the tongue, this operation may be modified by splitting the tongue down the centre and removing only the affected half.

In cases where the submaxillary lymph glands are involved, Kocher's operation should be resorted to. Having performed a preliminary tracheotomy, Kocher removes the tongue from the neck by an incision from near the lobule of the auricula, down the anterior border of the Sternocleidomastoideus to the level of the greater cornu of the hyoid bone, then forward to the body of the hyoid bone, and upward to near the symphysis menti. The lingual artery is now secured, and by a careful dissection the submaxillary lymph glands and the tongue are removed. If the lymph glands in the submaxillary region are in any way affected, an extensive dissection of these will be required if there is any chance of eradicating the disease, and for this purpose it will be found necessary to remove the submaxillary salivary gland.

The more recent operations aim at, first, clearing the neck thoroughly of affected glands, both in the submaxillary region and along the carotid sheath, and secondly, removal of the tongue from within the mouth, leaving if possible the mucous membrane of the floor of the mouth intact, so as to avoid soiling the large wound in the neck by discharges from the mouth.

The Salivary Glands (Fig. 952).—Three large pairs of salivary glands communicate with the mouth, and pour their secretion into its cavity; they are the **parotid**, **submaxillary**, and **sublingual**.

Parotid Gland (*glandulae parotis*).—The parotid gland (Figs. 950, 951), the largest of the three, varies in weight from 14 to 28 gm. It lies upon the side of the face, immediately below and in front of the external ear. The main portion of the gland is superficial, somewhat flattened and quadrilateral in form, and is placed between the ramus of the mandible in front and the mastoid process and Sternocleidomastoideus behind, overlapping, however, both boundaries. Above, it is broad and reaches nearly to the zygomatic arch; below, it tapers somewhat to about the level of a line joining the tip of the mastoid process to the angle of the mandible. The remainder of the gland is irregularly wedge-shaped, and extends deeply inward toward the pharyngeal wall.

The gland is enclosed within a capsule continuous with the deep cervical fascia; the layer covering the superficial surface is dense and closely adherent to the gland; a portion of the fascia, attached to the styloid process and the angle of the mandible, is thickened to form the stylomandibular ligament which intervenes between the parotid and submaxillary glands.

The **anterior surface** of the gland is moulded on the posterior border of the ramus of the mandible, clothed by the Pterygoideus internus and Masseter. The inner lip of the groove dips, for a short distance, between the two Pterygoid muscles,

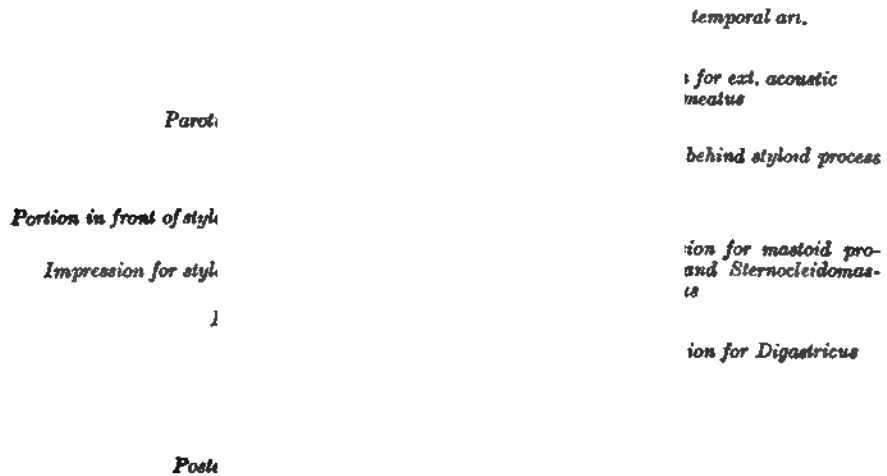

FIG. 950.—Right parotid gland. Posterior and deep aspects.

while the outer lip extends for some distance over the superficial surface of the Masseter; a small portion of this lip immediately below the zygomatic arch is usually detached, and is named the **accessory part** (*socii parotidis*) of the gland.

FIG. 951.—Right parotid gland. Deep and anterior aspects.

The **posterior surface** is grooved longitudinally and abuts against the external acoustic meatus, the mastoid process, and the anterior border of the Sternocleidomastoideus.

The **superficial surface**, slightly lobulated, is covered by the integument, the superficial fascia containing the facial branches of the great auricular nerve and some small lymph glands, and the fascia which forms the capsule of the gland.

The **deep surface** extends inward by means of two processes, one of which lies on the Digastricus, styloid process, and the styloid group of muscles, and projects under the mastoid process and Sternocleidomastoideus; the other is situated in front of the styloid process, and sometimes passes into the posterior part of the mandibular fossa behind the temporomandibular joint. The deep surface is in contact with the internal and external carotid arteries, the internal jugular vein, and the vagus and glossopharyngeal nerves.

The gland is separated from the pharyngeal wall by some loose connective tissue.

Structures within the Gland.—The *external carotid artery* lies at first on the deep surface, and then in the substance of the gland. The artery gives off its *posterior auricular* branch which emerges from the gland behind; it then divides into its terminal branches, the *internal maxillary* and *superficial temporal*; the former runs forward deep to the neck of the mandible; the latter runs upward across the zygomatic arch and gives off its *transverse facial* branch which emerges from the front of the gland. Superficial to the arteries are the *superficial temporal* and *internal maxillary veins*, uniting to form the *posterior facial* vein; in the lower part of the gland this vein splits into anterior and posterior divisions. The anterior division emerges from the gland and unites with the anterior facial to form the *common facial* vein; the posterior unites in the gland with the posterior auricular to form the *external jugular* vein. On a still more superficial plane is the facial nerve, the branches of which emerge from the borders of the gland. Branches of the *great auricular nerve* pierce the gland to join the facial, while the *auriculotemporal nerve* issues from the upper part of the gland.

The **parotid duct** (*ductus parotideus*; *Stensen's duct*) is about 7 cm. long. It begins by numerous branches from the anterior part of the gland, crosses the Masseter, and at the anterior border of this muscle turns inward nearly at a right angle, passes through the corpus adiposum of the cheek and pierces the Buccinator; it then runs for a short distance obliquely forward between the Buccinator and mucous membrane of the mouth, and opens upon the oral surface of the cheek by a small orifice, opposite the second upper molar tooth. While crossing the Masseter, it receives the duct of the accessory portion; in this position it lies between the branches of the facial nerve; the accessory part of the gland and the transverse facial artery are above it.

Structure.—The parotid duct is dense, its wall being of considerable thickness; its canal is about the size of a crow-quill, but at its orifice on the oral surface of the cheek its lumen is greatly reduced in size. It consists of a thick external fibrous coat which contains contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.

Vessels and Nerves.—The *arteries* supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The *veins* empty themselves into the external jugular, through some of its tributaries. The *lymphatic* end in the superficial and deep cervical lymph glands, passing in their course through two of three glands, placed on the surface and in the substance of the parotid. The *nerves* are derived from the plexus of the sympathetic on the external carotid artery, the facial, the auriculotemporal, and the great auricular nerves. It is probable that the branch from the auriculotemporal nerve is derived from the glossopharyngeal through the otic ganglion. At all events, in some of the lower animals this has been proved experimentally to be the case.

Submaxillary Gland (*glandula submaxillaris*).—The submaxillary gland (Fig. 952) is irregular in form and about the size of a walnut. A considerable part of it is situated in the submaxillary triangle, reaching forward to the anterior belly of the Digastricus and backward to the stylomandibular ligament, which intervenes between it and the parotid gland. Above, it extends under cover of the

body of the mandible; below, it usually overlaps the intermediate tendon of the Digastricus and the insertion of the Stylohyoideus, while from its deep surface a tongue-like *deep process* extends forward above the Mylohyoideus muscle.

Its **superficial surface** consists of an upper and a lower part. The **upper part** is directed outward, and lies partly against the submaxillary depression on the inner surface of the body of the mandible, and partly on the Pterygoideus internus. The **lower part** is directed downward and outward, and is covered by the skin, superficial fascia, Platysma, and deep cervical fascia; it is crossed by the anterior facial vein and by filaments of the facial nerve; in contact with it, near the mandible, are the submaxillary lymph glands.

of parotid
uct
illary duct

FIG. 952.--Dissection, showing salivary glands of right side

The **deep surface** is in relation with the Mylohyoideus, Hyoglossus, Styloglossus, Stylohyoideus, and posterior belly of the Digastricus; in contact with it are the mylohyoid nerve and the mylohyoid and submental vessels.

The external maxillary artery is imbedded in a groove in the posterior border of the gland.

The **deep process** of the gland extends forward between the Mylohyoideus below and externally, and the Hyoglossus and Styloglossus internally; above it, is the lingual nerve and submaxillary ganglion; below it, the hypoglossal nerve and its accompanying vein.

The **submaxillary duct** (*ductus submaxillaris*; *Wharton's duct*) is about 5 cm. long, and its wall is much thinner than that of the parotid duct. It begins by numerous branches from the deep surface of the gland, and runs forward between the Mylohyoideus and the Hyoglossus and Genioglossus, then between the sublingual gland and the Genioglossus, and opens by a narrow orifice on the summit of a small papilla, at the side of the frenulum linguae. On the Hyoglossus it lies between the

lingual and hypoglossal nerves, but at the anterior border of the muscle it is crossed laterally by the lingual nerve; the terminal branches of the lingual nerve ascend on its medial side.

Vessels and Nerves.—The arteries supplying the submaxillary gland are branches of the external maxillary and lingual. Its veins follow the course of the arteries. The nerves are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani of the facial nerve and the lingual branch of the mandibular, sometimes from the mylohyoid branch of the inferior alveolar, and from the sympathetic.

Sublingual Gland (*glandula sublingualis*).—The sublingual gland (Fig. 952) is the smallest of the three glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frenulum linguae, in contact with the sublingual depression on the inner surface of the mandible, close to the symphysis. It is narrow, flattened, shaped somewhat like an almond, and weighs nearly 2 gm. It is in relation, *above*, with the mucous membrane; *below*, with the Mylohyoideus; *in front*, with its fellow of the opposite side; *behind*, with the deep part of the submaxillary gland; *laterally*, with the mandible; and *medially*, with the Genioglossus, from which it is separated by the lingual nerve and the submaxillary duct. Its excretory ducts are from eight to twenty in number. Of the smaller sublingual ducts (*ducts of Rivinus*), some join the submaxillary duct; others open separately into the mouth, on the elevated crest of mucous membrane (*plica sublingualis*), caused by the projection of the gland, on either side of the frenulum linguae. One or more join to form the larger sublingual duct (*duct of Bartholin*), which opens into the submaxillary duct.

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual, the chorda tympani, and the sympathetic.

Structure of the Salivary Glands.—The salivary glands are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules, connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, the branches ending in dilated ends or alveoli on which the capillaries are distributed. The alveoli are enclosed by a basement-membrane, which is continuous with the membrana propria of the duct and consists of a net-work of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ in the appearance of their secreting cells, in their size, and in the nature of their secretion. (1) The mucous variety secretes a viscid fluid, which contains mucin; (2) the serous variety secretes a thinner and more watery fluid. The sublingual gland consists of mucous, the parotid of serous alveoli. The submaxillary contains both mucous and serous alveoli, the latter, however, preponderating.

The cells in the mucous alveoli are columnar in shape. In the fresh condition they contain large granules of mucinogen. In hardened preparations a delicate protoplasmic net-work is seen, and the cells are clear and transparent. The nucleus is usually situated near the basement-membrane, and is flattened.

In some alveoli are seen peculiar crescentic bodies, lying between the cells and the membrana propria. They are termed the *crescents of Gianuzzi*, or the *demilunes of Heidenhain* (Fig. 953), and are composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein. Fine canaliculi pass between the mucus-secreting cells to reach the demilunes and even penetrate the cells forming these structures.

In the serous alveoli the cells almost completely fill the cavity, so that there is hardly any lumen perceptible; they contain secretory granules imbedded in a closely reticulated protoplasm (Fig. 954). The cells are more cubical than those of the mucous type; the nucleus of each is spherical and placed near the centre of the cell, and the granules are smaller.

Both mucous and serous cells vary in appearance according to whether the gland is in a resting condition or has been recently active. In the former case the cells are large and contain many secretory granules; in the latter case they are shrunken and contain few granules, chiefly collected at the inner ends of the cells. The granules are best seen in fresh preparations.

The ducts are lined at their origins by epithelium which differs little from the pavement form. As the ducts enlarge, the epithelial cells change to the columnar type, and the part of the cell next the basement-membrane is finely striated.

The lobules of the salivary glands are richly supplied with bloodvessels which form a dense net-work in the intervalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The nerve fibrils pierce the basement-membrane of the alveoli, and end in branched varicose filaments between the secreting cells. In the hilus of the submaxillary gland there is a collection of nerve cells termed **Langley's ganglion**.

Demistune

FIG. 953.—Section of submaxillary gland of kitten. Duct semidiagrammatic. X 200.

FIG. 954.—Human submaxillary gland. (R. Heidenhain.) To the right of the figure is a group of mucous alveoli, to the left a group of serous alveoli.

Accessory Glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. Many of these glands are found at the posterior part of the dorsum of the tongue behind the vallate papillæ, and also along its margins as far forward as the apex. Others lie around and in the palatine tonsil between its crypts, and large numbers are present in the soft palate, the lips, and cheeks. These glands are of the same structure as the larger salivary glands, and are of the mucous or mixed type.

Applied Anatomy.—The parotid glands, and much less often the other salivary glands, are liable to an acute infectious inflammation, known in the case of the parotid as *mumps*. The affected glands swell up, becoming tense, tender, and painful; much pain is felt when swallowing or mastication is attempted, and salivation may or may not occur. The inflammation goes down after a few days; suppuration in the affected glands is very rare.

THE PHARYNX.

The **pharynx** is that part of the digestive tube which is placed behind the nasal cavities, mouth, and larynx. It is a musculomembranous tube, somewhat conical in form, with the base upward, and the apex downward, extending from the under surface of the skull to the level of the cricoid cartilage in front, and that of the sixth cervical vertebra behind.

The cavity of the pharynx is about 12.5 cm. long, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is immediately below the base of the skull, where it projects on either side, behind the pharyngeal ostium of the auditory tube, as the **pharyngeal recess** (*fossa of Rosenmüller*); its narrowest point is at its termination in the œsophagus. It is limited, *above*, by the body of the sphenoid and basilar part of the occipital bone; *below*, it is continuous with the œsophagus; *posteriorly*, it is connected by loose areolar tissue with the cervical portion of the vertebral column, and the prevertebral fascia covering the Longus colli and Longus capitis muscles; *anteriorly*, it is incomplete, and is attached in

succession to the medial pterygoid plate, pterygomandibular raphe, mandible, tongue, hyoid bone, and thyroid and cricoid cartilages; *laterally*, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, the glossopharyngeal, vagus, and hypoglossal nerves, and the sympathetics trunks, and above with small parts of the Pterygoidei interni. Seven cavities communicate with it, viz., the two nasal cavities, the two tympanic cavities, the mouth, the larynx, and the œsophagus. The cavity of the pharynx may be subdivided from above downward into three parts: nasal, oral, and laryngeal (Fig. 927).

Nasal septum

1 concha

Pharyngeal recess

Torus of auditory tube

Ostium of tube

FIG. 955.—Front of nasal part of pharynx, as seen with the laryngoscope.

The **Nasal Part of the Pharynx** (*pars nasalis pharyngis*; *nasopharynx*) lies behind the nose and above the level of the soft palate: it differs from the oral and laryngeal parts of the pharynx in that its cavity always remains patent. In front (Fig. 955) it communicates through the choanæ with the nasal cavities. On its lateral wall is the **pharyngeal ostium of the auditory tube**, somewhat triangular in shape, and bounded behind by a firm prominence, the **torus** or **cushion**, caused by the medial end of the cartilage of the tube which elevates the mucous membrane. A vertical fold of mucous membrane, the **salpingopharyngeal fold**, stretches from the lower part of the torus; it contains the Salpingopharyngeus muscle. A second and smaller fold, the **salpingopalatine fold**, stretches from the upper part of the torus to the palate. Behind the ostium of the auditory tube is a deep recess, the **pharyngeal recess** (*fossa of Rosenmüller*). On the posterior wall is a prominence, best marked in childhood, produced by a mass of lymphoid tissue, which is known as the **pharyngeal tonsil**. Above the pharyngeal tonsil, in the middle line, an irregular flask-shaped depression of the mucous membrane sometimes extends up as far as the basilar process of the occipital bone; it is known as the **pharyngeal bursa**.

The **oral part of the pharynx** (*pars oralis pharyngis*) reaches from the soft palate to the level of the hyoid bone. It opens anteriorly, through the isthmus faucium, into the mouth, while in its lateral wall, between the two palatine arches, is the **palatine tonsil**.

The **Palatine Tonsils** (*tonsillae palatinae*; *tonsil*) are two prominent masses situated one on either side between the glossopalatine and pharyngopalatine arches. Each tonsil consists fundamentally of an aggregation of lymphoid tissue underlying the mucous membrane between the palatine arches. The lymphoid mass, however, does not completely fill the interval between the two arches, so that a small depression, the **supratonsillar fossa**, exists at the upper part of the interval. Further,

the tonsil extends for a variable distance under cover of the glossopalatine arch, and is here covered by a reduplication of mucous membrane; the upper part of this fold reaches across the supratonsillar fossa, between the two arches, as a thin fold sometimes termed the *plica semilunaris*; the remainder of the fold is called the *plica triangularis*. Between the *plica triangularis* and the surface of the tonsil is a space known as the *tonsillar sinus*; in many cases, however, this sinus is obliterated by its walls becoming adherent. From this description it will be apparent that a portion of the tonsil is below the level of the surrounding mucous membrane, *i. e.*, is imbedded, while the remainder projects as the visible tonsil. In the child the tonsils are relatively (and frequently absolutely) larger than in the adult, and about one-third of the tonsil is imbedded. After puberty the imbedded portion diminishes considerably in size and the tonsil assumes a disk-like form, flattened from side to side; the shape and size of the tonsil, however, vary considerably in different individuals.

FIG. 956.—Section through one of the crypts of the tonsil. (Stöhr.) Magnified $\times 400$. *e*, Stratified epithelium of general surface, continued into crypt. *f, f*, Nodules of lymphoid tissue—opposite each nodule numbers of lymph cells are passing into or through the epithelium. *s, s*, Cells which have thus escaped to mix with the saliva as salivary corpuscles.

The **medial surface** of the tonsil is free except anteriorly, where it is covered by the *plica triangularis*; it presents from twelve to fifteen orifices leading into small crypts or recesses from which numerous follicles branch out into the tonsillar substance.

The **lateral or deep surface** is adherent to a fibrous capsule which is continued into the *plica triangularis*. It is separated from the inner surface of the Constrictor pharyngis superior usually by some loose connective tissue; this muscle intervenes between the tonsil and the external maxillary artery with its tonsillar and ascending palatine branches. The internal carotid artery lies behind and lateral to the tonsil at a distance of 20 to 25 mm. from it.

The tonsils form part of a circular band of adenoid tissue which guards the opening into the digestive and respiratory tubes. The anterior part of the ring is formed by the submucous adenoid collections (**lingual tonsil**) on the posterior part of the tongue; the lateral portions consist of the palatine tonsils and the adenoid collections in the vicinity of the auditory tubes, while the ring is completed

behind by the pharyngeal tonsil on the posterior wall of the pharynx. In the intervals between these main masses are smaller collections of adenoid tissue.

Structure (Fig. 956).—The follicles of the tonsil are lined by a continuation of the mucous membrane of the pharynx, covered with stratified squamous epithelium; around each follicle is a layer of closed capsules consisting of lymphoid tissue imbedded in the submucous tissue. Lymph corpuscles are found in large numbers invading the stratified epithelium. It is probable that they pass into the mouth and form the so-called *salivary corpuscles*. Surrounding each follicle is a close plexus of lymphatics, from which the lymphatic vessels pass to the deep cervical glands in the neighborhood of the greater cornu of the hyoid bone, behind and below the angle of the mandible.

Vessels and Nerves.—The **arteries** supplying the tonsil are the *dorsalis linguae* from the lingual, the ascending palatine and tonsillar from the external maxillary, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the small meningeal.

The **veins** end in the tonsillar plexus, on the lateral side of the tonsil.

The **nerves** are derived from the sphenopalatine ganglion, and from the glossopharyngeal.

Applied Anatomy.—The palatine tonsils can be easily inspected by instructing the patient to throw the head back and open his mouth widely; the tongue at the same time being depressed by a spatula or tongue-depressor. The normal tonsil should not project beyond the plane of the glossopalatine arch. They are prone to become enlarged, especially in tuberculous children; and when much increased in size they cause great trouble, owing to obstruction to respiration and deglutition. The tonsils may be the seat of acute inflammation, which may run on to suppuration, requiring evacuation of the pus. The incision into the tonsil should always be made from in front backward and medialward. Another form of acute inflammation of the tonsil is follicular tonsillitis, due to the lodgement of microorganisms in the crypts of the tonsil. The removal of an enlarged tonsil is, as a rule, a very simple operation, and is not usually attended with much hemorrhage, unless the patient is suffering from hemophilia. The tonsil may be the seat of malignant growth, either an epithelioma or a lymphosarcoma.

The **Laryngeal Part of the Pharynx** (*pars laryngea pharyngis*) reaches from the hyoid bone to the lower border of the cricoid cartilage, where it is continuous with the œsophagus. In front it presents the triangular entrance of the larynx, the base of which is directed forward and is formed by the epiglottis, while its lateral boundaries are constituted by the aryepiglottic folds. On either side of the laryngeal orifice is a recess, termed the *sinus piriformis*, which is bounded medially by the aryepiglottic fold, laterally by the thyroid cartilage and hyothyroid membrane.

Muscles of the Pharynx.—The muscles of the pharynx (Fig. 957) are:

Constrictor inferior.
Constrictor medius.
Constrictor superior.

Stylopharyngeus.
Salpingopharyngeus.
Pharyngopalatinus.¹

Dissection.—In order to examine the muscles of the pharynx, cut through the trachea and œsophagus just above the sternum, and draw them upward by dividing the loose areolar tissue connecting the pharynx with the front of the vertebral column. The parts being drawn well forward, apply the edge of the saw immediately behind the styloid processes, and saw the base of the skull through from below upward. The pharynx and mouth should then be stuffed with tow, in order to distend its cavity and render the muscles tense and easier of dissection.

The **Constrictor pharyngis inferior** (*Inferior constrictor*), the thickest of the three constrictors, *arises* from the sides of the cricoid and thyroid cartilage. From the cricoid cartilage it arises in the interval between the Cricothyroideus in front, and the articular facet for the inferior cornu of the thyroid cartilage behind. On the thyroid cartilage it arises from the oblique line on the side of the lamina, from the surface behind this nearly as far as the posterior border and from the inferior cornu. From these origins the fibres spread backward and medialward to be *inserted* with the muscle of the opposite side into the fibrous raphé in the posterior median line of the pharynx. The inferior fibres are horizontal and continuous with the circular fibres of the œsophagus; the rest ascend, increasing in obliquity, and overlap the Constrictor medius.

¹ The Pharyngopalatinus is described with the muscles of the palate (p. 1114).

Relations.—The Constrictor inferior is covered by the thin membrane which surrounds the entire pharynx (*buccopharyngeal fascia*). *Behind*, it is in relation with the vertebral column and the prevertebral fascia and muscles; *laterally*, with the thyroid gland, the common carotid artery, and the Sternothyroideus; by its *internal surface*, with the Constrictor medius, the Stylopharyngeus, the Pharyngopalatinus, the pharyngeal aponeurosis and the mucous membrane of the pharynx. The internal branch of the superior laryngeal nerve and the laryngeal branch of the superior thyroid artery run near the upper border, and the recurrent nerve and the laryngeal branch of the inferior thyroid artery pass beneath the lower border of this muscle, before they enter the larynx.

The **Constrictor pharyngis medius** (*Middle constrictor*) is a fan-shaped muscle, smaller than the preceding. It *arises* from the whole length of the upper border of the greater cornu of the hyoid bone, from the lesser cornu, and from the stylohyoid ligament. The fibres diverge from their origin: the lower ones descend beneath the Constrictor inferior, the middle fibres pass transversely, and the upper fibres ascend and overlap the Constrictor superior. It is *inserted* into the posterior median fibrous raphé, blending in the middle line with the muscle of the opposite side.

Relations.—This muscle is separated from the Constrictor superior by the glossopharyngeal nerve, the Stylopharyngeus and the stylohyoid ligament; and from the Constrictor inferior by the internal branch of the superior laryngeal nerve and laryngeal branch of the superior thyroid artery. *Behind*, it lies on the prevertebral fascia, the Longus colli, and the Longus capitis. *Laterally* it is in relation with the carotid vessels, the pharyngeal plexus, and

FIG. 967.—Muscles of the pharynx and cheek.

some lymph glands. Near its origin it is covered by the Hyoglossus, from which it is separated by the lingual vessels. It lies upon the Constrictor superior, the Stylopharyngeus, the Pharyngopalatinus, the pharyngeal aponeurosis, and the mucous membrane of the pharynx.

The **Constrictor pharyngis superior** (*Superior constrictor*) is a quadrilateral muscle, thinner and paler than the other two. It *arises* from the lower third of the posterior margin of the medial pterygoid plate and its hamulus, from the pterygomandibular raphé, from the alveolar process of the mandible above the posterior end of the mylohyoid line, and by a few fibres from the side of the tongue. The fibres curve backward to be inserted into the median raphé, being also prolonged by means of an aponeurosis to the pharyngeal spine on the basilar part of the occipital bone. The superior fibres arch beneath the Levator veli palatini and the auditory tube. The interval between the upper border of the muscle and the base of the skull is closed by the pharyngeal aponeurosis, and is known as the *sinus of Morgagni*.

Relations.—The Constrictor superior is in relation by its *outer surface* with the prevertebral fascia and muscles, the vertebral column, the internal carotid and ascending pharyngeal arteries, the internal jugular vein and pharyngeal venous plexus, and the glossopharyngeal, vagus, hypoglossal, and lingual nerves, the sympathetic trunks, the Constrictor medius and Pterygoideus internus, the styloid process, the stylohyoid ligament, and the Stylopharyngeus. By its *internal surface* it is in relation with the Pharyngopalatinus, the capsule of the palatine tonsil, the pharyngeal aponeurosis, and the mucous membrane of the pharynx. Its *lower border* is separated from the Constrictor medius by the Stylopharyngeus and the glossopharyngeal nerve.

The **Stylopharyngeus** (Fig. 947) is a long, slender muscle, cylindrical above, flattened below. It *arises* from the medial side of the base of the styloid process,

passes downward along the side of the pharynx between the *Constrictores superior* and *medius*, and spreads out beneath the mucous membrane. Some of its fibres are lost in the *Constrictor* muscles, while others, joining with the *Pharyngopalatinus*, are inserted into the posterior border of the thyroid cartilage. The *glossopharyngeal* nerve runs on the lateral side of this muscle, and crosses over it to reach the tongue.

The **Salpingopharyngeus** (Fig. 928) arises from the inferior part of the auditory tube near its orifice; it passes downward and blends with the posterior fasciculus of the *Pharyngopalatinus*.

Nerves.—The *Constrictores* and *Salpingopharyngeus* are supplied by branches from the *pharyngeal plexus*, the *Constrictor inferior* by additional branches from the *external laryngeal* and *recurrent* nerves, and the *Stylopharyngeus* by the *glossopharyngeal* nerve.

Actions.—When deglutition is about to be performed, the pharynx is drawn upward and dilated in different directions, to receive the food propelled into it from the mouth. The *Stylopharyngei*, which are much farther removed from one another at their origin than at their insertion, draw the sides of the pharynx upward and lateralward, and so increase its transverse diameter; its breadth in the antero-posterior direction is increased by the larynx and tongue being carried forward in their ascent. As soon as the bolus of food is received in the pharynx, the elevator muscles relax, the pharynx descends, and the *Constrictores* contract upon the bolus, and convey it downward into the *oesophagus*.

Structure.—The pharynx is composed of three coats: **mucous**, **fibrous**, and **muscular**.

The **pharyngeal aponeurosis**, or **fibrous coat**, is situated between the mucous and muscular layers. It is thick above where the muscular fibres are wanting, and is firmly connected to the basilar portion of the occipital and the petrous portions of the temporal bones. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band, which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downward, forming a median raphé, which gives attachment to the *Constrictores pharyngis*.

The **mucous coat** is continuous with that lining the auditory tubes, the nasal cavities, the mouth, and the larynx. In the nasal part of the pharynx it is covered by columnar ciliated epithelium; in the oral and laryngeal portions the epithelium is stratified squamous. Beneath the mucous membrane are found racemose mucous glands; they are especially numerous at the upper part of the pharynx around the orifices of the auditory tubes.

Applied Anatomy.—Hypertrophy of the lymphatic tissue in the nasal part of the pharynx commonly known as “adenoids,” is a frequent cause of mouth-breathing and all its attendant disadvantages and dangers in children. It entails a proneness to inflammation of all parts of the air passages and the auditory tubes, and leads to deformed development of the palate and dental arch. In many cases adenoids tend to atrophy about the age of puberty, by which time their presence is likely to have caused permanent injury to the health and development of the patient.

The pharynx is sometimes the seat of a pouch-like dilatation of its walls, in which the food collects when the patient swallows. A cure is effected by removing the diverticulum and accurately suturing the opening which has been made in the pharynx. The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments, introduced into the mouth and thrust through the wall of the pharynx. In aneurism of this vessel in the neck, the tumor necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin *Constrictor* muscles, whereas on the lateral side there are the dense cervical fascia, the muscles descending from the styloid process, and the margin of the *Sternocleidomastoideus*.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, since the numerous recesses are prone to lodge microorganisms. And, in addition, owing to its exposed situation, the mucous membrane is liable to be irritated by agents introduced during inspiration. The inflammation may be attended with serious consequences: it may extend up the auditory tube and involve the middle ear; it may spread to the entrance of the larynx, causing oedema and seriously interfering with respiration; or, invading the lymphatics, it may spread to the loose areolar tissue surrounding the pharyngeal wall, and may extend far and wide, sometimes into the posterior mediastinal cavity along the *oesophagus*. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as *retropharyngeal abscess*. This may be due to caries of the cervical vertebræ or may be caused by suppuration of the lymph glands situated in this position opposite the axis, and which receive the lymphatics from the cavities. In these cases the pus may be easily evacuated by incision with a guarded blade.

through the mouth, but, for aseptic reasons, it is desirable that the abscess should be opened from the neck. In some instances this is perfectly easy: the abscess can be felt bulging at the side of the neck, and merely requires an incision for its relief; but this is not always so, and then an incision should be made along the posterior border of the Sternocleidomastoideus and the deep fascia divided. A director is now to be inserted into the wound, the forefinger of the left hand being introduced into the mouth and pressure made upon the swelling. This acts as a guide, and the director is to be pushed onward until pus appears in the groove. A pair of sinus forceps is now inserted along the director and the opening into the cavity dilated.

Abscess also occurs in children, underneath the mucous membrane, between it and the pharyngeal aponeurosis. The condition usually arises from a peritonsillar inflammation, which spreads backward. In some cases an enormous swelling may form, which pushes forward the soft palate and gives rise to respiratory obstruction. In such the abscess should be opened through the mouth with the child in the inverted positions, so as to prevent the first gush of pus from entering the superior opening of the larynx.

Foreign bodies not infrequently become lodged in the pharynx, and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the œsophagus is about 15 cm.

THE ŒSOPHAGUS (Fig. 958).

The **œsophagus** or **gullet** is a muscular canal, about 23 to 25 cm. long, extending from the pharynx to the stomach. It begins in the neck at the lower border of the cricoid cartilage, opposite the sixth cervical vertebra, descends along the front of the vertebral column, through the superior and posterior mediastinal cavities, passes through the Diaphragma, and, entering the abdomen, ends at the cardiac orifice of the stomach, opposite the eleventh thoracic vertebra. The general direction of the œsophagus is vertical; but it presents two slight curves in its course. At its commencement it is placed in the middle line; but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again at the level of the fifth thoracic vertebra, and finally deviates to the left as it passes forward to the œsophageal hiatus in the Diaphragma. The œsophagus also presents antero-posterior flexures corresponding to the curvatures of the cervical and thoracic portions of the vertebral column. It is the narrowest part of the digestive tube, and is most contracted at its commencement, and at the point where it passes through the Diaphragma.

Relations.—The **cervical portion** of the œsophagus is in relation, *in front*, with the trachea; and at the lower part of the neck, where it projects to the left side, with the thyroid gland; *behind*, it rests upon the vertebral column and Longus colli muscles; *on either side* it is in relation with the common carotid artery (especially the left, as it inclines to that side), and parts of the lobes of the thyroid gland; the recurrent nerves ascend between it and the trachea; to its left side is the thoracic duct.

The **thoracic portion** of the œsophagus is at first situated in the superior mediastinal cavity between the trachea and the vertebral column, a little to the left of the median line. It then passes behind and to the right of the aortic arch, and descends in the posterior mediastinal cavity, along the right side of the descending aorta, then runs in front and a little to the left of the aorta, and enters the abdomen through the Diaphragma at the level of the tenth thoracic vertebra. Just before it perforates the Diaphragma it presents a distinct dilatation. It is in relation, *in front*, with the trachea, the left bronchus, the pericardium, and the Diaphragma; *behind*, it rests upon the vertebral column, the Longus colli muscles, the right aortic intercostal arteries, the thoracic duct, and the hemiazygos veins; and below, near the Diaphragma, upon the front of the aorta. On its *left side*, in the superior mediastinal cavity, are the terminal part of the aortic arch, the left subclavian artery, the thoracic duct, and left pleura, while running upward in the angle between it and the trachea is the left recurrent nerve; below, it is in relation with the descending thoracic aorta. On its *right side* are the right pleura, and the azygos vein which it overlaps. Below the roots of the lungs the vagi descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it; the two nerves uniting to form a plexus around the tube.

In the lower part of the posterior mediastinal cavity the thoracic duct lies to the right side of the œsophagus; higher up, it is placed behind it, and, crossing about the level of the fourth thoracic vertebra, is continued upward on its left side.

The abdominal portion of the œsophagus lies in the œsophageal groove on the posterior surface of the left lobe of the liver. It measures about 1.25 cm. in length, and only its front and left aspects are covered by peritoneum. It is somewhat conical with its base applied to the upper orifice of the stomach, and is known as the *antrum cardiacum*.

Structure (Fig. 959).—The œsophagus has four coats: an external or fibrous, a muscular, a submucous or areolar, and an internal or mucous coat.

The muscular coat (*tunica muscularis*) is composed of two planes of considerable thickness: an external of longitudinal and an internal of circular fibres.

The longitudinal fibres are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the lamina of the cricoid cartilage; and one at either side, which is continuous with the muscular fibres of the pharynx: as they descend they blend together, and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres pass between the œsophagus and the

FIG. 958.—The œsophagus.

left pleura, where the latter covers the thoracic aorta, or the root of the left bronchus, or the back of the pericardium.

The circular fibres are continuous above with the Constrictor pharyngis inferior; their direction is transverse at the upper and lower parts of the tube, but oblique in the intermediate part.

The muscular fibres in the upper part of the œsophagus are of a red color, and consist chiefly of the striped variety; but below, they consist of the most part of involuntary fibres.

The areolar or submucous coat (*tela submucosa*) connects loosely the mucous and muscular coats. It contains bloodvessels, nerves, and mucous glands.

The **mucous coat** (*tunica mucosa*) is thick, of a reddish color above, and pale below. It is disposed in longitudinal folds, which disappear on distension of the tube. Its surface is studded with minute papillæ, and it is covered throughout with a thick layer of stratified squamous epithelium. Beneath the mucous membrane, between it and the areolar coat, is a layer of longitudinally arranged non-stripped muscular fibres. This is the **muscularis mucosæ**. At the commencement of the œsophagus it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The **œsophageal glands** (*glandulæ œsophageæ*) are small compound racemose glands of the mucous type: they are lodged in the submucous tissue, and each opens upon the surface by a long excretory duct.

Vessels and Nerves.—The **arteries** supplying the œsophagus are derived from the inferior thyroid branch of the thyrocervical trunk, from the descending thoracic aorta, from the left gastric branch of the cœliac artery, and from the left inferior phrenic of the abdominal aorta. They have for the most part a longitudinal direction.

The **nerves** are derived from the vagi and from the sympathetic trunks; they form a plexus, in which are groups of ganglion cells, between the two layers of the muscular coats, and also a second plexus in the submucous tissue.

Applied Anatomy.—The œsophagus may be obstructed by foreign bodies, and also by changes in its coats producing stricture, or by pressure on it from without of new growths or aneurism, etc. The different forms of stricture are: (1) the fibrous, due to cicatrization following destruction of tissue, the result of swallowing boiling or corrosive fluids—here dilatation of the stricture may be carried out; and (2) malignant, usually epitheliomatous in its nature. This may be situated either at the upper end of the tube, opposite the cricoid cartilage, or at its lower end at the cardiac orifice, but is most commonly found in that part of the tube which is crossed by the left bronchus. In these cases, if the patient is losing weight from insufficient nourishment, the operation of gastrostomy may be performed in order to avoid death from starvation; death, however, most commonly occurs from ulceration of the growth into the mediastinal cavity or air passages. In cases of stricture of the œsophagus it may be necessary to dilate the canal by a bougie, when it is of importance that the direction of the œsophagus and its relations to surrounding parts should be remembered. In cases of malignant disease of the œsophagus, where its tissues have become softened from infiltration of the growth, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinal cavity or into one or other pleural cavity, or even into the pericardium.

In cases of obstruction of the œsophagus, and consequent symptoms of stricture, produced by an aneurism of some part of the aorta pressing upon this tube, the passage of a bougie will only hasten the fatal issue.

In passing a bougie, the left forefinger should be introduced into the mouth, and the epiglottis felt for, care being taken not to throw the head too far backward. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently onward, all violence being carefully avoided.

It occasionally happens that a foreign body becomes impacted in the œsophagus, and can neither be brought upward nor moved downward. When all ordinary means for its removal have failed, excision is the only resource. This, of course, can only be performed when it is not very low down. If the foreign body is allowed to remain, extensive inflammation and ulceration of the œsophagus may ensue. In one case the foreign body ultimately penetrated the intervertebral fibrocartilage, and destroyed life by inflammation of the membranes and substance of the medulla spinalis.

THE ABDOMEN.

The **abdomen** is the largest cavity in the body. It is of an oval shape, the extremities of the oval being directed upward and downward. The upper extremity is formed by the Diaphragma which extends as a dome over the abdomen, so that the cavity extends high into the bony thorax, reaching on the right side, in the mammary line, to the upper border of the fifth rib; on the left side it falls below this level by about 2.5 cm. The lower extremity is formed by the structures which clothe the inner surface of the bony pelvis, principally the Levator ani and Coccygeus on either side. These muscles are sometimes termed the **diaphragm of the pelvis**. The cavity is wider above than below, and measures more in the vertical than in the transverse diameter. In order to facilitate description, it is artificially divided into two parts: an upper and larger part, the **abdomen proper**; and a lower and smaller

part, the **pelvis**. These two cavities are not separated from each other, but the limit between them is marked by the superior aperture of the lesser pelvis.

The **abdomen proper** differs from the other great cavities of the body in being bounded for the most part by muscles and fasciæ, so that it can vary in capacity and shape according to the condition of the viscera which it contains; but, in addition to this, the abdomen varies in form and extent with age and sex. In the adult male, with moderate distension of the viscera, it is oval in shape, but at the same time flattened from before backward. In the adult female, with a fully developed pelvis, it is ovoid with the narrower pole upward, and in young children it is also ovoid but with the narrower pole downward.

Boundaries.—It is bounded *in front* and *at the sides* by the abdominal muscles and the Iliacus muscles; *behind* by the vertebral column and the Psoas and Quadratus lumborum muscles; *above* by the Diaphragma; *below* by the plane of the superior aperture of the lesser pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surfaces by a layer of fascia.

The abdomen contains the greater part of the digestive tube; some of the accessory organs to digestion, viz., the liver and pancreas; the spleen, the kidneys, and the suprarenal glands. Most of these structures, as well as the wall of the cavity in which they are contained, are more or less covered by an extensive and complicated serous membrane, the **peritoneum**.

The Apertures in the Walls of the Abdomen.—The apertures in the walls of the abdomen, for the transmission of structures to or from it, are, *in front*, the **umbilical** (in the fetus), for the transmission of the umbilical vessels, the allantois, and vitelline duct; *above*, the **vena caval opening**, for the transmission of the inferior vena cava, the **aortic hiatus**, for the passage of the aorta, azygos vein, and thoracic duct, and the **œsophageal hiatus**, for the œsophagus and vagi. *Below*, there are two apertures on either side: one for the passage of the femoral vessels and lumbo-inguinal nerve, and the other for the transmission of the spermatic cord in the male, and the round ligament of the uterus in the female.

Regions.—For convenience of description of the viscera, as well as of reference to the morbid conditions of the contained parts, the abdomen is artificially divided into nine regions by imaginary planes, two horizontal and two sagittal, passing through the cavity, the edges of the planes being indicated by lines drawn on the surface of the body. Of the horizontal planes the upper or **transpyloric** is indicated by a line encircling the body at the level of a point midway between the jugular notch and the symphysis pubis, the lower by a line carried around the trunk at the level of a point midway between the transpyloric and the symphysis pubis. The latter is practically the **intertubercular plane** of Cunningham, who pointed out¹ that its level corresponds with the prominent and easily defined tubercle on the iliac crest about 5 cm. behind the anterior superior iliac spine. By means of these imaginary planes the abdomen is divided into three zones, which are named from above downward the **subcostal**, **umbilical**, and **hypogastric zones**. Each of these is further subdivided into three regions by the two sagittal planes, which are indicated on the surface by lines drawn vertically through points half-way between the anterior superior iliac spines and the symphysis pubis.²

The middle region of the upper zone is called the **epigastric**; and the two lateral regions, the **right** and **left hypochondriac**. The central region of the middle zone is the **umbilical**; and the two lateral regions, the **right** and **left lumbar**. The middle region of the lower zone is the **hypogastric** or **pubic region**; and the lateral regions are the **right** and **left iliac** or **inguinal** (Fig. 960).

The **pelvis** is that portion of the abdominal cavity which lies below and behind a plane passing through the promontory of the sacrum, lineæ terminales of the hip bones, and the pubic crests. It is bounded behind by the sacrum, coccyx,

¹ Journal of Anatomy and Physiology, vol. xxvii.

² Ibid., vols. xxxiii, xxxiv, xxxv.

Piriformes, and the sacrospinous and sacrotuberous ligaments; in front and laterally by the pubes and ischia and Obturatores interni; above it communicates

with the abdomen proper; below it is closed by the Levatores ani and Coccygei and the urogenital diaphragm. The pelvis contains the urinary bladder, the sigmoid colon and rectum, a few coils of the small intestine, and some of the generative organs.

When the anterior abdominal wall is removed, the viscera are partly exposed as follows: above and to the right side is the liver, situated chiefly under the shelter of the right ribs and their cartilages, but extending across the middle line and reaching for some distance below the level of the xiphoid process. To the left of the liver is the stomach, from the lower border of which an apron-like fold of peritoneum, the **greater omentum**, descends for a varying distance, and obscures, to a greater or lesser extent, the other viscera. Below it, however, some of the coils of the small intestine can generally be seen, while in the right and left iliac regions respectively the cecum and the iliac colon are partly exposed. The bladder occupies the anterior part of the pelvis, and, if distended, will project above the symphysis pubis; the rectum lies in the concavity of the sacrum, but is usually obscured by the coils of the small intestine. The sigmoid colon lies between the rectum and the bladder.

When the stomach is followed from left to right it is seen to be continuous with the first part of the small intestine, or duodenum, the point of continuity being marked by a thickened ring which indicates the position of the pyloric valve. The duodenum passes toward the under surface of the liver, and then, curving downward, is lost to sight. If, however, the greater omentum be thrown upward over the chest, the inferior part of the duodenum will be observed passing across the vertebral column toward the left side, where it becomes continuous with the coils of the jejunum and ileum. These measure some 6 metres in length, and if followed downward the ileum will be seen to end in the right iliac fossa by opening into the cecum, the commencement of the large intestine. From the cecum the large intestine takes an arched course, passing at first upward on the right side, then across the middle line and downward on the left side, and forming respectively the ascending transverse, and descending parts of the colon. In the pelvis it assumes the form of a loop, the sigmoid colon, and ends in the rectum.

The spleen lies behind the stomach in the left hypochondriac region, and may be in part exposed by pulling the stomach over toward the right side.

The glistening appearance of the deep surface of the abdominal wall and of the surfaces of the exposed viscera is due to the fact that the former is lined, and the latter are more or less completely covered, by a serous membrane, the **peritoneum**.

The Peritoneum (Tunica Serosa).

The peritoneum is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which is applied against the abdominal parietes, while the remainder is reflected over the contained viscera. In the female the peritoneum is not a closed sac, since the free ends of the uterine tubes open directly into the peritoneal cavity. The part which lines the parietes is named the **parietal portion** of the peritoneum; that which is reflected over the contained viscera constitutes the **visceral portion** of the peritoneum. The free surface of the membrane is smooth, covered by a layer of flattened endothelium, and lubricated by a small quantity of serous fluid. Hence the viscera can glide freely against the wall of the cavity or upon one another with the least possible amount of friction. The attached surface is rough, being connected to the viscera and inner surface of the parietes by means of areolar tissue, termed the **subserous areolar tissue**. The parietal portion is loosely connected with the fascial lining of the abdomen and pelvis, but is more closely adherent to the under surface of the Diaphragma, and also in the middle line of the abdomen.

The space between the parietal and visceral layers of the peritoneum is named the **peritoneal cavity**; but under normal conditions this cavity is merely a potential

one, since the parietal and visceral layers are in contact. The peritoneal cavity gives off a large diverticulum, the omental bursa, which is situated behind the stomach and adjoining structures; the neck of communication between the cavity and the bursa is termed the epiploic foramen (*foramen of Winslow*). Formerly the main portion of the cavity was described as the greater, and the omental bursa as the lesser sac.

The peritoneum differs from the other serous membranes of the body in presenting a much more complex arrangement, and one that can only be clearly understood by following the changes which take place in the digestive tube during its development; the student therefore is advised to preface his study of the peritoneum by reviewing the chapter dealing with this subject in the section on Embryology (page 162).

To trace the membrane from one viscus to another, and from the viscera to the parietes, it is necessary to follow its continuity in the vertical and horizontal directions, and it will be found simpler to describe the main portion of the cavity and the omental bursa separately.

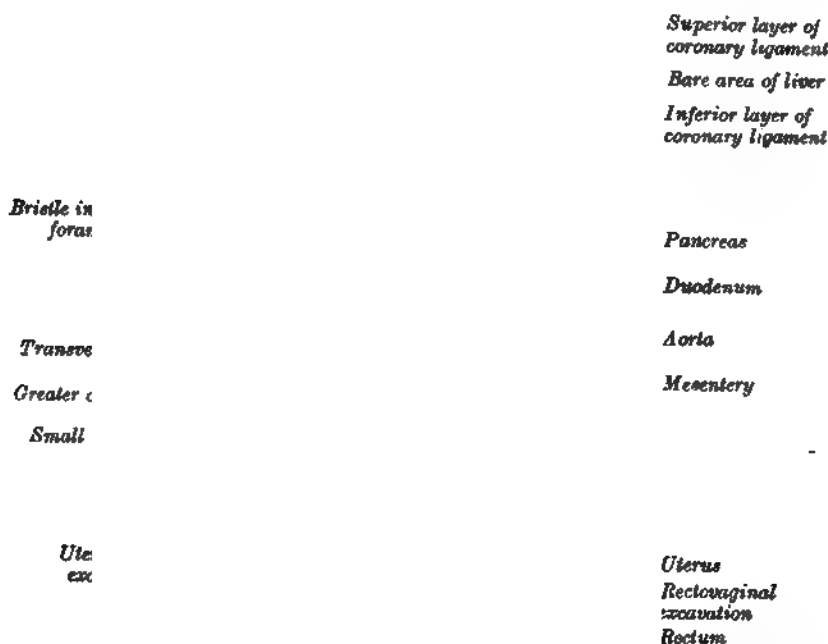

FIG. 961.—Vertical disposition of the peritoneum. Main cavity, red, omental bursa, blue.

Vertical Disposition of the Main Peritoneal Cavity (greater sac) (Fig. 961).—It is convenient to trace this from the back of the abdominal wall at the level of the umbilicus. On following the peritoneum upward from this level it is seen to be reflected around a fibrous cord, the ligamentum teres (*obliterated umbilical vein*), which reaches from the umbilicus to the under surface of the liver. This reflection forms a somewhat triangular fold, the falciform ligament of the liver, attaching the upper and anterior surfaces of the liver to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the whole of the under surface of the anterior part of the Diaphragm, and is continued from it on to the upper surface of the right lobe of the liver as

the **superior layer of the coronary ligament**, and on to the upper surface of the left lobe as the **superior layer of the left triangular ligament** of the liver. Covering the upper and anterior surfaces of the liver, it is continued around its sharp margin on to the under surface, where it presents the following relations: (a) It covers the under surface of the right lobe and is reflected from the back part of this on to the right suprarenal gland and upper extremity of the right kidney, forming in this situation the **inferior layer of the coronary ligament**; a special fold, the **hepatorenal ligament**, is frequently present between the inferior surface of the liver and the front of the kidney. From the kidney it is carried downward to the duodenum and right colic flexure and medialward in front of the inferior vena cava, where it is continuous with the posterior wall of the omental bursa. Between the two layers of the coronary ligament there is a large triangular surface of the liver devoid of peritoneal covering; this is named the **bare area** of the liver, and is attached to the Diaphragma by areolar tissue. Toward the right margin of the liver the two layers of the coronary ligament gradually approach each other, and ultimately fuse to form a small triangular fold connecting the right lobe of the liver to the Diaphragma, and named the **right triangular ligament** of the liver. The apex of the triangular bare area corresponds with the point of meeting of the two layers of the coronary ligament, its base with the fossa for the inferior vena cava. (b) It covers the lower surface of the quadrate lobe, the under and lateral surfaces of the gall-bladder, and the under surface and posterior border of the left lobe; it is then reflected from the upper surface of the left lobe to the Diaphragma as the **inferior layer of the left triangular ligament**, and from the porta of the liver and the fossa for the ductus venosus to the lesser curvature of the stomach and the first 2.5 cm. of the duodenum as the anterior layer of the **hepatogastric** and **hepatoduodenal ligaments**, which together constitute the **lesser omentum**. If this layer of the lesser omentum be followed to the right it will be found to turn around the hepatic artery, bile duct, and portal vein, and become continuous with the anterior wall of the omental bursa, forming a free folded edge of peritoneum. Traced downward, it covers the antero-superior surface of the stomach and the commencement of the duodenum, and is carried down into a large free fold, known as the **gastrocolic ligament** or **greater omentum**. Reaching the free margin of this fold, it is reflected upward to cover the under and posterior surfaces of the transverse colon, and thence to the posterior abdominal wall as the inferior layer of the **transverse mesocolon**. It reaches the abdominal wall at the head and anterior border of the pancreas, is then carried down over the lower part of the head and over the inferior surface of the pancreas on the superior mesenteric vessels, and thence to the small intestine as the anterior layer of the **mesentery**. It encircles the intestine, and subsequently may be traced, as the posterior layer of the mesentery, upward and backward to the abdominal wall. From this it sweeps down over the aorta into the pelvis, where it invests the sigmoid colon, its reduplication forming the **sigmoid mesocolon**. Leaving first the sides and then the front of the rectum, it is reflected on to the seminal vesicles and fundus of the urinary bladder and, after covering the upper surface of that viscus, is carried along the medial and lateral umbilical ligaments (Fig. 962) on to the back of the abdominal wall to the level from which a start was made.

Between the rectum and the bladder it forms, in the male, a pouch, the **rectovesical excavation**, the bottom of which is slightly below the level of the upper ends of the vesiculæ seminales—i. e., about 7.5 cm. from the orifice of the anus. When the bladder is distended, the peritoneum is carried up with the expanded viscus so that a considerable part of the anterior surface of the latter lies directly against the abdominal wall without the intervention of peritoneal membrane. In the female the peritoneum is reflected from the rectum over the posterior vaginal fornix to the cervix and body of the uterus, forming the **rectouterine excavation** (*pouch of Douglas*). It is continued over the intestinal surface and fundus of the

uterus on to its vesical surface, which it covers as far as the junction of the body and cervix uteri, and then to the bladder, forming here a second, but shallower, pouch, the **vesicouterine excavation**. It is also reflected from the sides of the uterus to the lateral walls of the pelvis as two expanded folds, the **broad ligaments of the uterus**, in the free margin of each of which is the uterine tube.

Fig. 962.—Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel)

Vertical Disposition of the Omental Bursa (*lesser peritoneal sac*) (Fig. 961).—A start may be made in this case on the posterior abdominal wall at the anterior border of the pancreas. From this region the peritoneum may be followed upward over the pancreas on to the inferior surface of the Diaphragma, and thence on to the caudate lobe and caudate process of the liver to the fossa from the ductus venosus and the porta of the liver. Traced to the right, it is continuous over the inferior vena cava with the posterior wall of the main cavity. From the liver it is carried downward to the lesser curvature of the stomach and the commencement of the duodenum as the posterior layer of the lesser omentum, and is continuous on the right, around the hepatic artery, bile duct, and portal vein, with the anterior layer of this omentum. The posterior layer of the lesser omentum is carried down as a covering for the postero-inferior surfaces of the stomach and commencement of the duodenum, and is continued downward as the deep layer of the **gastrocolic ligament** or **greater omentum**. From the free margin of this fold it is reflected upward on itself to the anterior and superior surfaces of the transverse colon, and thence as the superior layer of the transverse mesocolon to the anterior border of the pancreas, the level from which a start was made. It will be seen that the loop formed by

de
ater
fossa
empt

the wall of the omental bursa below the transverse colon follows, and is closely applied to, the deep surface of that formed by the peritoneum of the main cavity, and that the greater omentum or large fold of peritoneum which hangs in front of the small intestine therefore consists of four layers, two anterior and two posterior separated by the potential cavity of the omental bursa.

Horizontal Disposition of the Peritoneum.—Below the transverse colon the arrangement is simple, as it includes only the main cavity; above the level of the transverse colon it is more complicated on account of the existence of the omental regions, viz.,

ritoneum of

The anterior pelvic wall covers the superior surface of the bladder, and on either side of this viscus forms a depression, termed the **paravesical fossa**, which is limited laterally by the fold of peritoneum covering the ductus deferens. The size of this fossa is dependent on the state of distension of the bladder; when the bladder is empty, a variable fold of peritoneum, the **plica vesicalis transversa**, divides the fossa into two portions. On the peritoneum between the paravesical and pararectal fossæ the only elevations are those produced by the ureters and the hypogastric vessels. (b) In the female, pararectal and paravesical fossæ similar to those in the

male are present: the lateral limit of the paravesical fossa is the peritoneum investing the round ligament of the uterus. The rectovesical excavation is, however, divided by the uterus and vagina into a small anterior vesicouterine and a large, deep, posterior rectouterine excavation. The sacrogenital folds form the margins of the latter, and are continued on to the back of the uterus to form a transverse fold, the *torus uterinus*. The broad ligaments extend from the sides of the uterus to the lateral walls of the pelvis; they contain in their free margins the uterine tubes, and in their posterior layers the ovaries. Below, the broad ligaments are continuous with the peritoneum on the lateral walls of the pelvis. On the lateral pelvic wall behind the attachment of the broad ligament, in the angle between the elevations produced by the diverging hypogastric and external iliac vessels is a slight fossa, the *ovarian fossa*, in which the ovary normally lies.

(3) In the bursa is superadded to the general sac, and the communication of the two cavities with one another through the epiploic foramen can be demonstrated.

(a) *Main Cavity*.—Commencing on the posterior abdominal wall at the inferior vena cava, the peritoneum may be followed to the right over the front of the suprarenal gland and upper part of the right kidney on to the antero-lateral

abdominal wall. From the middle line of the anterior wall a backwardly directed fold encircles the obliterated umbilical vein and forms the falciform ligament of the liver. Continuing to the left, the peritoneum lines the antero-lateral abdominal wall and covers the lateral part of the front of the left kidney, and is reflected to the posterior border of the hilus of the spleen as the posterior layer of the **phrenicocolic ligament**. It can then be traced around the surface of the spleen to the front of the hilus, and thence to the cardiac end of the greater curvature of the stomach as the anterior layer of the **gastrosplenic ligament**. It covers the antero-superior surfaces of the stomach and commencement of the duodenum, and extends up from the lesser curvature of the stomach to the liver as the anterior layer of the lesser omentum.

FIG. 965.—Horizontal disposition of the peritoneum in the upper part of the abdomen.

(b) **Omental Bursa** (*bursa omentalis*; *lesser peritoneal sac*).—On the posterior abdominal wall the peritoneum of the general cavity is continuous with that of the omental bursa in front of the inferior vena cava. Starting from here, the bursa may be traced across the aorta and over the medial part of the front of the left kidney and Diaphragma to the hilus of the spleen as the anterior layer of the phrenicocolic ligament. From the spleen it is reflected to the stomach as the posterior layer of the gastrosplenic ligament. It covers the postero-inferior surfaces of the stomach and commencement of the duodenum, and extends upward to the liver as the posterior layer of the lesser omentum; the right margin of this layer is continuous around the hepatic artery, bile duct, and portal vein, with the wall of the general cavity.

The **epiploic foramen** (*foramen epiploicum*; *foramen of Winslow*) is the passage of communication between the general cavity and the omental bursa. It is bounded *in front* by the free border of the lesser omentum, with the common bile duct, hepatic artery, and portal vein between its two layers; *behind* by the peritoneum covering the inferior vena cava; *above* by the peritoneum on the caudate process of the liver, and *below* by the peritoneum covering the commencement of the duodenum and the hepatic artery, the latter passing forward below the foramen before ascending between the two layers of the lesser omentum.

The boundaries of the *omental bursa* will now be evident. It is bounded *in front*

from above downward, by the caudate lobe of the liver, the lesser omentum, the stomach, and the anterior two layers of the greater omentum. *Behind*, it is limited, from below upward, by the two posterior layers of the greater omentum, the transverse colon, and the ascending layer of the transverse mesocolon, the upper surface of the pancreas, the left suprarenal gland, and the upper end of the left kidney. To the right of the oesophageal opening of the stomach it is formed by that part of the Diaphragma which supports the caudate lobe of the liver. *Laterally*, the bursa extends from the epiploic foramen to the spleen, where it is limited by the phrenicocolical and gastrosplenic ligaments.

The omental bursa, therefore, consists of a series of pouches or recesses to which the following terms are applied: (1) the **vestibule**, a narrow channel continued from the epiploic foramen, over the head of the pancreas to the **gastropancreatic fold**; this fold extends from the omental tuberosity of the pancreas to the right side of the fundus of the stomach, and contains the left gastric artery and coronary vein; (2) the **superior omental recess**, between the caudate lobe of the liver and the Diaphragma; (3) the **lienal recess**, between the spleen and the stomach; (4) the **inferior omental recess**, which comprises the remainder of the bursa.

In the fetus the bursa reaches as low as the free margin of the greater omentum, but in the adult its vertical extent is usually more limited owing to adhesions between the layers of the omentum. During a considerable part of fetal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own, the two posterior layers of the greater omentum passing at this stage in front of the colon. This condition occasionally persists throughout life, but as a rule adhesion occurs between the mesentery of the transverse colon and the posterior layer of the greater omentum, with the result that the colon appears to receive its peritoneal covering by the splitting of the two posterior layers of the latter fold. In the adult the omental bursa intervenes between the stomach and the structures on which that viscus lies, and performs therefore the functions of a serous bursa for the stomach.

Numerous peritoneal folds extend between the various organs or connect them to the parietes; they serve to hold the viscera in position, and, at the same time, enclose the vessels and nerves proceeding to them. They are grouped under the three headings of **ligaments**, **omenta**, and **mesenteries**.

The **ligaments** will be described with their respective organs.

There are two **omenta**, the lesser and the greater.

The **lesser omentum** (*omentum minus*; *small omentum*; *gastrohepatic omentum*) is the duplicature which extends to the liver from the lesser curvature of the stomach and the commencement of the duodenum. It is extremely thin, and is continuous with the two layers of peritoneum which cover respectively the antero-superior and postero-inferior surfaces of the stomach and first part of the duodenum. When these two layers reach the lesser curvature of the stomach and the upper border of the duodenum, they join together and ascend as a double fold to the porta of the liver; to the left of the porta the fold is attached to the bottom of the fossa for the ductus venosus, along which it is carried to the Diaphragma, where the two layers separate to embrace the end of the oesophagus. At the right border of the omentum the two layers are continuous, and form a free margin which constitutes the anterior boundary of the epiploic foramen. The portion of the lesser omentum extending between the liver and stomach is termed the **hepatogastric ligament**, while that between the liver and duodenum is the **hepatoduodenal ligament**. Between the two layers of the lesser omentum, close to the right free margin, are the hepatic artery, the common bile duct, the portal vein, lymphatics, and the hepatic plexus of nerves—all these structures being enclosed in a **fibrous capsule** (*Glisson's capsule*). Between the layers of the lesser omentum, where they are attached to the stomach, run the right and left gastric vessels.

The **greater omentum** (*omentum majus*; *great omentum*; *gastrocolic omentum*) is the largest peritoneal fold. It consists of a double sheet of peritoneum, folded on itself so that it is made up of four layers. The two layers which descend from the stomach and commencement of the duodenum pass in front of the small intestines, sometimes as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These individual layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. The left border of the greater omentum is continuous with the gastrosplenic ligament; its right border extends as far as the commencement of the duodenum. The greater omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat people accumulates in considerable quantity. Between its two anterior layers, a short distance from the greater curvature of the stomach, is the anastomosis between the right and left gastroepiploic vessels.

The **mesenteries** are: the **mesentery proper**, the **transverse mesocolon**, and the **sigmoid mesocolon**. In addition to these there are sometimes present an ascending and a descending mesocolon.

The **mesentery proper** (*mesenterium*) is the broad, fan-shaped fold of peritoneum which connects the convolutions of the jejunum and ileum with the posterior wall of the abdomen. Its **root**—the part connected with the structures in front of the vertebral column—is narrow, about 15 cm. long, and is directed obliquely from the duodenojejunal flexure at the left side of the second lumbar vertebra to the right sacroiliac articulation (Fig. 966). Its **intestinal border** is about 6 metres long; and here the two layers separate to enclose the intestine, and form its peritoneal coat. It is narrow above, but widens rapidly to about 20 cm., and is thrown into numerous plaits or folds. It suspends the small intestine, and contains between its layers the intestinal branches of the superior mesenteric artery, with their accompanying veins and plexuses of nerves, the lacteal vessels, and mesenteric lymph glands.

The **transverse mesocolon** (*mesocolon transversum*) is a broad fold, which connects the transverse colon to the posterior wall of the abdomen. It is continuous with the two posterior layers of the greater omentum, which, after separating to surround the transverse colon, join behind it, and are continued backward to the vertebral column, where they diverge in front of the anterior border of the pancreas. This fold contains between its layers the vessels which supply the transverse colon.

The **sigmoid mesocolon** (*mesocolon sigmoideum*) is the fold of peritoneum which retains the sigmoid colon in connection with the pelvic wall. Its line of attachment forms a V-shaped curve, the apex of the curve being placed about the point of division of the left common iliac artery. The curve begins on the medial side of the left Psoas major, and runs upward and backward to the apex, from which it bends sharply downward, and ends in the median plane at the level of the third sacral vertebra. The sigmoid and superior hemorrhoidal vessels run between the two layers of this fold.

In most cases the peritoneum covers only the front and sides of the ascending and descending parts of the colon. Sometimes, however, these are surrounded by the serous membrane and attached to the posterior abdominal wall by an ascending and a descending mesocolon respectively. A fold of peritoneum, the **phrenicocolic ligament**, is continued from the left colic flexure to the Diaphragm opposite the tenth and eleventh ribs; it passes below and serves to support the spleen, and therefore has received the name of **sustentaculum lienis**.

The **appendices epiploicae** are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse and sigmoid parts of the colon.

Peritoneal Recesses or Fossae (*retroperitoneal fossae*).—In certain parts of the abdominal cavity there are recesses of peritoneum forming culs-de-sac or pouches,

which are of surgical interest in connection with the possibility of the occurrence of "retroperitoneal" herniæ. The largest of these is the omental bursa (already described), but several others, of smaller size, require mention, and may be divided into three groups, viz.: **duodenal**, **cecal**, and **intersigmoid**.

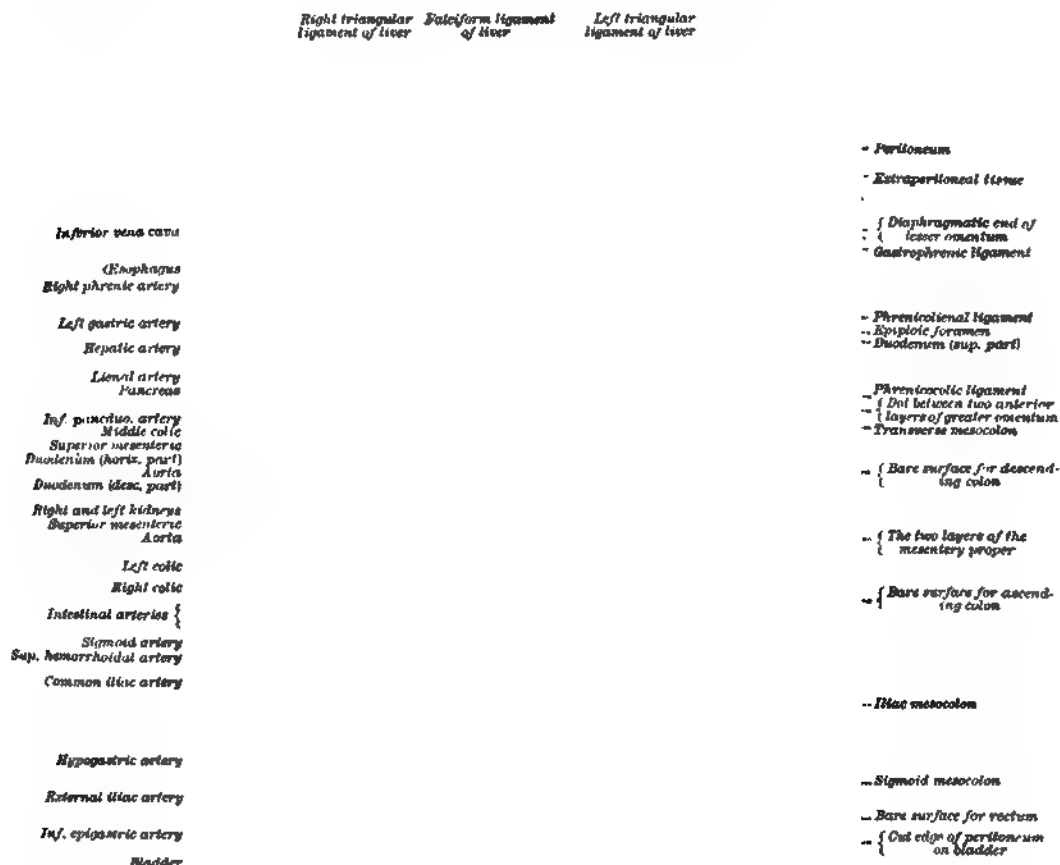

FIG. 966.—Diagram devised by Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.

1. **Duodenal Fossæ** (Figs. 967, 968).—Three are fairly constant, viz.: (a) The **inferior duodenal fossa**, present in from 70 to 75 per cent. of cases, is situated opposite the third lumbar vertebra on the left side of the ascending portion of the duodenum. Its opening is directed upward, and is bounded by a thin sharp fold of peritoneum with a concave margin, called the **duodenomesocolic fold**. The tip of the index finger introduced into the fossa under the fold passes some little distance behind the ascending portion of the duodenum. (b) The **superior duodenal fossa**, present in from 40 to 50 per cent. of cases, often coexists with the inferior one, and its orifice looks downward. It lies on the left of the ascending portion of the duodenum, in front of the second lumbar vertebra, and behind a

sickle-shaped fold of peritoneum, the **duodenojejunal fold**, and has a depth of about 2 cm. (c) The **duodenojejunal fossa** exists in from 15 to 20 per cent. of cases, but has never yet been found in conjunction with the other forms of duodenal fossæ; it can be seen by pulling the jejunum downward and to the right, after the

transverse colon has been pulled upward. It is bounded above by the pancreas, to the right by the aorta, and to the left by the kidney; beneath is the left renal vein. It has a depth of from 2 to 3 cm., and its orifice, directed downward and to the right, is nearly circular and will admit the tip of the little finger.

2. **Cecal Fossæ (pericecal folds or fossæ).**—There are three principal pouches or recesses in the neighborhood of the cecum (Figs. 969 to 971): (a) The **superior ileocecal fossa** is formed by a fold of peritoneum, arching over the branch of the

ileocolic artery which supplies the ileocolic junction. The fossa is a narrow chink situated between the mesentery of the small intestine, the ileum, and the small portion of the cecum behind. (b) The **inferior ileocecal fossa** is situated behind the angle of junction of the ileum and cecum. It is formed by the **ileocecocolic fold** of peritoneum (*bloodless fold of Treves*), the upper border of which is fixed to the ileum,

Inferior
ileocecocolic
fold
Ileum

opposite its mesenteric attachment, while the lower border, passing over the ileocecal junction, joins the mesenteriole of the vermiform process, and sometimes the process itself. Between this fold and the mesenteriole of the vermiform process is the **inferior ileocecal fossa**. It is bounded above by the posterior surface of the ileum and the mesentery; in front and below by the ileocecal fold, and behind by the upper part of the mesenteriole of the vermiform process. (c) The **cecal fossa** is situated immediately behind the cecum, which has to be raised to bring it into view. It varies much in size and extent. In some cases

FIG. 969.—Superior ileocecal fossa. (Poirier and Charpy.)

it is sufficiently large to admit the index finger, and extends upward behind the ascending colon in the direction of the kidney; in others it is merely a shallow depression. It is bounded on the right by the cecal fold, which is attached by one edge to the abdominal wall from the lower border of the kidney to the iliac fossa and by the other to the postero-lateral aspect of the colon. In some instances additional fossæ, the **retrocæcal fossæ**, are present.

3. The **intersigmoid fossa** (*recessus intersigmoideus*) is constant in the fetus and during infancy, but disappears in a certain percentage of cases as age advances. Upon drawing the sigmoid colon upward, the left surface of the sigmoid mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, in the interspace between the Psoas and Iliacus muscles. This is the orifice leading to the intersigmoid fossa, which lies behind the sigmoid

mesocolon, and in front of the parietal peritoneum. The fossa varies in size; in some instances it is a mere dimple, whereas in others it will admit the whole of the index finger.

Applied Anatomy.—Any of these fossae may be the site of a “retroperitoneal” hernia. The cecal fossae are of special interest, because hernia of the vermiform process frequently takes place into one of them, and it may there become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the vermiform process, where it travels upward behind the ascending colon as far as the Diaphragma.¹

The Stomach (Ventriculus; Gaster).

The stomach is the most dilated part of the digestive tube, and is situated between the end of the œsophagus and the beginning of the small intestine. It lies in the epigastric, umbilical, and left hypochondriac regions of the abdomen, and occupies a recess bounded by the upper abdominal viscera, and completed in front and on the left side by the anterior abdominal wall and the Diaphragma.

The shape and position of the stomach are so greatly modified by changes within itself and in the surrounding viscera that no one form can be described as typical. The chief modifications are determined by (1) the amount of the stomach contents, (2) the stage which the digestive process has reached, (3) the degree of development of the gastric musculature, and (4) the condition of the adjacent intestines. It is, however, possible by comparing a series of stomachs to determine certain markings more or less common to all (Figs. 972, 973).

The stomach presents two openings, two borders or curvatures, and two surfaces.

Openings.—The opening by which the œsophagus communicates with the stomach is known as the **cardiac orifice**, and is situated on the left of the middle line at the level of the tenth thoracic vertebra. The short abdominal portion of the œsophagus (*antrum cardiacum*) is conical in shape and curved sharply to the left, the base of the cone being continuous with the cardiac orifice of the stomach. The right margin of the œsophagus is continuous with the lesser curvature of the

¹ On the anatomy of these fossae, see the Arris and Gale Lectures by Moynihan, 1890.

stomach, while the left margin joins the greater curvature at an acute angle, termed the *incisura cardiaca*.

The **pyloric orifice** communicates with the duodenum, and its position is usually indicated on the surface of the stomach by a circular groove, the **duodenopyloric constriction**. This orifice lies to the right of the middle line at the level of the upper border of the first lumbar vertebra.

Curvatures.—The **lesser curvature** (*curvatura ventriculi minor*), extending between the cardiac and pyloric orifices, forms the right or posterior border of the stomach. It descends as a continuation of the right margin of the cesophagus in front of the fibres of the right crus of the Diaphragma, and then, turning to the right, it crosses the first lumbar vertebra and ends at the pylorus. Nearer its pyloric than its cardiac end is a well-marked notch, the *incisura angularis*, which varies somewhat in position with the state of distension of the viscus; it serves to separate the stomach into a right and a left portion. The lesser curvature gives attachment to the two layers of the hepatogastric ligament, and between these two layers are the left gastric artery and the right gastric branch of the hepatic artery.

FIG. 972.—Outline of stomach, showing its anatomical landmarks.

FIG. 973.—Outline of stomach at an early stage of gastric digestion.

The **greater curvature** (*curvatura ventriculi major*) is directed mainly forward, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice at the *incisura cardiaca*, it forms an arch backward, upward, and to the left; the highest point of the convexity is on a level with the sixth left costal cartilage. From this level it may be followed downward and forward, with a slight convexity to the left as low as the cartilage of the ninth rib; it then turns to the right, to the end of the pylorus. Directly opposite the *incisura angularis* or the lesser curvature the greater curvature presents a dilatation, which is the left extremity of the **pyloric part**; this dilatation is limited on the right by a slight groove, the **sulcus intermedius**, which is about 2.5 cm, from the duodenopyloric constriction. The portion between the sulcus intermedius and the duodenopyloric constriction is termed the **pyloric antrum**. At its commencement the greater curvature is covered by peritoneum continuous with that covering the front of the organ. The left part of the curvature gives attachment to the gastrosplenic ligament, while to its anterior portion are attached the two layers of the greater omentum, separated from each other by the gastroepiploic vessels.

Surfaces.—When the stomach is in the contracted condition, its surfaces are directed upward and downward respectively, but when the viscus is distended they are directed forward, and backward. They may therefore be described as antero-superior and postero-inferior.

Antero-superior Surface.—The left half of this surface is in contact with the Diaphragma, which separates it from the base of the left lung, the pericardium,

and the seventh, eighth, and ninth ribs, and intercostal spaces of the left side. The right half is in relation with the left and quadrate lobes of the liver and with the anterior abdominal wall. When the stomach is empty, the transverse colon may lie on the front part of this surface. The whole surface is covered by peritoneum.

The **Postero-inferior Surface** is in relation with the Diaphragma, the spleen, the left suprarenal gland, the upper part of the front of the left kidney, the anterior surface of the pancreas, the left colic flexure, and the upper layer of the transverse mesocolon. These structures form a shallow bed, the **stomach bed**, on which the viscus rests. The transverse mesocolon separates the stomach from the duodeno-jejunal flexure and small intestine. The postero-inferior surface is covered by peritoneum, except over a small area close to the cardiac orifice; this area is limited by the lines of attachment of the **gastrophrenic ligament**, and lies in apposition with the Diaphragma, and frequently with the upper portion of the left suprarenal gland.

Component Parts of the Stomach.—The stomach is capable of subdivision into distinctive parts, and the divisions may be made on either anatomical or clinical grounds.

Anatomical Subdivisions.—A plane passing through the incisura angularis on the lesser curvature and the left limit of the opposed dilatation on the greater curvature divides the stomach into a left portion or **body** and a right or **pyloric portion**. The left portion of the body is known as the **fundus**, and is marked off from the remainder of the body by a plane passing horizontally through the cardiac orifice. The pyloric portion is divided by a plane through the sulcus intermedius at right angles to the long axis of this portion; the part to the right of this plane is the **pyloric antrum** (Fig. 972).

Clinical Subdivisions.—If the stomach be examined during the process of digestion it will be found divided by a muscular constriction into a large dilated left portion, and a narrow contracted tubular right portion. The constriction is in the body of the stomach, and does not follow any of the anatomical landmarks; indeed, it shifts gradually toward the left as digestion progresses, *i. e.*, more of the body is gradually absorbed into the tubular part. These two portions are known as the **fundus** and **pyloric portions**. It will be seen therefore that the clinical fundus includes the anatomical fundus and the proximal part of the body, while the clinical pyloric portion comprises the distal part of the body, and the anatomical pyloric part (Fig. 973).

Position of the Stomach.—The position of the stomach varies with the posture, with the amount of the stomach contents and with the condition of the intestines on which it rests. In the erect posture the empty stomach is somewhat J-shaped; the part above the cardiac orifice is usually distended with gas; the pylorus descends to the level of the second lumbar vertebra and the most dependent part of the stomach is at the level of the umbilicus. Variation in the amount of its contents affects mainly the cardiac portion, the pyloric portion remaining in a more or less contracted condition during the process of digestion. As the stomach fills it tends to expand forward and downward in the direction of least resistance, but when this is interfered with by a distended condition of the colon or intestines the fundus presses upward on the liver and Diaphragma and gives rise to the feelings of oppression and palpitation complained of in such cases. His¹ and Cunningham² have shown by hardening the viscera *in situ* that the contracted stomach has a sickle shape, the fundus looking directly backward. The surfaces are directed upward and downward, the upper surface having, however, a gradual downward slope to the right. The greater curvature is in front and at a slightly higher level than the lesser.

The position of the full stomach depends, as already indicated, on the state of the intestines; when these are empty the fundus expands vertically and also forward, the pylorus is displaced toward the right and the whole organ assumes an oblique position, so that its surfaces are directed more forward and backward. The lowest part of the stomach is at the pyloric vestibule, which reaches to the region of the umbilicus. Where the intestines interfere with the downward expansion of the fundus the stomach retains the horizontal position which is characteristic of the contracted viscus.

Examination of the stomach during life by x-rays has confirmed these findings, and has demonstrated that, in the erect posture, the full stomach usually presents a hook-like appearance, the long axis of the clinical fundus being directed downward, medialward, and forward toward the umbilicus, while the pyloric portion curves upward to the duodenopyloric junction.

Interior of the Stomach.—When examined after death, the stomach is usually fixed at some temporary stage of the digestive process. A common form is that shown in Fig. 974. If the viscus be laid open by a section through the plane of its two curvatures, it is seen to consist of two segments: (a) a large globular portion on the left and (b) a narrow tubular part on the

¹ Archiv für Anatomie und Physiologie, anat. Abth., 1903.

² Transactions of the Royal Society of Edinburgh, vol. xiv, part i.

right. These correspond to the clinical subdivisions of fundus and pyloric portions already described, and are separated by a constriction which indents the body and greater curvature, but does not involve the lesser curvature. To the left of the cardiac orifice is the *incisura cardiaca*: the projection of this notch into the cavity of the stomach increases as the organ distends, and has been supposed to act as a valve preventing regurgitation into the oesophagus. In the pyloric portion are seen: (a) the elevation corresponding to the *incisura angularis*, and (b) the circular projection from the duodenopyloric constriction which forms the pyloric valve; the separation of the pyloric antrum from the rest of the pyloric part is scarcely indicated.

The **pyloric valve** (*valvula pylori*) is formed by a reduplication of the mucous membrane of the stomach, covering a muscular ring composed of a thickened portion of the circular layer of the muscular coat. Some of the deeper longitudinal fibres turn in and interlace with the circular fibres of the valve.

FIG. 974.—Interior of the stomach

Structure.—The wall of the stomach consists of four coats: **serous, muscular, areolar, and mucous**, together with vessels and nerves.

The **serous coat** (*tunica serosa*) is derived from the peritoneum, and covers the entire surface of the organ, excepting along the greater and lesser curvatures at the points of attachment of the greater and lesser omenta; here the two layers of peritoneum leave a small triangular space, along which the nutrient vessels and nerves pass. On the posterior surface of the stomach, close to the cardiac orifice, there is also a small area uncovered by peritoneum, where the organ is in contact with the under surface of the Diaphragm.

The **muscular coat** (*tunica muscularis*) (Figs. 975, 976) is situated immediately beneath the serous covering, with which it is closely connected. It consists of three sets of fibres: longitudinal, circular, and oblique.

The **longitudinal fibres** (*stratum longitudinale*) are the most superficial, and are arranged in two sets. The first set consists of fibres continuous with the longitudinal fibres of the oesophagus; they radiate in a stellate manner from the cardiac orifice and are practically all lost before the pyloric portion is reached. The second set commences on the body of the stomach and passes to the right, its fibres becoming more thickly distributed as they approach the pylorus. Some of the more superficial fibres of this set pass on to the duodenum, but the deeper fibres dip inward and interlace with the circular fibres of the pyloric valve.

The **circular fibres** (*stratum circulare*) form a uniform layer over the whole extent of the stomach beneath the longitudinal fibres. At the pylorus they are most abundant, and are aggregated into a circular ring, which projects into the lumen, and forms, with the fold of mucous membrane covering its surface, the **pyloric valve**. They are continuous with the circular fibres of the oesophagus, but are sharply marked off from the circular fibres of the duodenum.

The **oblique fibres** (*fibrae obliquae*) internal to the circular layer, are limited chiefly to the cardiac end of the stomach, where they are disposed as a thick uniform layer, covering both surfaces, some passing obliquely from left to right, others from right to left, around the cardiac end.

The **areolar or submucous coat** (*tela submucosa*) consists of a loose, areolar tissue, connecting the mucous and muscular layers

The **mucous membrane** (*tunica mucosa*) is thick and its surface is smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown color

FIG. 975.—The longitudinal and circular muscular fibres of the stomach, viewed from above and in front. (Spalteholz.)

over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugæ, which, for the most part,

FIG. 976.—The oblique muscular fibres of the stomach, viewed from above and in front. (Spalteholz.)

have a longitudinal direction, and are most marked toward the pyloric end of the stomach, and along the greater curvature (Fig. 974). These folds are entirely obliterated when the organ becomes distended.

Structure of the Mucous Membrane.—When examined with a lens, the inner surface of the mucous membrane presents a peculiar honeycomb appearance from being covered with small shallow depressions or alveoli, of a polygonal or hexagonal form, which vary from 0.12 to 0.25 mm. in diameter. These are the ducts of the gastric glands, and at the bottom of each may be seen one or more minute orifices, the openings of the gland tubes. The surface of the mucous membrane is covered by a single layer of columnar epithelium with occasional goblet cells. This epithelium commences very abruptly at the cardiac orifice, where there is a sudden transition from the stratified epithelium of the œsophagus. The epithelial lining of the gland ducts is of the same character and is continuous with the general epithelial lining of the stomach (Fig. 979).

The Gastric Glands.—The gastric glands are of three kinds: (a) *pyloric*, (b) *cardiac*, and (c) *fundus* or *oxyntic glands*. They are tubular in character, and are formed of a delicate basement-membrane, consisting of flattened transparent endothelial cells lined by epithelium. The *pyloric glands* (Fig. 978) are found in the pyloric portion of the stomach. They consist of two or three short closed tubes opening into a common duct or mouth. These tubes are wavy, and are about one-half the length of the duct. The duct is lined by columnar cells, continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes by shorter and more cubical cells which are finely granular. The *cardiac glands* (Fig. 977), few in number, occur close to the cardiac orifice. They are of two kinds: (1) simple tubular

m a

n

FIG. 977.—Section of mucous membrane of human stomach, near the cardiac orifice (v. Ebner, after J. Schaffer.) $\times 45$. c. Cardiac glands. d. Their ducts. cr. Gland similar to the intestinal glands, with goblet cells. mm. Mucous membrane. m. Muscularis mucosae. m' Muscular tissue within the mucous membrane.

glands resembling those of the pyloric end of the stomach, but with short ducts; (2) compound racemose glands resembling the duodenal glands. The *fundus glands* (Fig. 979) are found in the body and fundus of the stomach; they are simple tubes, two or more of which open into a single duct. The duct, however, in these glands is shorter than in the pyloric variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. The gland tubes are straight and parallel to each other. At the point where they open into the duct, which is termed the neck, the epithelium alters, and consists of short columnar or polyhedral, granular cells, which almost fill the tube, so that the lumen becomes suddenly constricted and is continued down as a very fine channel. They are known as the *chief* or *central cells* of the glands. Between these cells and the basement-membrane, larger oval cells, which stain deeply with eosin, are found; these cells are studded throughout the tube at intervals, giving it a beaded or varicose appearance. These are known as the *parietal* or *oxyntic cells*, and they are connected with the lumen by fine channels which run into their substance. Between the glands the mucous membrane consists of a connective-tissue frame-work, with lymphoid tissue. In places, this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary nodules of the intestine, and are termed the *lenticular glands* of the stomach. They are not, however, so distinctly circumscribed as the solitary nodules. Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscular fibre (*muscularis mucosae*), which in some parts

consists only of a single longitudinal layer; in others of two layers, an inner circular and an outer longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are: the left gastric, the right gastric and right gastroepiploic branches of the hepatic, and the left gastroepiploic and short gastric branches of the lienal. They supply the muscular coat, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes, and also form hexagonal meshes around the ducts. From these the veins arise, and pursue a straight course downward, between the tubules, to the submucous tissue; they end either in the lienal and superior mesenteric veins, or directly in the portal vein. The lymphatics are numerous: they consist of a superficial and a deep set, and pass to the lymph glands found along the two curvatures of the organ (page 792). The nerves are the terminal branches of the right and left

FIG. 978.—A pyloric gland, from a section of the dog's stomach. (Ebstein.) m. Mouth. n. Neck. tr. A deep portion of a tubule cut transversely.

FIG. 979.—A fundus gland. A. Transverse section of gland.

vagi, the former being distributed upon the back, and the latter upon the front part of the organ. A great number of branches from the coeliac plexus of the sympathetic are also distributed to it. Nerve plexuses are found in the submucous coat and between the layers of the muscular coat as in the intestine. From these plexuses fibrils are distributed to the muscular tissue and the mucous membrane.

Applied Anatomy.—Operations on the stomach are frequently performed. By *gastrotomy* is meant an incision into the stomach for the removal of a foreign body, the opening being immediately afterward closed—in contradistinction to *gastrostomy*, the making of a more or less permanent fistulous opening. *Gastrotomy* is probably best performed by an incision in the linea alba, especially if the foreign body be large, but may be performed by an incision over the foreign body itself, where this can be felt, or by one of the incisions for gastrostomy mentioned below. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound, and gauze is carefully packed around it. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert's sutures, i. e., by sutures passed through

the peritoneal and muscular coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition. In *gastrostomy*, the incision is commenced opposite the eighth left intercostal space, 5 cm. from the median line, and carried downward for 7.5 cm. By this incision the fibres of the Rectus abdominis are exposed, and these are separated in the same line. The posterior layer of the sheath, the Transversus muscle and transversalis fascia, and the peritoneum are then divided, and the peritoneal cavity opened. The anterior wall of the stomach is now seized and drawn out of the wound, and a silk suture passed through its muscular and serous coats at the point selected for opening the viscus. This is held by an assistant so that a long conical diverticulum of the stomach protrudes from the external wound, and the parietal peritoneum and the posterior layer of the sheath of the Rectus are sutured to it. A second incision is made through the skin, over the margin of the costal cartilage, above and a little to the outer side of the first incision. A tract is made under the skin through the subcutaneous tissue from the one opening to the other, and the diverticulum of the stomach is drawn along this tract by means of the suture inserted into it, so that its apex appears at the second opening. A small perforation is now made into the stomach through this protruding apex, and its margins are carefully and accurately sutured to the edge of the external wound. The remainder of this incision and the whole of the first incision are then closed in the ordinary way and the wound dressed.

In cases of gastric ulcer perforation sometimes takes place, and this was formerly regarded as an almost fatal complication. In the present day, by opening the abdomen and closing the perforation, which is generally situated on the anterior surface of the stomach, a considerable number of cases are cured, provided the operation is done not longer than twelve or fifteen hours after the perforation has taken place. The opening is best closed by bringing the peritoneal surfaces on either side into apposition by means of Lambert's sutures. Free drainage of the peritoneal cavity should be established at the same time.

Excision of the pylorus has occasionally been performed, but the results of this operation are by no means favorable, and, in cases of cancer of the pylorus, before operative proceedings are undertaken, the tumor has become so fixed and has so far implicated surrounding parts that removal of the pylorus is impossible and gastroenterostomy has to be substituted. The object of this operation is to make a fistulous communication between the stomach, on the cardiac side of the disease, and the small intestine, as high up as is possible. In cases of cancer of the stomach involving other parts than the pylorus, the question of removing the whole or greater part of the stomach has to be considered. This operation has been performed by Schlatter and others with success.

Hypertrophy and spasm of the circumferential muscular coat of the pylorus coming on during the first few weeks or months of life, and somewhat erroneously described as *congenital hypertrophic stenosis of the pylorus*, is a serious disorder of infancy. It is characterized by abdominal pains and obstinate vomiting coming on after food has been given. Gastric peristalsis can be observed by inspection of the child's epigastrium after it has been fed and before vomiting has occurred. Progressive wasting for want of nourishment and death from exhaustion tend to ensue. Treatment should be by washing out the stomach, and the administration at frequent intervals of small quantities of easily digested food, so as to minimize irritation of the gastric mucous membrane. Surgical interference entailing a severe operation, gives favorable results in a small proportion of cases.

The stomach is seldom ruptured from external violence on account of its protected position. If it occurs, it is when the organ is distended with food. The stomach is sometimes injured in gunshot wounds. There is intense shock and severe pain, localized at first at the seat of the injury, but soon radiating over the whole abdomen. The treatment consists of opening the peritoneal cavity, clearing away all the extruded contents of the stomach, and repairing the rent.

The Small Intestine (*Intestinum Tenue*).

The **small intestine** is a convoluted tube, extending from the pylorus to the colic valve, where it ends in the large intestine. It is about 6 metres long,¹ and gradually diminishes in size from its commencement to its termination. It is contained in the central and lower part of the abdominal cavity, and is surrounded above and at the sides by the large intestine; a portion of it extends below the superior aperture of the pelvis and lies in front of the rectum. It is in relation, in front, with the greater omentum and abdominal parietes, and is connected to the vertebral

¹ Treves states that, in one hundred cases, the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches; but that it varies very much, the extremes in the male being 31 feet 10 inches, and 15 feet 6 inches. He states that in the adult the length of the bowel is independent of age, height, and weight.

column by a fold of peritoneum, the **mesentery**. The small intestine is divisible into three portions: the **duodenum**, the **jejunum**, and the **ileum**.

The **Duodenum** (Fig. 980) has received its name from being about equal in length to the breadth of twelve fingers (25 cm.). It is the shortest, the widest, and the most fixed part of the small intestine, and has no mesentery, being only partially covered by peritoneum. Its course presents a remarkable curve, somewhat of the shape of an imperfect circle, so that its termination is not far removed from its starting-point.

In the adult the course of the duodenum is as follows: commencing at the pylorus it passes backward, upward, and to the right, beneath the quadrate lobe of the liver to the neck of the gall-bladder, varying slightly in direction according to the degree of distension of the stomach: it then takes a sharp curve and descends along the right margin of the head of the pancreas, for a variable distance, generally to the level of the upper border of the body of the fourth lumbar vertebra. It now takes a second bend, and passes from right to left across the vertebral column,

FIG. 980.—The duodenum and pancreas.

having a slight inclination upward; and on the left side of the vertebral column it ascends for about 2.5 cm., and then ends opposite the second lumbar vertebra in the jejunum. As it unites with the jejunum it turns abruptly forward, forming the **duodenojejunal flexure**. From the above description it will be seen that the duodenum may be divided into four portions: **superior**, **descending**, **horizontal**, and **ascending**.

Relations.—The **superior portion** (*pars superior; first portion*) is about 5 cm. long. Beginning at the pylorus, it ends at the neck of the gall-bladder. It is the most movable of the four portions. It is almost completely covered by peritoneum, but a small part of its posterior surface near the neck of the gall-bladder and the inferior vena cava is uncovered; the upper border of its first half has the hepatoduodenal ligament attached to it, while to the lower border of the same segment the greater omentum is connected. It is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface. It is in relation above and in front with the quadrate lobe of the liver and the gall-

bladder; behind with the gastroduodenal artery, the common bile duct, and the portal vein; and below and behind with the head and neck of the pancreas.

The **descending portion** (*pars descendens; second portion*) is from 7 to 10 cm. long, and extends from the neck of the gall-bladder, on a level with the first lumbar vertebra, along the right side of the vertebral column as low as the upper border of the body of the fourth lumbar vertebra. It is crossed in its middle third by the transverse colon, the posterior surface of which is uncovered by peritoneum and is connected to the duodenum by a small quantity of connective tissue. The supra- and infracolic portions are covered in front by peritoneum, the infracolic part by the right leaf of the mesentery. Posteriorly the descending portion of the duodenum is not covered by peritoneum. The descending portion is in relation, in front, from above downward, with the duodenal impression on the right lobe of the liver, the transverse colon, and the small intestine; behind, it has a variable relation to the front of the right kidney in the neighborhood of the hilus, and is connected to it by loose areolar tissue; the renal vessels, the inferior vena cava, and the Psoas below, are also behind it. At its medial side is the head of the pancreas, and the common

Probe in common bile-duct

Fig. 981.—Interior of the descending portion of the duodenum, showing bile papilla.

bile duct; to its lateral side is the right colic flexure. The common bile duct and the pancreatic duct together perforate the medial side of this portion of the intestine obliquely (Figs. 981 and 1014), some 7 to 10 cm. below the pylorus; the accessory pancreatic duct sometimes pierces it about 2 cm. above and slightly in front of these.

The **horizontal portion** (*pars horizontalis; third or preaortic or transverse portion*) is from 5 to 7.5 cm. long. It begins at the right side of the upper border of the fourth lumbar vertebra and passes from right to left, with a slight inclination upward, in front of the great vessels and crura of the Diaphragma, and ends in the ascending portion in front of the abdominal aorta. It is crossed by the superior mesenteric vessels and the mesentery. Its front surface is covered by peritoneum, except near the middle line, where it is crossed by the superior mesenteric vessels. Its posterior surface is uncovered by peritoneum, except toward its left extremity, where the posterior layer of the mesentery may sometimes be found covering it to a variable extent. This surface rests upon the right crus of the Diaphragma, the inferior vena cava, and the aorta. The upper surface is in relation with the head of the pancreas.

The **ascending portion** (*pars ascendens*; *fourth portion*) of the duodenum is about 2.5 cm long. It ascends on the left side of the aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly forward to become the jejunum, forming the **duodenojejunal flexure**. It lies in front of the left Psoas major and left renal vessels, and is covered in front, and partly at the sides, by peritoneum continuous with the left portion of the mesentery.

The superior part of the duodenum, as stated above, is somewhat movable, but the rest is practically fixed, and is bound down to neighboring viscera and the posterior abdominal wall by the peritoneum. In addition to this, the ascending part of the duodenum and the duodenojejunal flexure are fixed by a structure to which the name of *Musculus suspensorius duodeni* has been given. This structure commences in the connective tissue around the coeliac artery and left crus of the Diaphragma, and passes downward to be inserted into the superior border of the duodenojejunal curve and a part of the ascending duodenum, and from this it is continued into the mesentery. It possesses, according to Treitz, plain muscular fibres mixed with the fibrous tissue of which it is principally made up. It is of little importance as a muscle, but acts as a suspensory ligament.

Vessels and Nerves.—The arteries supplying the duodenum are the right gastric and superior pancreaticoduodenal branches of the hepatic, and the inferior pancreaticoduodenal branch of the superior mesenteric. The veins end in the lienal and superior mesenteric. The nerves are derived from the coeliac plexus.

Jejunum and Ileum.—The remainder of the small intestine from the end of the duodenum is named **jejunum** and **ileum**; the former term being given to the upper two-fifths and the latter to the lower three-fifths. There is no morphological line of distinction between the two, and the division is arbitrary; but at the same time the character of the intestine gradually undergoes a change from the commencement of the jejunum to the end of the ileum, so that a portion of the bowel taken from these two situations would present characteristic and marked differences. These are briefly as follows:

The **Jejunum** (*intestinum jejunum*) is wider, its diameter being about 4 cm., and is thicker, more vascular, and of a deeper color than the ileum, so that a given length weighs more. The circular folds (*valvulae conniventes*) of its mucous membrane are large and thickly set, and its villi are larger than in the ileum. The aggregated lymph nodules are almost absent in the upper part of the jejunum, and in the lower part are less frequently found than in the ileum, and are smaller and tend to assume a circular form. By grasping the jejunum between the finger and thumb the circular folds can be felt through the walls of the gut; these being absent in the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

The **Ileum** (*intestinum ileum*) is narrow, its diameter being 3.75 cm., and its coats thinner and less vascular than those of the jejunum. It possesses but few circular folds, and they are small and disappear entirely toward its lower end, but aggregated lymph nodules (Peyer's patches) are larger and more numerous. The jejunum for the most part occupies the umbilical and left iliac regions, while the ileum occupies chiefly the umbilical, hypogastric, right iliac, and pelvic regions. The terminal part of the ileum usually lies in the pelvis, from which it ascends over the right Psoas and right iliac vessels; it ends in the right iliac fossa by opening into the medial side of the commencement of the large intestine. The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the **mesentery**, which allows the freest motion, so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its posterior border or root, about 15 cm. long, is attached to the posterior abdominal wall from the left side of the body of the second lumbar vertebra to the right sacroiliac articulation, crossing successively the horizontal part of the duodenum, the

aorta, the inferior vena cava, the ureter, and right Psoas muscle (Fig. 966). Its breadth between its vertebral and intestinal borders averages about 20 cm., and is greater in the middle than at its upper and lower ends. According to Lockwood it tends to increase in breadth as age advances. Between the two layers of which it is composed are contained bloodvessels, nerves, lacteals, and lymph glands, together with a variable amount of fat.

FIG. 982.—Section of duodenum of cat. (After Schäfer.) $\times 60$.

Meckel's Diverticulum (*diverticulum ilei*).—This consists of a pouch which projects from the lower part of the ileum in about 2 per cent. of subjects. Its average position is about 1 meter above the colic valve, and its average length about 5 cm. Its calibre is generally similar to that of the ileum, and its blind extremity may be free or may be connected with the abdominal wall or with some other portion of the intestine by a fibrous band. It represents the remains of the proximal part of the vitelline duct, the duct of communication between the yolk-sac and the primitive digestive tube in early fetal life.

Structure. The wall of the small intestine (Fig. 982) is composed of four coats: **serous**, **muscular**, **areolar**, and **mucosa**.

The **serous coat** (*tunica serosa*) is derived from the peritoneum. The superior portion of the duodenum is almost completely surrounded by this membrane near its pyloric end, but is only

covered in front at the other extremity; the descending portion is covered by it in front, except where it is carried off by the transverse colon; and the inferior portion lies behind the peritoneum which passes over it without being closely incorporated with the other coats of this part of the intestine, and is separated from it in and near the middle line by the superior mesenteric vessels. The rest of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

The **muscular coat** (*tunica muscularis*) consists of two layers of fibres: an external, longitudinal, and an internal, circular layer. The *longitudinal fibres* are thinly scattered over the surface of the intestine, and are more distinct along its free border. The *circular fibres* form a thick, uniform layer, and are composed of plain muscle cells of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.

The **areolar or submucous coat** (*tela submucosa*) connects together the mucous and muscular layers. It consists of loose, filamentous areolar tissue containing bloodvessels, lymphatics, and nerves.

The **mucous membrane** (*tunica mucosa*) is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a double layer of unstriated muscular fibres, outer longitudinal and inner circular, the **muscularis mucosae**; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph corpuscles, and in this the bloodvessels and nerves ramify; lastly, a basement-membrane, supporting a single layer of epithelial cells, which throughout the intestine are columnar in character. The cells are granular in appearance, and each possesses a clear oval nucleus. At their superficial or unattached ends they present a distinct layer of highly refracting material, marked by vertical striæ, the **striated border**.

The mucous membrane presents for examination the following structures, contained within it or belonging to it:

Circular folds.

Villi.

Intestinal glands.

Duodenal glands.

Solitary lymphatic nodules.

Aggregated lymphatic nodules.

The **circular folds** (*plicae circulares* [Kerkringi]; *valvulae conniventes*; *valves of Kerkring*) are large valvular flaps projecting into the lumen of the bowel. They are composed of reduplications of the mucous membrane, the two layers of the fold being bound together by submucous tissue; unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely around the cylinder of the intestine for about one-half or two-thirds of its circumference, but some form complete circles, and others have a spiral direction; the latter usually extend a little more than once around the bowel, but occasionally two or three times. The larger folds are about 8 mm. in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but begin to appear about 2.5 or 5 cm. beyond the pylorus. In the lower part of the descending portion, below the point where the bile and pancreatic ducts enter the intestine, they are very large and closely approximated. In the horizontal and ascending portions of the duodenum and upper half of the jejunum they are large and numerous, but from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine, as compared with the duodenum and jejunum. The circular folds retard the passage of the food along the intestines, and afford an increased surface for absorption.

The **intestinal villi** (*villi intestinales*) are highly vascular processes, projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum.

Structure of the villi (Figs. 983, 984).—The essential parts of a villus are: the lacteal vessel, the bloodvessels, the epithelium, the basement-membrane, and the muscular tissue of the mucosa, all being supported and held together by retiform lymphoid tissue.

The *lacteals* are in some cases double, and in some animals multiple, but usually there is a single vessel. Situated in the axis of the villus, each commences by dilated cecal extremities near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells.

The *muscular fibres* are derived from the muscularis mucosae, and are arranged in longitudinal bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off, laterally, individual muscle cells, which are enclosed by the reticulum, and by it are attached to the basement-membrane and to the lacteal.

The *bloodvessels* (Fig. 985) form a plexus under the basement membrane, and are enclosed in the reticular tissue.

These structures are surrounded by the *basement-membrane*, which is made up of a stratum of endothelial cells, and upon this is placed a layer of *columnar epithelium*, the characteristics

of which have been described. The *retiform tissue* forms a net-work (Fig. 984) in the meshes of which a number of leucocytes are found.

The **intestinal glands** (*glandulae intestinales* [Lieberkühn]; *crypts of Lieberkühn*) (Fig. 986) are found in considerable numbers over every part of the mucous membrane of the small intestine.

Capillaries
Lymphatic vessel

Capillaries

Lymphatic vessel

Small artery *Lymphatic plexus*

FIG. 985.—Villi of small intestine, showing bloodvessels and lymphatic vessels. (Cadiat.)

They consist of minute tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid

of a lens, their orifices appearing as minute dots scattered between the villi. Their walls are thin, consisting of a basement membrane lined by columnar epithelium, and covered on their exterior by capillary vessels.

The **duodenal glands** (*glandulae duodenales* [Brunneri]; *Brunner's glands*) are limited to the duodenum (Fig. 982), and are found in the submucous areolar tissue. They are largest and most numerous near the pylorus, forming an almost complete layer in the superior portion and upper half of the descending portions of the duodenum. They then begin to diminish in number, and practically disappear at the junction of the duodenum and jejunum. They are small compound acinotubular glands consisting of a number of alveoli lined by short columnar epithelium and opening by a single duct on the inner surface of the intestine.

The **solitary lymphatic nodules** (*noduli lymphatici solitarii*, *solitary glands*) are found scattered throughout the mucous membrane of the small intestine, but are most numerous in the lower part of the ileum. Their free surfaces are covered with rudimentary villi, except at the summits, and each gland is surrounded by the openings of the intestinal glands. Each consists of a dense interlacing retiform tissue closely packed with lymph-corpuscles, and permeated with an abundant capillary network. The interspaces of the retiform tissue are continuous with larger lymph spaces which surround the gland, through which they communicate with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous membrane, where they form slight projections of its epithelial layer (see Fig. 998).

The **aggregated lymphatic nodules** (*noduli lymphatici aggregati*; *Peyer's patches*; *Peyer's glands*, *agminated follicles*; *tonsillae intestinales*) (Fig. 987) form circular or oval patches, from twenty to thirty in number, and varying in length from 2 to 10 cm. They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, circular, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated in the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of solitary lymphatic nodules covered with mucous membrane, but the patches do not, as a rule, possess villi on their free surfaces. They are best marked in the

young subject, become indistinct in middle age, and sometimes disappear altogether in advanced life. They are freely supplied with bloodvessels (Fig. 988), which form an abundant

plexus around each follicle and give off fine branches permeating the lymphoid tissue in the interior of the follicle. The lymphatic plexuses are especially abundant around these patches.

Vessels and Nerves.—The jejunum and ileum are supplied by the **superior mesenteric artery**, the intestinal branches of which, having reached the attached border of the bowel, run between the serous and muscular coats, with frequent inosculations to the free border, where they also anastomose with other branches running around the opposite surface of the gut. From these

FIG. 989.—The myenteric plexus from the rabbit.
× 50.

FIG. 988.—Transverse section through the equatorial plane of three aggregated lymphatic nodules from the rabbit.

vessels numerous branches are given off, which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels pass to the glands and villi of the mucous membrane. The **veins** have a similar course and arrangement to the arteries. The **lymphatics** of the small intestine (lacteals) are arranged in two sets, those of the mucous membrane and those of the muscular coat. The lymphatics of the villi commence in these structures in the manner described above. They form an intricate plexus in the mucous

and submucous tissue, being joined by the lymphatics from the lymph spaces at the bases of the solitary nodules, and from this pass to larger vessels at the mesenteric border of the gut. The lymphatics of the muscular coat are situated to a great extent between the two layers of muscular fibres, where they form a close plexus; throughout their course they communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner as these into the origins of the lacteal vessels at the attached border of the gut.

The **nerves** of the small intestines are derived from the plexuses of sympathetic nerves around the superior mesenteric artery. From this source they run to the **mesenteric plexus** (*Auerbach's plexus*) (Fig. 989) of nerves and ganglia situated between the circular and longitudinal muscular fibres from which the nervous branches are distributed to the muscular coats of the intestine. From this a secondary plexus, the **plexus of the submucosa** (*Meissner's plexus*) (Fig. 990) is derived, and is formed by branches which have per-

FIG. 990.—The plexus of the submucosa from the rabbit.
× 50

forated the circular muscular fibres. This plexus lies in the submucous coat of the intestine; it also contains ganglia from which nerve fibres pass to the muscularis mucosae and to the mucous membrane. The nerve bundles of the submucous plexus are finer than those of the myenteric plexus.

The Large Intestine (*Intestinum Crassum*).

The **large intestine** extends from the end of the ileum to the anus. It is about 1.5 metres long, being one-fifth of the whole extent of the intestinal canal. Its calibre is largest at its commencement at the cecum, and gradually diminishes

as far as the rectum, where there is a dilatation of considerable size just above the anal canal. It differs from the small intestine in its greater calibre, its more fixed position, its sacculated form, and in possessing certain appendages to its external coat, the **appendices epiploicae**. Further, its longitudinal muscular fibres do not form a continuous layer around the gut, but are arranged in three **longitudinal bands** or **taeniae**. The large intestine, in its course, describes an arch which surrounds the convolutions of the small intestine. It commences in the right iliac region, in a dilated part, the **caecum**. It ascends through the right lumbar and hypochondriac regions to the under surface of the liver; it here takes a bend, the **right colic flexure**, to the left and passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; it then bends again, the **left colic flexure**, and descends through the left lumbar and iliac regions to the pelvis, where it forms a bend called the **sigmoid flexure**; from this it is continued along the posterior wall of the pelvis to the anus. The large intestine is divided into the **caecum**, **colon**, **rectum**, and **anal canal**.

tery

idicular
y

FIG. 991.—The caecum and vermiform process, with their arteries.

The **Caecum** (*intestinum caecum*) (Fig. 991), the commencement of the large intestine, is the large blind pouch situated below the colic valve. Its blind end is directed downward, and its open end upward, communicating directly with the colon, of which this blind pouch appears to be the beginning or head, and hence the old name of **caput caecum coli** was applied to it. Its size is variously estimated by different authors, but on an average it may be said to be 6.25 cm. in length and 7.5 in breadth. It is situated in the right iliac fossa, above the lateral half of the inguinal ligament: it rests on the Iliacus and Psoas major, and usually lies in contact with the anterior abdominal wall, but the greater omentum and, if the caecum be empty, some coils of small intestine may lie in front of it. As a rule, it is entirely enveloped by peritoneum, but in a certain number of cases (5 per cent., Berry) the peritoneal covering is not complete, so that the upper part of the posterior surface is uncovered and connected to the iliac fascia by connective tissue. The caecum lies quite free in the abdominal cavity and enjoys a considerable amount of movement, so that

it may become herniated down the right inguinal canal, and has occasionally been found in an inguinal hernia on the left side. The cecum varies in shape, but, according to Treves, in man it may be classified under one of four types. In early fetal life it is short, conical, and broad at the base, with its apex turned upward and medialward toward the ileocolic junction. It then resembles the cecum of some monkeys, *e. g.*, mangabey monkey. As the fetus grows the cecum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and without the broad base, but with the same inclination of the apex toward the ileocolic junction. This form is seen in other monkeys, *e. g.*, the spider monkey. As development goes on, the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that at birth there is a narrow tube, the vermiform process, hanging from a conical projection, the cecum. This is the infantile form, and as it persists throughout life in about 2 per cent. of cases, it is regarded by Treves as the *first* of his four types of human ceca. The cecum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the second type, the conical cecum has become quadrate by the growing out of a sacculus on either side of the anterior longitudinal band. These sacculi are of equal size, and the appendix arises from between them, instead of from the apex of a cone. This type is found in about 3 per cent. of cases. The *third* type is the normal type of man. Here the two sacculi, which in the second type were uniform, have grown at unequal rates: the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the growing downward of the right sacculus, and the original apex, with the appendix attached, is pushed over to the left toward the ileocolic junction. The three longitudinal bands still start from the base of the vermiform process, but they are now no longer equidistant from each other, because the right sacculus has grown between the anterior and posterolateral bands, pushing them over to the left. This type occurs in about 90 per cent. of cases. The *fourth* type is merely an exaggerated condition of the third; the right sacculus is still larger, and at the same time the left sacculus has become atrophied, so that the original apex of the cecum, with the vermiform process, is close to the ileocecal junction, and the anterior band courses medialward to the same situation. This type is present in about 4 per cent. of cases.

The **Vermiform Process** or **Appendix** (*processus vermiformis*) (Fig. 991) is a long, narrow, worm-shaped tube, which starts from what was originally the apex of the cecum, and may pass in one of several directions: upward behind the cecum; to the left behind the ileum and mesentery; or downward into the lesser pelvis. It varies from 2 to 20 cm. in length, its average being about 8.3 cm. It is retained in position by a fold of peritoneum (mesenteriole), derived from the left leaf of the mesentery. This fold, in the majority of cases, is more or less triangular in shape, and as a rule extends along the entire length of the tube. Between its two layers and close to its free margin lies the appendicular artery (Fig. 991). The canal of the vermiform process is small, extends throughout the whole length of the tube, and communicates with the cecum by an orifice which is placed below and behind the ileocecal opening. It is sometimes guarded by a semilunar valve formed by a fold of mucous membrane, but this is by no means constant.

Structure.—The coats of the vermiform process are the same as those of the intestine: serous, muscular, submucous, and mucous. The **serous coat** forms a complete investment for the tube, except along the narrow line of attachment of its mesenteriole in its proximal two-thirds. The **longitudinal muscular fibres** do not form three bands as in the greater part of the large intestine, but invest the whole organ, except at one or two points where both the longitudinal and circular fibres are deficient so that the peritoneal and submucous coats are contiguous over small areas.

The **circular muscle fibres** form a much thicker layer than the longitudinal fibres, and are separated from them by a small amount of connective tissue. The **submucous coat** is well marked, and contains a large number of masses of lymphoid tissue which cause the mucous

membrane to bulge into the lumen and so render the latter of small size and irregular shape. The **mucous membrane** is lined by columnar epithelium and resembles that of the rest of the large intestine, but the intestinal glands are fewer in number (Fig. 992)

The Colic Valve (*valvula coli*; *ileocecal valve*) (Fig. 993).—The lower end of the ileum ends by opening into the medial and back part of the large intestine, at the point of junction of the cecum with the colon. The opening is guarded by a valve, consisting of two segments or lips, which project into the lumen of the large intestine. If the intestine has been inflated and dried, the lips are of a semilunar shape. The upper one, nearly horizontal in direction, is attached by its convex border

to the line of junction of the ileum with the colon; the lower lip, which is longer and more concave, is attached to the line of junction of the ileum with the cecum. At the ends of the aperture the two segments of the valve coalesce, and are continued as narrow membranous ridges around the canal for a short distance, forming the **frenula of the valve**. The left or anterior end of the aperture is rounded; the right or posterior is narrow and pointed. In the fresh condition, or in specimens which

have been hardened *in situ*, the lips project as thick cushion-like folds into the lumen of the large gut, while the opening between them may present the appearance of a slit or may be somewhat oval in shape.

Each lip of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly from the small to the large intestine.

The surfaces of the valve directed toward the ileum are covered with villi, and present the characteristic structure of the mucous membrane of the small intestine; while those turned toward the large intestine are destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. These differences in structure continue as far as the free margins of the valve. It is generally maintained that this valve prevents reflux from the cecum into the ileum, but in all probability it acts as a sphincter around the end of the ileum and prevents the contents of the ileum from passing too quickly into the cecum.

The **Colon** is divided into four parts: the **ascending**, **transverse**, **descending**, and **sigmoid**.

The **Ascending Colon** (*colon ascendens*) is smaller in calibre than the cecum, with which it is continuous. It passes upward, from its commencement at the cecum, opposite the colic valve, to the under surface of the right lobe of the liver, on the right of the gall-bladder, where it is lodged in a shallow depression, the **colic impression**; here it bends abruptly forward and to the left, forming the **right colic (hepatic) flexure** (Fig. 980). It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Iliacus, Quadratus lumborum, aponeurotic origin of Transversus abdominis, and with the front of the lower and lateral part of the right kidney. Sometimes the peritoneum completely invests it, and forms a distinct but narrow mesocolon.¹ It is in relation, in front, with the convolutions of the ileum and the abdominal parietes.

The **Transverse Colon** (*colon transversum*) the longest and most movable part of the colon, passes with a downward convexity from the right hypochondriac region across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves sharply on itself beneath the lower end of the spleen, forming the **left colic (splenic) flexure**. In its course it describes an arch, the concavity of which is directed backward and a little upward; toward its splenic end there is often an abrupt U-shaped curve which may descend lower than the main curve. It is almost completely invested by peritoneum, and is connected to the inferior border of the pancreas by a large and wide duplicature of that membrane, the **transverse mesocolon**. It is in relation, by its upper surface, with the liver and gall-bladder, the greater curvature of the stomach, and the lower end of the spleen; by its under surface, with the small intestines; by its anterior surface, with the anterior layers of the greater omentum and the abdominal parietes; its posterior surface is in relation from right to left with the descending portion of the duodenum, the head of the pancreas, and some of the convolutions of the jejunum and ileum.

The **left colic or splenic flexure** (Fig. 980) is situated at the junction of the transverse and descending parts of the colon, and is in relation with the lower end of the spleen and the tail of the pancreas; the flexure is so acute that the end of the transverse colon usually lies in contact with the front of the descending colon. It lies

¹ Treves states that, after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colotomy a mesocolon may be expected upon the left side in 36 per cent. of all cases, and on the right in 26 per cent.—The Anatomy of the Intestinal Canal and Peritoneum in Man, 1885, p. 55.

at a higher level than, and on a plane posterior to, the right colic flexure, and is attached to the Diaphragma, opposite the tenth and eleventh ribs, by a peritoneal fold, named the **phrenicocolic ligament**, which assists in supporting the lower end of the spleen (see page 1157).

The **Descending Colon**¹ (*colon descendens*) passes downward through the left hypochondriac and lumbar regions along the lateral border of the left kidney. At the lower end of the kidney it turns medialward toward the lateral border of the Psoas, and then descends, in the angle between Psoas and Quadratus lumborum, to the crest of the ilium, where it ends in the iliac colon. The peritoneum covers its anterior surface and sides, while its posterior surface is connected by areolar tissue with the lower and lateral part of the left kidney, the aponeurotic origin of the Transversus abdominis, and the Quadratus lumborum (Fig. 980). It is smaller in calibre and more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves). In front of it are some coils of small intestine.

FIG. 994.—Iliac colon, sigmoid or pelvic colon, and rectum seen from the front, after removal of pubic bones and bladder.

The **Iliac Colon** (Fig. 994) is situated in the left iliac fossa, and is about 12 to 15 cm. long. It begins at the level of the iliac crest, where it is continuous with the descending colon, and ends in the sigmoid colon at the superior aperture of the lesser pelvis. It curves downward and medialward in front of the Iliacus and Psoas, and, as a rule, is covered by peritoneum on its sides and anterior surface only.

The **Sigmoid Colon** (*colon sigmoideum*; *pelvic colon*; *sigmoid flexure*) (Fig. 994) forms a loop which averages about 40 cm. in length, and normally lies within the pelvis, but on account of its freedom of movement it is liable to be displaced into

¹ In the *Basis* nomenclature the descending colon is the portion between the left colic flexure and the superior aperture of the lesser pelvis; it is, however, convenient to still describe its lowest part as the iliac colon.

the abdominal cavity. It begins at the superior aperture of the lesser pelvis, where it is continuous with the iliac colon, and passes transversely across the front of the sacrum to the right side of the pelvis; it then curves on itself and turns toward the left to reach the middle line at the level of the third piece of the sacrum, where it bends downward and ends in the rectum. It is completely surrounded by peritoneum, which forms a mesentery (**sigmoid mesocolon**), which diminishes in length from the centre toward the ends of the loop, where it disappears, so that the loop is fixed at its junctions with the iliac colon and rectum, but enjoys a considerable range of movement in its central portion. *Behind* the sigmoid colon are the external iliac vessels, the left Piriformis, and left sacral plexus of nerves; in *front*, it is separated from the bladder in the male, and the uterus in the female, by some coils of the small intestine.

FIG. 995.—The posterior aspect of the rectum exposed by removing the lower part of the sacrum and the coccyx.

The **Rectum** (*intestinum rectum*) (Fig. 995) is continuous above with the sigmoid colon, while below it ends in the anal canal. From its origin at the level of the third sacral vertebra it passes downward, lying in the sacrococcygeal curve, and extends for about 2.5 cm. in front of, and a little below, the tip of the coccyx, as far as the apex of the prostate. It then bends sharply backward into the anal canal. It therefore presents two antero-posterior curves: an upper, with its con-

vexity backward, and a lower, with its convexity forward. Two lateral curves are also described, one to the right opposite the junction of the third and fourth sacral vertebræ, and the other to the left, opposite the left sacrococcygeal articulation; they are, however, of little importance. The rectum is about 12 cm. long, and at its commencement its calibre is similar to that of the sigmoid colon, but near its termination it is dilated to form the **rectal ampulla**. The rectum has no sacculations comparable to those of the colon, but when the lower part of the rectum is contracted, its mucous membrane is thrown into a number of folds, which are longitudinal in direction and are effaced by the distension of the gut. Besides these there are certain permanent transverse folds, of a semilunar shape, known as **Houston's valves** (Fig. 996). They are usually three in number; sometimes a fourth is found, and occasionally only two are present. One is situated near the commencement of the rectum, on the right side; a second extends inward from the left side of the tube, opposite the middle of the sacrum; a third, the largest and most constant, projects backward from the forepart of the rectum, opposite the fundus of the urinary bladder. When a fourth is present, it is situated nearly 2.5 cm. above the anus on the left and posterior wall of the tube. These folds are about 12 mm. in width, and contain some of the circular fibres of the gut. In the empty state of the intestines they overlap each other, as Houston remarks, so effectually as to require considerable manœuvring to conduct a bougie or the finger along the canal. Their use seems to be, "to support the weight of fecal matter, and prevent its urging toward the anus, where its presence always excites a sensation demanding its discharge."¹

The peritoneum is related to the upper two-thirds of the rectum, covering at first its front and sides, but lower down its front only; from the latter it is reflected on to the seminal vesicles in the male and the posterior vaginal wall in the female.

The level at which the peritoneum leaves the anterior wall of the rectum to be reflected on to the viscus in front of it is of considerable importance from a surgical point of view, in connection with the removal of the lower part of the rectum. It is higher in the male than in the female. In the former the height of the rectovesical excavation is about 7.5 cm., *i. e.*, the height to which an ordinary index finger can reach from the anus. In the female the height of the rectouterine excavation is about 5.5 cm. from the anal orifice. The rectum is surrounded by a dense tube of fascia derived from the fascia endopelvina, but fused behind with the fascia covering the sacrum and coccyx. The fascial tube is loosely attached to the rectal wall by areolar tissue in order to allow of distension of the viscus.

Relations of the Rectum.—The upper part of the rectum is in relation, *behind*, with the superior hemorrhoidal vessels, the left Piriformus, and left sacral plexus of nerves, which separate it from the pelvic surfaces of the sacral vertebræ; in its lower part it lies directly on the sacrum, coccyx, and Levatores ani, a dense fascia alone intervening; *in front*, it is separated above, in the male, from the fundus of the bladder; in the female, from the intestinal surface of the uterus and its

FIG. 996.—Coronal section of rectum and anal canal.

¹ Paterson ("The Form of the Rectum," *Journal of Anatomy and Physiology*, vol. xliii) utilizes the third fold for the purpose of dividing the rectum into an upper and a lower portion; he considers the latter "to be just as much a duct as the narrower anal canal below," and maintains that, under normal conditions, it does not contain feces except during the act of defecation.

appendages, by some convolutions of the small intestine, and frequently by the sigmoid colon; below, it is in relation in the male with the triangular portion of the fundus of the bladder, the vesiculæ seminales, and ductus deferentes, and more anteriorly with the posterior surface of the prostate; in the female, with the posterior wall of the vagina.

The **Anal Canal** (*pars analis recti*) (Fig. 997), or terminal portion of the large intestine, begins at the level of the apex of the prostate, is directed downward and backward, and ends at the anus. It forms an angle with the lower part of the rectum, and measures from 2.5 to 4 cm. in length. It has no peritoneal covering, but is invested by the Sphincter ani internus, supported by the Levatores ani, and surrounded at its termination by the Sphincter ani externus. In the empty condition it presents the appearance of an antero-posterior longitudinal slit. Behind it is a mass of muscular and fibrous tissue, the **anococcygeal body** (Symington); in front of it, in the male, but separated by connective tissue from it, are the membranous portion and bulb of the urethra, and the fascia of the urogenital diaphragm; and in the female it is separated from the lower end of the vagina by a mass of muscular and fibrous tissue, named the **perineal body**.

FIG. 997.—Coronal section through the anal canal. (Symington). B. Cavity of urinary bladder. V.D. Ductus deferens. S.V. Seminal vesicle. R. Second part of rectum. A.C. Anal canal. L.A. Levator ani. I.S. Sphincter ani internus. E.S. Sphincter ani externus.

The lumen of the anal canal presents, in its upper half, a number of vertical folds, produced by an infolding of the mucous membrane and some of the muscular tissue. They are known as the **rectal columns** [*Morgagni*] (Fig. 996), and are separated from one another by furrows (**rectal sinuses**), which end below in small valve-like folds, termed **anal valves**, which join together the lower ends of the rectal columns.

Structure of the Colon.—The large intestine has four coats: **serous, muscular, areolar, and mucous**.

The **serous coat** (*tunica serosa*) is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The cecum is completely covered by the serous membrane, except in about 5 per cent. of cases where the upper part of the posterior surface is uncovered. The ascending, descending, and iliac parts of the colon are usually covered only in front and at the sides; a variable amount of the posterior surface is uncovered.¹ The transverse colon is almost completely invested, the parts corresponding to the attachment of the greater omentum and transverse mesocolon being alone excepted. The sigmoid colon is entirely surrounded. The rectum is covered above on its anterior surface and sides; below, on its anterior aspect only; the anal canal is entirely devoid of any serous covering. In the course of the colon the peritoneal coat is thrown into a number of small pouches filled with fat, called **appendices epiploicae**. They are most numerous on the transverse colon.

The **muscular coat** (*tunica muscularis*) consists of an external longitudinal, and an internal circular, layer of non-striped muscular fibres.

The **longitudinal fibres** do not form a continuous layer over the whole surface of the large intestine. In the cecum and colon they are especially collected into three flat longitudinal bands (*taeniae coli*), each of about 12 mm. in width; one, the posterior, is placed along the attached border of the intestine; the anterior, the largest, corresponds along the arch of the colon to the attachment of the greater omentum, but is in front in the ascending, descending, and iliac parts of the colon, and in the sigmoid colon; the third, or lateral band, is found on the medial side of the ascending and descending parts of the colon, and on the under aspect of the transverse colon.

¹ See footnote, p. 1180.

These bands are shorter than the other coats of the intestine, and serve to produce the sacculi which are characteristic of the cecum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. In the sigmoid colon the longitudinal fibres become more scattered; and around the rectum they spread out and form a layer, which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, where it forms two bands, than on the lateral surfaces. In addition, two bands of plain muscular tissue arise from the second and third coccygeal vertebra, and pass downward and forward to blend with the longitudinal muscular fibres on the posterior wall of the anal canal. These are known as the **Rectococcygeal muscles**.

The *circular fibres* form a thin layer over the cecum and colon, being especially accumulated in the intervals between the sacculi; in the rectum they form a thick layer, and in the anal canal they become numerous, and constitute the *Sphincter ani internus*.

The **areolar coat** (*tela submucosa*; *submucous coat*) connects the muscular and mucous layers closely together.

The **mucous membrane** (*tunica mucosa*) in the cecum and colon, is pale, smooth, destitute of villi, and raised into numerous *crenate* folds which correspond to the intervals between the sacculi. In the rectum it is thicker, of a darker color, more vascular, and connected loosely to the muscular coat, as in the oesophagus.

*Leucocytes in
epithelium* *Gland*

Solitary lymphatic nodule

FIG. 998.—Section of mucous membrane of human rectum. (Sobotta.) $\times 60$.

As in the small intestine, the mucous membrane (Fig. 998) consists of a muscular layer, the *muscularis mucosae*; a quantity of retiform tissue in which the vessels ramify; a basement-membrane and epithelium which is of the columnar variety, and resembles the epithelium found in the small intestine. The mucous membrane of the large intestine presents for examination glands and solitary lymphatic nodules.

The glands of the great intestine are minute tubular prolongations of the mucous membrane arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and placed in much closer apposition than those of the small intestine; and they open by minute rounded orifices upon the surface, giving it a cribriform appearance. Each gland is lined by short columnar epithelium and contains numerous goblet cells.

The **solitary lymphatic nodules** (*noduli lymphatici solitarii*) (Fig. 998) of the large intestine are most abundant in the cecum and vermiform process, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

Vessels and Nerves.—The **arteries** supplying the colon are derived from the colic and sigmoid branches of the mesenteric arteries. They give off large branches, which ramify between and supply the muscular coats, and after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The rectum is supplied by the superior hemorrhoidal branch of the inferior mesenteric, and the anal canal by the middle hemorrhoidal from the hypogastric, and the inferior hemorrhoidal from the internal pudendal artery. The superior hemorrhoidal, the continuation of the superior mesenteric, divides into two branches, which run down either side of the rectum to within about 12.5 cm. of the anus; they here split up into about six branches, which pierce the muscular coat and descend between it and the mucous membrane in a longi-

tudinal direction, parallel with each other as far as the Sphincter ani internus, where they anastomose with the other hemorrhoidal arteries and form a series of loops around the anus. The veins of the rectum commence in a plexus of vessels which surrounds the anal canal. In the vessels forming this plexus are smaller saccular dilatations just within the margin of the anus; from the plexus about six vessels of considerable size are given off. These ascend between the muscular and mucous coats for about 12.5 cm., running parallel to each other; they then pierce the muscular coat, and, by their union, form a single trunk, the superior hemorrhoidal vein. This arrangement is termed the **hemorrhoidal plexus**; it communicates with the tributaries of the middle and inferior hemorrhoidal veins, at its commencement, and thus a communication is established between the systemic and portal circulations. The **lymphatics** of the large intestine are described on page 792. The **nerves** are derived from the sympathetic plexuses around the branches of the superior and inferior mesenteric arteries. They are distributed in a similar way to those found in the small intestine.

Applied Anatomy.—The small intestine is much exposed to injury, but, in consequence of elasticity and the ease with which one coil glides over another, it is not so frequently ruptured as would otherwise be the case. Any part of it may be ruptured, but probably the most common situation is the horizontal portion of the duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the intestine is struck by a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and so lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under, it is said, 6 mm. in length, no extravasation of the contents of the bowel takes place; the mucous membrane becomes everted and plugs the little opening. The small intestine, and most frequently the ileum, may become strangulated by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or an adherent omentum from the same cause; or the band may be formed by Meckel's diverticulum, which has contracted adhesions at its distal extremity; or it may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicae, or an adherent vermiform process or uterine tube. Intussusception, most commonly an invagination of the small intestine into the large, may take place; it may attain great size, and it is not uncommon in these cases to find the colic valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (*volvulus*) may also lead to intestinal obstruction.

Resection of a portion of the intestine may be required in cases of gangrene; for the removal of new growth in the bowel; in dealing with artificial anus; and in cases of rupture. The operation is termed *enterectomy*, and is performed as follows: the abdomen having been opened and the amount of bowel requiring removal having been determined upon, the intestine must be clamped on either side of this portion in order to prevent the escape of any of its contents during the operation: The portion of the bowel is then separated above and below by means of scissors. If the portion resected is small, it may be simply removed from the mesentery at its attachment, and the bleeding vessels tied; but if it be large it will be necessary to take away a triangular piece of the mesentery, and, having secured the vessels, suture the cut edges of this structure together. In doing this, care must be taken not to leave any intestine projecting beyond the line of the section of mesentery, as gangrene is very likely to occur in the projecting part if this is done. The surgeon then proceeds to unite the cut ends of the bowel together by what is termed end-to-end anastomosis. There are many ways of doing this, which may be divided into two classes, one where the anastomosis is made by means of some mechanical appliance, such as Murphy's button, or one of the forms of decalcified bone bobbin; and the other, where the operation is performed by suturing the ends of the bowel in such a manner that the peritoneum covering the two divided ends is brought into contact, so that speedy union may ensue.

The vermiform process is very liable to become inflamed, because it contains a relatively large amount of lymphoid tissue, which is prone to bacterial infection. In many cases the inflammation is set up by the impaction in it of a solid mass of feces or a foreign body, or by the inspissation of its mucous secretion in catarrhal conditions. The inflammation may result in ulceration and perforation, or if very acute in gangrene of the process. These conditions generally require immediate operative interference, and in chronic cases with recurring attacks of inflammation it is always advisable to remove this diverticulum of the bowel. In incising the abdominal wall for this operation, the muscles should be split in the direction of their fibres rather than cut across in order to prevent subsequent weakening of the abdominal parietes and the occurrence of a ventral hernia. After the process has been removed it is better to suture the planes of the abdominal wall separately.

In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved it is usually the cecum, and this may occur even on the left side. In some few cases the vermiform process has been the part implicated in strangulated hernia.

Chronic ulcer of the duodenum is sometimes met with, probably produced by the same causes as chronic ulcer of the stomach. It may perforate and set up a rapidly fatal peritonitis, or it

may open into one of the large duodenal vessels and cause death from hemorrhage. An acute ulcer sometimes, but rarely, follows extensive burns of the skin.

The calibre of the large intestine gradually diminishes from the cecum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid colon with the rectum. At or a little below this point stricture most commonly occurs, and diminishes in frequency as one proceeds upward to the cecum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the right and left colic flexures, which are more deeply placed; the distension is most obvious in the flanks and on the front of the abdomen just above the umbilicus. The cecum, however, is the portion of the bowel which becomes most distended. It may assume enormous dimensions, and has been known to give way from the distension, causing fatal peritonitis. The right colic flexure and the right extremity of the transverse colon are in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the colon, and gallstones may find their way into the latter and may become impacted or may be discharged per anum. The mobility of the sigmoid colon renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the mesocolon is elongated. The gut at this part, being loaded with feces, falls over the part below, and so gives rise to the twist.

Hernia.—The two chief sites at which external hernia may take place are the inguinal region and the femoral canal. The description of the inguinal canal and its relations will be found on page 508, and that of the femoral canal on page 712. Some points in regard to the disposition of the peritoneum in these regions may, however, be recapitulated here. P. 1182

Between the upper margin of the front of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into five folds, with intervening depressions, by more or less prominent bands which converge to the umbilicus (Fig. 962). The middle umbilical ligament, situated in the middle line, is covered by a fold of peritoneum known as the **middle umbilical fold**. On either side of this a fold of peritoneum around the obliterated umbilical artery forms the **lateral umbilical fold**. To either side of these three cords is the inferior epigastric artery covered by the **epigastric fold**. Between these raised folds are depressions constituting the so-called **foveæ**. The most medial, between the middle and lateral umbilical folds, is known as the **supravesical fovea**. The intermediate one is situated medial to the plica epigastrica, and is termed the **medial inguinal fovea**. The third is lateral to the plica epigastrica, and is known as the **lateral inguinal fovea**. Occasionally the inferior epigastric artery corresponds in position to the obliterated hypogastric artery, and then there is but one fold on each side of the middle line. In the usual position of the parts, the floor of the lateral inguinal fovea corresponds to the abdominal inguinal ring, and into this fovea an oblique inguinal hernia descends. Medial to the epigastric fold are the medial inguinal and the supravesical foveæ, and through either of these a direct hernia may descend. The whole of the space between the inferior epigastric artery, the margin of the Rectus abdominis, and the inguinal ligament is known as **Hesselbach's triangle**. Below the level of the inguinal ligament is a small depression corresponding to the position of the femoral ring. It is known as the **femoral fovea**, and into it a femoral hernia descends.

Inguinal Hernia.—Inguinal hernia is that form of protrusion which makes its way through the abdominal wall in the inguinal region. There are two principal varieties of it: lateral or oblique, and medial or direct.

In **oblique inguinal hernia** the intestine escapes from the abdominal cavity at the abdominal inguinal ring, pushing before it a pouch of peritoneum which forms the hernial sac. As it enters the inguinal canal it receives an investment from the extraperitoneal tissue and is enclosed in the infundibuliform fascia. In passing along the inguinal canal it displaces upward the arched fibres of the Transversus and Obliquus internus, and receives a covering of Cremaster muscle and cremasteric fascia. It then passes along the front of the spermatic cord and escapes from the inguinal canal at the subcutaneous inguinal ring, becoming invested by intercrural fascia. Lastly it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

The seat of stricture in oblique inguinal hernia is at either the abdominal or the subcutaneous inguinal ring; most frequently in the latter situation. If it is situated at the subcutaneous ring, the division of a few fibres at one point of the circumference is all that is necessary for the replacement of the hernia. If at the abdominal ring, it is necessary to divide the aponeurosis of the Obliquus externus so as to lay open the inguinal canal, in dividing the aponeurosis the incision should be directed parallel to the inguinal ligament, and the constriction at the abdominal ring should then be divided directly upward.

When the intestine passes along the inguinal canal and escapes from the subcutaneous ring into the scrotum, it is called **complete oblique inguinal** or **scrotal hernia**. If the intestine does not escape from the subcutaneous ring, but is retained in the inguinal canal, it is called **incomplete inguinal hernia** or **bubonocoele**. In each of these cases the coverings which invest it will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia (Fig. 999) depending upon congenital defects in the saccus vaginalis, the pouch of peritoneum which precedes the descent of the testis. Normally this pouch is closed before birth, closure commencing at two points, viz., at the abdominal inguinal ring and at the top of the epididymis, and gradually extending until the whole of the intervening portion is converted into a fibrous cord.

FIG. 999.—Varieties of oblique inguinal hernia.

From failure in the completion of this process, variations in the relation of the hernial protrusion to the testis and tunica vaginalis are produced; these constitute distinct varieties of inguinal hernia, viz., the hernia of the funicular process and the complete congenital variety.

Where the saccus vaginalis remains patent throughout, the cavity of the tunica vaginalis communicates directly with that of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis which constitutes the sac of the hernia, and the gut lies in contact with the testis. Though this form of hernia is termed *complete congenital*, the term does not imply that the hernia existed at birth, but merely that a condition is present which may allow of the descent of the hernia at any moment. As a matter of fact, congenital herniæ frequently do not appear until adult life.

Where the processus vaginalis is occluded at the lower point only, i. e., just above the testis, the intestine descends into the pouch of peritoneum as far as the testis, but is prevented

from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch. This is known as *hernia into the funicular process* or *incomplete congenital hernia*; it differs from the former in that instead of enveloping the testis it lies above it.

In *direct inguinal hernia* the protrusion makes its way through some part of Hesselbach's triangle, either through (a) the lateral part, where only extraperitoneal tissue and transversalis fascia intervene between the peritoneum and the aponeurosis of the Obliquus externus; or through (b) the inguinal aponeurotic falx which stretches across the medial two-thirds of the triangle between the artery and the middle line. In the former the hernial protrusion escapes from the abdomen on the lateral side of the inguinal falx, pushes before it the peritoneum, extraperitoneal tissue, and transversalis fascia, and enters the inguinal canal. It passes along nearly the whole length of the canal and finally emerges from the subcutaneous ring, receiving an investment from the intercrural fascia. The coverings of this form of hernia are similar to those of the oblique form, except that a portion derived from the general layer of transversalis fascia replaces the infundibuliform fascia.

In the second form, which is the more frequent, the hernia is either forced through the fibres of the inguinal falx, or the falx is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the subcutaneous ring, lying on the medial side of the cord, and receives additional coverings from the intercrural fascia, the superficial fascia and the integument. The coverings of this form therefore differ from those of the oblique form in that the inguinal falx is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion of the general layer of the transversalis fascia.

The seat of stricture in both varieties of direct hernia is usually found either at the neck of the sac or at the subcutaneous ring. In that form which perforates the inguinal falx it not infrequently occurs at the edges of the fissure through which the gut passes. In all cases of inguinal hernia, whether direct or oblique, it is proper to divide the stricture directly upward; by cutting in this direction the incision is made parallel to the inferior epigastric artery—lateral to it in the oblique variety, medial to it in the direct form of hernia; all chance of wounding the vessel is thus avoided. Direct inguinal hernia is of much less frequent occurrence than oblique, and is found more often in men than in women. The main differences in position between it and the oblique form are: (a) it is placed over the pubis and not in the course of the inguinal canal; (b) the inferior epigastric artery runs on the lateral or iliac side of the neck of the sac; and (c) the spermatic cord lies along its lateral and posterior sides, not directly behind it as in oblique inguinal hernia.

Femoral Hernia.—In femoral hernia the protrusion of the intestine takes place through the femoral ring. As already described (page 712), this ring is closed by the femoral septum, a partition of modified extraperitoneal tissue; it is therefore a weak spot in the abdominal wall, and especially in the female, where the ring is larger and where profound changes are produced in the tissues of the abdomen by pregnancy. Femoral hernia is therefore more common in women than in men.

When a portion of intestine is forced through the femoral ring, it carries before it a pouch of peritoneum, which forms the hernial sac. It receives an investment from the extraperitoneal tissue or femoral septum, and descends along the femoral canal, or inner compartment of the sheath of the femoral vessels, as far as the fossa ovalis; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the latter, and its close contact with the vessels, and also the close attachment of the superficial fascia and femoral sheath to the lower part of the circumference of the fossa ovalis. The tumor is consequently directed forward, pushing before it the fascia cribrosa, and then curves upward over the inguinal ligament and the lower part of the aponeurosis of the *Obliquus externus*, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts, but when it escapes from the fossa ovalis into the loose areolar tissue of the groin it becomes considerably enlarged. The direction taken by a femoral hernia is at first downward, then forward and upward; in the application of taxis for the reduction of a femoral hernia therefore, pressure should be directed in the reverse order.

The coverings of a femoral hernia from within outward are: peritoneum, femoral septum, femoral sheath, fascia cribrosa, superficial fascia, and integument. Sir Astley Cooper has described an investment for femoral hernia under the name of *fascia propria*, lying immediately external to the peritoneal sac but frequently separated from it by some adipose tissue. Surgically it is important to remember the frequent existence of this layer on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum, as there is often a great excess of subperitoneal fatty tissue enclosed in the "*fascia propria*." In many cases it resembles a fatty tumor, but on further dissection the true hernial sac will be found in the centre of the mass of fat. The *fascia propria* is merely modified extraperitoneal tissue which has been thickened to form a membranous sheet by the pressure of the hernia.

When the intestine descends along the femoral canal only as far as the fossa ovalis the condition is known as *incomplete femoral hernia*. The small size of the protrusion in this form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia would be from without inward: integument, superficial fascia, superior cornu of falciform margin of the fossa ovalis, femoral sheath, femoral septum, and peritoneum.

The seat of stricture of a femoral hernia varies: it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it is at the point of junction of the falciform margin of the fossa ovalis with the free edge of the lacunar ligament; or it may be at the margin of the fossa ovalis. The stricture should in every case be divided in a direction upward and medialward for a distance of about 4 to 6 mm. All vessels or other structures of importance in relation to the neck of the sac will thus be avoided.

The pubic tubercle forms an important landmark in serving to differentiate the inguinal from the femoral variety of hernia. The inguinal protrusion is above and medial to the tubercle, while the femoral is below and lateral to it.

There are several details of practical interest in connection with the mesentery which merit notice. (1) The depth of the mesentery—that is to say, the distance from its parietal to its intestinal attachment—is normally less than 20 cm., generally nearer 15 cm.; but under certain abnormal conditions it may become elongated, and this would appear to favor the occurrence of hernia of the intestine. (2) Not only may the depth of the mesentery be increased, but its point of attachment to the posterior abdominal wall may yield, and descend over the lumbar vertebrae. This condition, which is known under the name of *enteroptosis*, usually occurs in women who have borne many children, and is attended with general relaxation of the abdominal parietes. It produces a characteristic appearance, the abdomen being prominent and pendulous below, while above, it is flattened and constricted. (3) Holes are sometimes present in the mesentery, and these may be congenital, or may be the result of injury. They are of practical importance, since a knuckle of intestine may become herniated into one of them, causing acute strangulation. (4) The lymph glands contained between the two layers of the mesentery are frequently the seat of tuberculous deposit, especially in children.

The colon frequently requires opening in cases of intestinal obstruction, and by some surgeons this operation is performed in cases of cancer of the rectum as soon as the disease is recognized, in the hope that the symptoms may be relieved by removing the irritation produced by the passage of fecal matter over the diseased surface. The operation of colostomy may be performed

either in the iliac or lumbar region; but iliac colostomy has in the present day entirely superseded the lumbar operation. The main reason for preferring this operation is that a spur-shaped process of the mesocolon can be formed, which prevents any fecal matter finding its way past the artificial anus, and the greater ease in maintaining cleanliness. The sigmoid colon being entirely surrounded by peritoneum, a coil can be drawn out of the wound and opened, leaving the attachment of the mesocolon to form a spur, much as it does in an artificial anus caused by sloughing of the intestine after a strangulated hernia, and this prevents any fecal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision 5 to 7 cm. long from a point 2.5 cm. medial to the anterior superior iliac spine, parallel to the inguinal ligament. The various muscular layers are cut through, and the peritoneum opened; the sigmoid colon is now sought for, pulled out of the wound, and fixed by passing a needle threaded with carbolized silk first through the mesocolon close to the gut, and then through the abdominal wall. The wound is dressed, and about the second day the protruding coil of intestine is opened.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformations due to arrest of, or imperfection in, development. Thus, there may be no proctodæal invagination (see page 174), and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the ectodermal invagination may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fetal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath, and thus favors prolapse, especially in children. The vessels of the rectum are arranged, as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favors varicosity. Moreover, the veins, after running upward in a longitudinal direction for about 12.5 cm. in the submucous tissue, pierce the muscular coats, and are liable to become constricted at this spot by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hemorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened feces. The anatomical arrangement, therefore, of the hemorrhoidal vessels explains the great tendency to the occurrence of piles. The presence of the Sphincter ani externus is of surgical importance, since it is the constant contraction of this muscle which prevents an ischiorectal abscess from healing, and causes it to become a fistula. Also the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the bowel are of importance in connection with the operation of removal of the rectum for malignant disease. This membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface, to become reflected, in the male on to the posterior wall of the bladder, forming the rectovesical excavation, and in the female on to the posterior wall of the vagina, forming the rectouterine excavation. The rectovesical excavation extends to within 7.5 cm. from the anus. Within recent years much more extensive operations have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily been opened. If, in these cases, the opening is plugged with antiseptic gauze until the operation is completed and then the edges of the wound in the peritoneum are accurately brought together with sutures, no evil result appears to follow. For cases of cancer of the rectum which are too low to be reached by abdominal section, and too high to be removed by the perineum, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the last piece of the sacrum to the anus. The soft parts are now separated from the back of the sides of the sacrum and coccyx, and the sacrotuberous and sacrospinous ligaments are separated. The coccyx is removed, and if necessary a small piece of the sacrum, and the edges of the wound being now forcibly drawn outward, a considerable length of the rectum is brought into view, and the diseased portion can be removed, leaving the anal portion of the gut, if healthy. The two divided ends of the gut can sometimes be approximated and sutured together, the posterior part being left open for drainage.

The loose connective tissue around the rectum is occasionally the site of an abscess, the active focus of which, however, may be located elsewhere. This form of abscess may be described as the *superior pelvic rectal*; it is placed above the pelvic diaphragm but beneath the peritoneum. The acute variety is generally due to ulceration or perforation of the bowel (possibly produced by a foreign body) above the level of attachment of the Levator ani. The abscess may also occur above a stricture (simple or malignant) of the rectum; occasionally it arises from suppuration around the prostate, and more rarely follows abscess of the vesiculæ seminales. Chronic abscesses also appear in the same region either from caries of the anterior surface of the sacrum or from caseation of the presacral lymph glands, while in other cases an abscess finds its way down into the pelvis from disease of the anterior surfaces of the bodies of the lumbar vertebrae.

The Liver (Hepar).

The liver is the largest gland in the body, and is situated in the upper and right parts of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and not uncommonly extending into the left hypochondrium as far as the mammary line. In the male it weighs from 1.4 to 1.6 kilogram., in the female from 1.2 to 1.4 kilogram. It is relatively much larger in the fetus than in the adult, constituting, in the former, about one-eighteenth, and in the latter about one thirty-sixth of the entire body weight. Its greatest transverse measurement is from 20 to 22.5 cm. Vertically, near its lateral or right surface, it measures about 15 to 17.5 cm., while its greatest antero-posterior diameter is on a level with the upper end of the right kidney, and is from 10 to 12.5 cm. Opposite the vertebral column its measurement from before backward is reduced to about 7.5 cm. Its consistence is that of a soft solid; it is, however, friable and easily lacerated; its color is a dark reddish brown, and its specific gravity is 1.05.

To obtain a correct idea of its shape it must be hardened *in situ*, and it will then be seen to present the appearance of a wedge, the base of which is directed to the right and the thin edge toward the left. Symington describes its shape as that "of a right-angled triangular prism with the right angle rounded off."

Surfaces.—The liver possesses five surfaces, viz., **superior, inferior, anterior, posterior, and right lateral**. A sharp, well-defined margin divides the inferior from the superior, anterior, and right lateral surfaces, but the other surfaces are separated from one another by rounded borders. The superior and anterior surfaces are attached to the Diaphragma and anterior abdominal wall by a triangular or falciform fold of peritoneum, the **falciform ligament**, in the free margin of which is a rounded cord, the **ligamentum teres** (*obliterated umbilical vein*). The line of attachment of the falciform ligament divides the liver into two parts, termed the **right and left lobes**, the right being much the larger. The inferior and posterior surfaces are divided into five lobes by five fossæ, which are arranged in the form of the letter H. The left limb of the H marks on these surfaces the division of the liver into right and left lobes; it is known as the **left sagittal fossa**, and consists of two parts, viz., the **fossa for the umbilical vein** in front and the **fossa for the ductus venosus** behind. The right limb of the H is formed in front by the **fossa for the gall-bladder**, and behind by the **fossa for the inferior vena cava**; these two fossæ are separated from one another by a band of liver substance, termed the **caudate process**. The bar connecting the two limbs of the H is the **porta** (*transverse fissure*); in front of it is the **quadrate lobe**, behind it the **caudate lobe**.

The **superior surface** (*facies superior*) (Fig. 1000) comprises a part of both lobes, and, as a whole, is convex, and fits under the vault of the Diaphragma; its central part, however, presents a shallow depression, which corresponds with the position of the pericardium on the upper surface of the Diaphragma. It is separated from the anterior, posterior, and right lateral surfaces by rounded borders. Its left extremity is separated from the under surface by a prominent sharp margin. Except along the lines of attachment of the falciform ligament it is completely covered by peritoneum.

The **anterior surface** is large, triangular in shape, and also comprises a part of both lobes. It is directed forward, and the greater part of it is in contact with the Diaphragma, which separates it on the right from the sixth to the tenth ribs and their cartilages, and on the left from the seventh and eighth costal cartilages. Its middle part lies behind the xiphoid process, and, in the angle between the diverging rib cartilage of opposite sides, is in contact with the abdominal wall. It is separated from the inferior surface by a sharp margin, and from the superior and right lateral surfaces by rounded borders. It is completely covered by peritoneum except along the line of attachment of the falciform ligament.

The **right lateral surface** is covered by peritoneum, and is convex from before backward and slightly so from above downward. It is directed toward the right side, forming the base of the wedge, and lies against the lateral portion of the Diaphragma, which separates it from the lower part of the pleura and lung, outside which are the right costal arches from the seventh to the eleventh inclusive.

Gall-bladder

Left triangular ligament

ligament

FIG. 1000.—The superior, anterior, and right lateral surfaces of the liver (From model by His.)

The **inferior surface** (*facies inferior; visceral surface*) (Figs. 1001 1002) is uneven, concave, directed downward, backward, and to the left, and is in relation with the stomach and duodenum, the right colic flexure, and the right kidney and suprarenal gland. The surface is almost completely invested by peritoneum; the only parts devoid of this covering are where the gall-bladder is attached to the liver, and at the porta hepatis where the two layers of the lesser omentum are separated from each other by the bloodvessels and ducts of the liver. The inferior surface of the left lobe presents behind and to the left the **gastric impression**, moulded over the antero-superior surface of the stomach, and to the right of this a rounded eminence, the **tuber omentale**, which fits into the concavity of the lesser curvature of the stomach and lies in front of the anterior layer of the lesser omentum. The under surface of the right lobe is divided into two unequal portions by the fossa for the gall-bladder; the portion to the left, the smaller of the two, is the **quadrate lobe**, and is in relation with the pyloric end of the stomach, the superior portion of the duodenum, and the transverse colon. The portion of the under surface of the right lobe to the right of the fossa for the gall-bladder presents two impressions, one situated behind the other, and separated by a ridge. The anterior of these two impressions, the **colic impression**, is shallow and is produced by the right colic flexure; the posterior, the **renal impression**, is deeper and is occupied by the upper part of the right kidney and lower part of the right suprarenal gland. Medial to the renal impression is a third and slightly marked impression, lying between it and the neck of the gall-bladder. This is caused by the descending portion of the duodenum, and is known as the **duodenal impression**. Just in front of the inferior vena cava is a narrow strip of liver tissue, the **caudate process**, which connects the right inferior angle of the caudate lobe to the under surface of the right lobe. It forms the upper boundary of the epiploic foramen of the peritoneum.

The **posterior surface** (*facies posterior*) (Fig. 1002) is rounded and broad behind the right lobe, but narrow on the left. Over a large part of its extent it is not covered by peritoneum; this uncovered portion is about 7.5 cm. broad at its widest

part, and is in direct contact with the Diaphragma. It is marked off from the upper surface by the line of reflection of the upper layer of the coronary ligament, and from the under surface by the line of reflection of the lower layer of the coronary

ligament. The central part of the posterior surface presents a deep concavity which is moulded on the vertebral column and crura of the Diaphragma. To the right of this the inferior vena cava is lodged in its fossa between the uncovered

area and the caudate lobe. Close to the right of this fossa and immediately above the renal impression is a small triangular depressed area, the **suprarenal impression**, the greater part of which is devoid of peritoneum; it lodges the right suprarenal gland. To the left of the inferior vena cava is the **caudate lobe**, which lies between the fossa for the vena cava and the fossa for the ductus venosus. Its lower end projects and forms part of the posterior boundary of the porta; on the right, it is connected with the under surface of the right lobe of the liver by the **caudate process**, and on the left it presents an elevation, the **papillary process**. Its posterior surface rests upon the Diaphragma, being separated from it merely by the upper part of the omental bursa. To the left of the fossa for the ductus venosus is a groove in which lies the antrum cardiacum of the oesophagus.

The **anterior border** (*margo anterior*) is thin and sharp, and marked opposite the attachment of the falciform ligament by a deep notch, the **umbilical notch**, and opposite the cartilage of the ninth rib by a second notch for the fundus of the gall-bladder. In adult males this border generally corresponds with the lower margin of the thorax in the right mammary line; but in women and children it usually projects below the ribs.

The **left extremity of the liver** is thin and flattened from above downward.

Fossæ.—The **left sagittal fossa** (*fossa sagittalis sinistra; longitudinal fissure*) is a deep groove, which extends from the notch on the anterior margin of the liver to the upper border of the posterior surface of the organ; it separates the right and left lobes. The porta joins it, at right angles, and divides it into two parts. The anterior part, or **fossa for the umbilical vein**, lodges the umbilical vein in the fetus, and its remains (the ligamentum teres) in the adult; it lies between the quadrate lobe and the left lobe of the liver, and is often partially bridged over by a prolongation of the hepatic substance, the **pons hepatis**. The posterior part, or **fossa for the ductus venosus**, lies between the left lobe and the caudate lobe; it lodges in the fetus, the ductus venosus, and in the adult a slender fibrous cord, the **ligamentum venosum**, the obliterated remains of that vessel.

The **porta or transverse fissure** (*porta hepatis*) is a short but deep fissure, about 5 cm. long, extending transversely across the under surface of the left portion of the right lobe, nearer its posterior surface than its anterior border. It joins nearly at right angles with the left sagittal fossa, and separates the quadrate lobe in front from the caudate lobe and process behind. It transmits the portal vein, the hepatic artery and nerves, and the hepatic duct and lymphatics. The hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

The **fossa for the gall-bladder** (*fossa vesicae felleae*) is a shallow, oblong fossa, placed on the under surface of the right lobe, parallel with the left sagittal fossa. It extends from the anterior free margin of the liver, which is notched by it, to the right extremity of the porta.

The **fossa for the inferior vena cava** (*fossa venae cavae*) is a short deep depression, occasionally a complete canal in consequence of the substance of the liver surrounding the vena cava. It extends obliquely upward on the posterior surface between the caudate lobe and the bare area of the liver, and is separated from the porta by the caudate process. On slitting open the inferior vena cava the orifices of the hepatic veins will be seen opening into this vessel at its upper part, after perforating the floor of this fossa.

Lobes.—The **right lobe** (*lobus hepatis dexter*) is much larger than the left; the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe on its upper and anterior surfaces by the falciform ligament; on its under and posterior surfaces by the left sagittal fossa; and in front by the umbilical notch. It is of a somewhat quadrilateral form, its under and posterior surfaces being marked by three fossæ: the porta and the

fossæ for the gall-bladder and inferior vena cava, which separate its left part into two smaller lobes; the **quadrate** and **caudate lobes**. The impressions on the right lobe have already been described.

The **quadrate lobe** (*lobus quadratus*) is situated on the under surface of the right lobe, bounded in front by the anterior margin of the liver; behind by the porta; on the right, by the fossa for the gall-bladder; and on the left, by the fossa for the umbilical vein. It is oblong in shape, its antero-posterior diameter being greater than its transverse.

The **caudate lobe** (*lobus caudatus*; *Spigelian lobe*) is situated upon the posterior surface of the right lobe of the liver, opposite the tenth and eleventh thoracic vertebræ. It is bounded, below, by the porta; on the right, by the fossa for the inferior vena cava; and, on the left, by the fossa for the ductus venosus. It looks backward, being nearly vertical in position; it is longer from above downward than from side to side, and is somewhat concave in the transverse direction. The **caudate process** is a small elevation of the hepatic substance extending obliquely lateralward, from the lower extremity of the caudate lobe to the under surface of the right lobe. It is situated behind the porta, and separates the fossa for the gall-bladder from the commencement of the fossa for the inferior vena cava.

The **left lobe** (*lobus hepatis sinister*) is smaller and more flattened than the right. It is situated in the epigastric and left hypochondriac regions. Its upper surface is slightly convex and is moulded on to the Diaphragma; its under surface presents the cardiac impression and omental tuberosity, already referred to page 1192.

Ligaments.—The liver is connected to the under surface of the Diaphragma and to the anterior wall of the abdomen by five ligaments; four of these—the **falciform**, the **coronary**, and the two **lateral**—are peritoneal folds; the fifth, the **round ligament**, is a fibrous cord, the obliterated umbilical vein. The liver is also attached to the lesser curvature of the stomach by the hepatogastric and to the duodenum by the hepatoduodenal ligament (see page 1156).

The **falciform ligament** (*ligamentum falciforme hepatis*) is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed downward and backward, its apex upward and backward. It is situated in an antero-posterior plane, but lies obliquely so that one surface faces forward and is in contact with the peritoneum behind the right Rectus and the Diaphragma, while the other is directed backward and is in contact with the left lobe of the liver. It is attached by its left margin to the under surface of the Diaphragma, and the posterior surface of the sheath of the right Rectus as low down as the umbilicus; by its right margin it extends from the notch on the anterior margin of the liver, as far back as the posterior surface. It is composed of two layers of peritoneum closely united together. Its base or free edge contains between its layers the round ligament and the parumbilical veins.

The **coronary ligament** (*ligamentum coronarium hepatis*) consists of an upper and a lower layer. The **upper layer** is formed by the reflection of the peritoneum from the upper margin of the bare area of the liver to the under surface of the Diaphragma, and is continuous with the right layer of the falciform ligament. The **lower layer** is reflected from the lower margin of the bare area on to the right kidney and suprarenal gland, and is termed the **hepatorenal ligament**.

The **triangular ligaments** (*lateral ligaments*) are two in number, right and left. The **right triangular ligament** (*ligamentum triangulare dextrum*) is situated at the right extremity of the bare area, and is a small fold which passes to the Diaphragma, being formed by the apposition of the upper and lower layers of the coronary ligament. The **left triangular ligament** (*ligamentum triangulare sinistrum*) is a fold of some considerable size, which connects the posterior part of the upper surface of the left lobe to the Diaphragma; its anterior layer is continuous with the left layer of the falciform ligament.

The **round ligament** (*ligamentum teres hepatis*) is a fibrous cord resulting from the obliteration of the umbilical vein. It ascends from the umbilicus, in the free margin of the falciform ligament, to the umbilical notch of the liver, from which it may be traced in its proper fossa on the inferior surface of the liver to the porta, where it becomes continuous with the *ligamentum venosum*.

(After Kiernan.)

FIG. 1004.—Longitudinal section of a small portal vein
and canal. (After Kiernan.)

Vessels and Nerves.—The vessels connected with the liver are: the **hepatic artery**, the **portal vein**, and the **hepatic veins**.

The **hepatic artery** and **portal vein**, accompanied by numerous nerves, ascend to the porta, between the layers of the lesser omentum. The *bile duct* and the lymphatic vessels descend from the porta between the layers of the same omentum. The relative positions of the three structures are as follows: the bile duct lies to the right, the hepatic artery to the left, and the

lobular vein

Intralobular vein

FIG. 1005.—Section of injected liver (dog)

portal vein behind and between the other two. They are enveloped in a loose areolar tissue, the **fibrous capsule of Glisson**, which accompanies the vessels in their course through the portal canals in the interior of the organ (Fig. 1004).

The **hepatic veins** (Fig. 1003) convey the blood from the liver, and are described on page 764. They have very little cellular investment, and what there is binds their parietes closely to the

walls of the canals through which they run; so that, on section of the organ, they remain widely open and are solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed, and always accompanied by an artery and duct.

The **lymphatic vessels** of the liver are described on page 792.

The **nerves** of the liver, derived from the left vagus and sympathetic, enter at the porta and accompany the vessels and ducts to the interlobular spaces. Here, according to Korolkow, the medullated fibres are distributed almost exclusively to the coats of the bloodvessels; while the non-medullated enter the lobules and ramify between the cells.

Structure of the Liver.—The substance of the liver is composed of lobules, held together by an extremely fine areolar tissue, in which ramify the portal vein, hepatic ducts, hepatic artery, hepatic veins, lymphatics, and nerves; the whole being invested by a serous and a fibrous coat.

The **serous coat** (*tunica serosa*) is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

The **fibrous coat** (*capsula fibrosa* [Glisson]; *areolar coat*) lies beneath the serous investment, and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the porta it is continuous with the fibrous capsule of Glisson, and on the surface of the organ with the areolar tissue separating the lobules.

The **lobules** (*lobuli hepatis*) form the chief mass of the hepatic substance; they may be seen either on the surface of the organ, or by making a section through the gland, as small granular bodies, about the size of a millet-seed, measuring from 1 to 2.5 mm. in diameter. In the human subject their outlines are very irregular; but in some of the lower animals (for example, the pig) they are well-defined, and, when divided transversely, have polygonal outlines. The bases of the lobules are clustered around the smallest radicles (*sublobular*) of the hepatic veins, to which each is connected (Fig. 1003) by means of a small branch which issues from the centre of the lobule (*intra-lobular*). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of areolar tissue, in which is contained a plexus of vessels, the **interlobular plexus**, and ducts. In some animals, as the pig, the lobules are completely isolated from one another by the interlobular areolar tissue (Fig. 1006).

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in a form resembling a tessellated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intra-lobular vein (Fig. 1003).

Microscopic Appearance (Fig. 1006).—Each lobule consists of a mass of cells, **hepatic cells**, arranged in irregular radiating columns between which are the blood channels (*sinusoids*). These convey the blood from the circumference to the centre of the lobule, and end in the **intra-lobular vein**, which runs through its centre, to open at its base into one of the **sublobular veins**. Between the cells are also the minute bile capillaries. Therefore, in the lobule there are all the essentials of a secreting gland; that is to say: (1) **cells**, by which the secretion is formed; (2) **blood-vessels**, in close relation with the cells, containing the blood from which the secretion is derived; (3) **ducts**, by which the secretion, when formed, is carried away.

1. The **hepatic cells** are polyhedral in form. They vary in size from 12 to 25 μ in diameter. They contain one or sometimes two distinct nuclei. The nucleus exhibits an intranuclear net-work and one or two refractile nucleoli. The cells usually contain granules; some of which are protoplasmic, while others consist of glycogen, fat, or an iron compound. In the lower vertebrates, *e. g.*, frog, the cells are arranged in tubes with the bile duct forming the lumen and bloodvessels externally. According to Delépine, evidences of this arrangement can be found in the human liver.

2. The **Bloodvessels**.—The blood in the capillary plexus around the liver cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery.

The **hepatic artery**, entering the liver at the porta with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off **vaginal branches**, which ramify

Sinus

Intra-lobular vein

Sublobular

FIG. 1006.—A single lobule of the liver of a pig. $\times 60$.

in the fibrous capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the vessels and ducts. It also gives off **capsular branches**, which reach the surface of the organ, ending in its fibrous coat in stellate plexuses. Finally, it gives off **interlobular branches**, which form a plexus outside each lobule, to supply the walls of the interlobular veins and the accompanying bile ducts. From this plexus lobular branches enter the lobule and end in the net-work of sinusoids between the cells.

The **portal vein** also enters at the porta, and runs through the portal canals (Fig. 1007), enclosed in Glisson's capsule, dividing in its course into branches, which finally break up into a plexus, the **interlobular plexus**, in the interlobular spaces. These branches receive the vaginal

Bile duct

Hepatic artery

Lymphatic vessel

Portal vein

and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery. Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic artery finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which converge from the circumference to the

FIG. 1007.—Section across portal canal of pig $\times 250$.

FIG. 1008.—Bile capillaries of rabbit, shown by Golgi's method. $\times 450$.

centre of the lobule, and are connected by transverse branches (Fig. 1005). The walls of these small vessels are incomplete so that the blood is brought into direct relationship with the liver cells. The lining endothelium consists of irregularly branched, disconnected cells (*stellate cells of Kupffer*). Moreover, according to Herring and Simpson, minute channels penetrate the liver cells themselves, conveying the constituents of the blood into their substance. It will be seen that the blood capillaries of the liver lobule differ structurally from capillaries elsewhere. Developmentally they are formed by the growth of the columns of liver cells into large blood spaces or sinuses, and hence they have received the name of "sinusoids." Arrived at the centre of the lobule, the sinusoids empty themselves into one vein, of considerable size, which runs down the centre of the lobule from apex to base, and is called the **intralobular vein**. At the base of the lobule this vein opens directly into the **sublobular vein**, with which the lobule is connected. The sublobular veins unite to form larger and larger trunks, and end at last in the hepatic veins, these converge to form three large trunks which open into the inferior vena cava while that vessel is situated in its fossa on the posterior surface of the liver.

3. The **bile ducts** commence by little passages in the liver cells which communicate with canaliculi termed **intercellular biliary passages** (*bile capillaries*). These passages are merely little channels or spaces left between the contiguous surfaces of two cells, or in the angle where three or more liver cells meet (Fig. 1008), and they are always separated from the blood capillaries by at least half the width of a liver cell. The channels thus formed radiate to the circumference of the lobule, and open into the interlobular bile ducts which run in Glisson's capsule, accompanying the portal vein and hepatic artery (Fig. 1007). These join with other ducts to form two main trunks, which leave the liver at the transverse fissure, and by their union form the **hepatic duct**.

Structure of the Ducts. The walls of the biliary ducts consist of a connective-tissue coat, in which are muscle cells, arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells resting on a distinct basement-membrane.

Excretory Apparatus of the Liver. The excretory apparatus of the liver consists of (1) the **hepatic duct**, formed by the junction of the two main ducts, which

pass out of the liver at the porta; (2) the **gall-bladder**, which serves as a reservoir for the bile; (3) the **cystic duct**, or the duct of the gall-bladder; and (4) the **common bile duct**, formed by the junction of the hepatic and cystic ducts.

The Hepatic Duct (*ductus hepaticus*).—Two main trunks of nearly equal size issue from the liver at the porta, one from the right, the other from the left lobe; these unite to form the hepatic duct, which passes downward and to the right for about 4 cm., between the layers of the lesser omentum, where it is joined at an acute angle by the cystic duct, and so forms the common bile duct. The hepatic duct is accompanied by the hepatic artery and portal vein.

The Gall-bladder (*vesica fellea*) (Fig. 1009).—The gall-bladder is a conical or pear-shaped musculomembranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and extending from near the right extremity of the porta to the anterior border of the organ. It is from 7 to 10 cm. in length, 2.5 cm. in breadth at its widest part, and holds from 30 to 35 c.c. It is divided into a fundus, body, and neck. The **fundus**, or broad extremity, is directed downward, forward, and to the right, and projects beyond the anterior border of the liver; the **body** and **neck** are directed upward and backward to the left. The upper surface of the gall-bladder is attached to the liver by connective tissue and vessels. The under surface is covered by peritoneum, which is reflected on to it from the surface of the liver. Occasionally the whole of the organ is invested by the serous membrane, and is then connected to the liver by a kind of mesentery.

Relations.—The **body** is in relation, by its upper surface, with the liver; by its under surface, with the commencement of the transverse colon; and farther back usually with the upper end of the descending portion of the duodenum, but sometimes with the superior portion of the duodenum or pyloric end of the stomach. The **fundus** is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind with the transverse colon. The **neck** is narrow, and curves upon itself like the letter S; at its point of connection with the cystic duct it presents a well-marked constriction.

Structure (Fig. 1010).—The gall-bladder consists of three coats: **serous**, **fibromuscular**, and **mucous**.

The **external** or **serous coat** (*tunica serosa vesicae felleae*) is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their under surfaces.

The **fibromuscular coat** (*tunica muscularis vesicae felleae*), a thin but strong layer forming the frame-work of the sac, consists of dense fibrous tissue, which interlaces in all directions, and is mixed with plain muscular fibres, disposed chiefly in a longitudinal direction, a few running transversely.

The **internal** or **mucous coat** (*tunica mucosa vesicae felleae*) is loosely connected with the fibrous layer. It is generally of a yellowish-brown color, and is elevated into minute rugae. Opposite the neck of the gall-bladder the mucous membrane projects inward in the form of oblique ridges or folds, forming a sort of spiral valve.

The mucous membrane is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the common bile duct with the mucous membrane of the duodenum. It is covered with columnar epithelium, and secretes mucin; in some animals it secretes a nucleoprotein instead of mucin.

FIG. 1009.—The gall-bladder and bile ducts laid open. (Spalteholz.)

The **Cystic Duct** (*ductus cysticus*).—The cystic duct about 4 cm. long, runs backward, downward, and to the left from the neck of the gall-bladder, and joins the hepatic duct to form the common bile duct. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely around the tube, presenting much the appearance of a continuous spiral valve. When the duct is distended, the spaces between the folds are dilated, so as to give to its exterior a twisted appearance.

Columnar epithelium

FIG. 1010.—Transverse section of gall-bladder.

The **Common Bile Duct** (*ductus choledochus*).—The common bile duct is formed by the junction of the cystic and hepatic ducts; it is about 7.5 cm. long, and of the diameter of a goose-quill.

It descends along the right border of the lesser omentum behind the superior portion of the duodenum, in front of the portal vein, and to the right of the hepatic artery; it then runs in a groove near the right border of the posterior surface of the head of the pancreas; here it is situated in front of the inferior vena cava, and is occasionally completely imbedded in the pancreatic substance. At its termination it lies for a short distance along the right side of the terminal part of the pancreatic duct and passes with it obliquely between the mucous and muscular coats. The two ducts unite and open by a common orifice upon the summit of the duodenal papilla, situated at the medial side of the descending portion of the duodenum, a little below its middle and about 7 to 10 cm. from the pylorus (Fig. 1015). The short tube formed by the union of the two ducts is dilated into an ampulla, the **ampulla of Vater**.

Structure.—The coats of the large biliary ducts are an **external** or **fibrous**, and an **internal** or **mucous**. The **fibrous coat** is composed of strong fibroareolar tissue, with a certain amount of muscular tissue, arranged, for the most part, in a circular manner around the duct. The **mucous coat** is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices scattered irregularly in the larger ducts.

Applied Anatomy.—On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the other abdominal viscera. The rupture may vary from a slight scratch to an extensive and complete laceration of its substance, dividing it into two parts. Sometimes an internal rupture, without laceration of the peritoneal covering, takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hemorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragma. It may be injured by stabs or

other punctured wounds, and when these are inflicted through the chest wall the pleural and peritoneal cavities may both be opened up, and both lung and liver wounded. In cases of wound of the liver from the front, hernia of a part of this viscus may take place, but generally can be easily replaced. In cases of laceration of the liver, when there is evidence that bleeding is going on, the abdomen must be opened, the laceration sought for, and the bleeding arrested. This may be done temporarily by introducing the forefinger into the epiploic foramen and placing the thumb on the lesser omentum, and compressing the hepatic artery and portal vein between the two. The margins of the laceration, if small, can be brought together and sutured by means of a blunt curved needle passed from one side of the wound to the other. All sutures must be passed before any are tied, and this must be done with the greatest gentleness, as the liver substance is very friable. When the laceration is extensive it must be packed with gauze, the end of which is allowed to hang out of the external wound.

Abscess of the liver is of not infrequent occurrence. The so-called *tropical abscess* is due to absorption from the intestine of the amœba of dysentery, which reaches the liver through the portal system and causes the formation of a large chronic abscess; this may open in many different ways on account of the relations of the liver to other organs. Thus it has been known to burst into the lungs when the pus is coughed up, or into the stomach when the pus is vomited; it may burst into the colon, or duodenum; or, by perforating the Diaphragma, it may empty itself into the pleural cavity. It often makes its way forward, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardial cavities. Abscesses of the liver frequently require opening, and this must be done by an incision in the abdominal wall, in the thoracic wall, or in the lumbar region, according to the direction in which the abscess is tracking. The incision through the abdominal wall is to be preferred when possible. The abdominal wall is incised over the swelling, and, unless the peritoneum is adherent, gauze is packed all around the exposed liver surface, the abscess opened, and a large drainage-tube inserted.

Hydatid cysts are more often found in the liver than in any of the other viscera. The reason of this is not far to seek. The embryo of the egg of the tœnia echinococcus, being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a bloodvessel, and is carried by the blood stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid.

Ptois of the liver, or *hepatoptosis*, from abnormal laxity of its ligaments and failure of the support it usually receives from the subjacent viscera, is an occasional cause of various nervous and gastro-intestinal disturbances. It has been very fully described by Glénard and his pupils. In women who have used very tight corsets and in men who have worn tightly buckled belts, the lower margin of the right lobe may become elongated by the pressure, producing an abnormal lobe known as the *linguiform* or *Riedel's lobe*. This may cause indefinite abdominal symptoms suggesting dyspepsia or disease of the gall-bladder; and if discovered accidentally, a Riedel's lobe may be mistaken for a tumor of the right kidney, of the right suprarenal gland, of the transverse colon or pancreas, or even of the vermiform process.

The gall-bladder may become distended in cases of obstruction of its duct or the common bile duct, or from a collection of gall-stones in its interior, thus forming a large tumor. The swelling is pear-shaped, and projects downward and forward to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve this condition, the gall-bladder must be opened (*cholecystotomy*) and the gall-stones removed. The operation is performed by an incision, 5 to 7 cm. long, through the lateral part of the right Rectus, commencing at the costal margin. The peritoneal cavity is opened, and, the tumor having been found, gauze is packed around it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised; any gall-stones in the bladder are now removed. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct; or it may be crushed from without by the fingers or carefully padded forceps. If this does not succeed, the safest plan is to incise the duct, extract the stone, and close the incision by fine sutures in two layers. After all obstruction has been removed, the edges of the incision in the gall-bladder may be sutured to the posterior sheath of the Rectus and a fistulous communication established between the gall-bladder and the exterior, a drainage-tube being inserted into the cavity; this fistulous opening usually closes in the course of a few weeks. The gall-bladder may be completely removed if it be quite certain that no cause for biliary obstruction remain: this is also done for primary malignant growth of the viscus.

The Pancreas (Figs. 1011, 1012).

Dissection.—The pancreas may be exposed for dissection in three different ways: (1) By raising the liver, drawing down the stomach, and tearing through the gastrohepatic omentum, and the ascending layer of the transverse mesocolon. (2) By raising the stomach, the arch of the colon, and greater omentum, and then dividing the inferior layer of the transverse mesocolon

and raising its ascending layer (3) By dividing the two layers of peritoneum, which descend from the greater curvature of the stomach to form the greater omentum; turning the stomach upward, and then cutting through the ascending layer of the transverse mesocolon (see Fig. 981).

FIG. 1011.—Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.

FIG. 1012 -The duodenum and pancreas.

The **pancreas** is a compound racemose gland, analogous in its structures to the salivary glands, though softer and less compactly arranged than those organs.

It is long and irregularly prismatic in shape; its right extremity, being broad, is called the **head**, and is connected to the main portion of the organ, or **body**, by a slight constriction, the **neck**; while its left extremity gradually tapers to form the **tail**. It is situated transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from 12.5 to 15 cm., and its weight from 60 to 100 gm.

Relations.—The **Head** (*caput pancreatis*) is flattened from before backward, and is lodged within the curve of the duodenum. Its upper border is overlapped by the superior part of the duodenum and its lower overlaps the horizontal part; its right and left borders overlap in front, and insinuate themselves behind, the descending and ascending parts of the duodenum respectively. The angle of junction of the lower and left lateral borders forms a prolongation, termed the **uncinate process**. In the groove between the duodenum and the right lateral and lower borders in front are the anastomosing superior and inferior pancreaticoduodenal arteries; the common bile duct descends behind, close to the right border, to its termination in the descending part of the duodenum.

FIG. 1013.—The pancreas and duodenum from behind. (From model by His.)

Anterior Surface.—The greater part of the right half of this surface is in contact with the transverse colon, only areolar tissue intervening. From its upper part the **neck** springs, its right limit being marked by a groove for the gastroduodenal artery. The lower part of the right half, below the transverse colon, is covered by peritoneum continuous with the inferior layer of the transverse mesocolon, and is in contact with the coils of the small intestine. The superior mesenteric artery passes down in front of the left half across the uncinate process; the superior mesenteric vein runs upward on the right side of the artery and, behind the neck, joins with the lienal vein to form the portal vein.

Posterior Surface.—The posterior surface is in relation with the inferior vena cava, the common bile duct, the renal veins, the right crus of the Diaphragma, and the aorta.

The **Neck** springs from the right upper portion of the front of the head. It is about 2.5 cm. long, and is directed at first upward and forward, and then upward

and to the left to join the body; it is somewhat flattened from above downward and backward. Its antero-superior surface supports the pylorus; its postero-inferior surface is in relation with the commencement of the portal vein; on the right it is grooved by the gastroduodenal artery.

The **Body** (*corpus pancreatis*) is somewhat prismatic in shape, and has three surfaces: **anterior**, **posterior**, and **inferior**.

The **anterior surface** (*facies anterior*) is somewhat concave; and is directed forward and upward: it is covered by the postero-inferior surface of the stomach which rests upon it, the two organs being separated by the omental bursa. Where it joins the neck there is a well-marked prominence, the **tuber omentale**, which abuts against the posterior surface of the lesser omentum.

The **posterior surface** (*facies posterior*) is devoid of peritoneum, and is in contact with the aorta, the lienal vein, the left kidney and its vessels, the left suprarenal gland, the origin of the superior mesenteric artery, and the crura of the Diaphragma.

The **inferior surface** (*facies inferior*) is narrow on the right but broader on the left, and is covered by peritoneum; it lies upon the duodenojejunal flexure and on some coils of the jejunum; its left extremity rests on the left colic flexure.

The **superior border** (*margo superior*) is blunt and flat to the right; narrow and sharp to the left, near the tail. It commences on the right in the omental tuberosity, and is in relation with the coeliac artery, from which the hepatic artery courses to the right just above the gland, while the lienal artery runs toward the left in a groove along this border.

The **anterior border** (*margo anterior*) separates the anterior from the inferior surface, and along this border the two layers of the transverse mesocolon diverge from one another; one passing upward over the anterior surface, the other backward over the inferior surface.

The **inferior border** (*margo inferior*) separates the posterior from the inferior surface; the superior mesenteric vessels emerge under its right extremity.

The **Tail** (*cauda pancreatis*) is narrow; it extends to the left as far as the lower part of the gastric surface of the spleen, lying in the phrenicocolial ligament, and it is in contact with the left colic flexure.

Birmingham described the body of the pancreas as projecting forward as a prominent ridge into the abdominal cavity and forming part of a shelf on which the stomach lies. "The portion of the pancreas to the left of the middle line has a very considerable antero-posterior thickness; as a result the anterior surface is of considerable extent; it looks strongly upward, and forms a large and important part of the shelf. As the pancreas extends to the left toward the spleen it crosses the upper part of the kidney, and is so moulded on to it that the top of the kidney forms an extension inward and backward of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pancreas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upward and backward into the concave gastric surface of the spleen, which completes the bed behind and to the left, and, running upward, forms a partial cap for the wide end of the stomach.¹

The **Pancreatic Duct** (*ductus pancreaticus* [*Wirsungi*]; *duct of Wirsung*) extends transversely from left to right through the substance of the pancreas (Fig. 1014). It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, it receives the ducts of the various lobules composing the gland. Considerably augmented in size, it reaches the neck, and turning downward, backward, and to the right, it comes into relation with the common bile duct, which lies to its right side; leaving the head of the gland, it passes very obliquely through the mucous and muscular coats of the duodenum,

¹ Journal of Anatomy and Physiology, pt. 1, xxxi, 102.

and ends by an orifice common to it and the common bile duct upon the summit of the duodenal papilla, situated at the medial side of the descending portion of the duodenum, 7.5 to 10 cm. below the pylorus. The pancreatic duct, near the duodenum, is about the size of an ordinary quill. Sometimes the pancreatic duct and the common bile duct open separately into the duodenum. Frequently there is an additional duct, which is given off from the pancreatic duct in the neck of the pancreas and opens into the duodenum about 2.5 cm. above the duodenal papilla. It receives the ducts from the lower part of the head, and is known as the **accessory pancreatic duct** (*duct of Santorini*).

Hepatic artery

bile-d
creati*

FIG. 1014 --The pancreatic duct

Structure (Fig. 1015).—In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, ending in a number of recal pouches or alveoli, which are tubular and somewhat convoluted. The minute ducts connected with the alveoli are narrow and lined with flattened cells. The alveoli are almost completely filled with secreting cells, so that scarcely any lumen is visible. In some animals spindle-shaped cells occupy the centre of the alveolus and are known as the **centro-acinar cells of Langerhans**. These are prolongations of the terminal ducts. The true secreting cells which line the wall of the alveolus are very characteristic. They are columnar in shape and present two zones: an outer one, clear and finely striated next the basement-membrane, and an inner granular one next the lumen. In hardened specimens the outer zone stains deeply with various dyes, whereas the inner zone stains slightly. During activity the granular zone gradually diminishes in size, and when exhausted is only seen as a small area next to the lumen. During the resting stages it gradually increases until it forms nearly three-fourths of the cell. In some of the secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cell; this is termed the **paranucleus**, and is believed to be an extension from the nucleus. The connective tissue between the alveoli presents in certain parts collections of cells, which are termed **interalveolar cell islets** (*islands of Langerhans*). The cells of these stain lightly with hematoxylin or carmine, and are more or less polyhedral in shape, forming a net-work in which ramify many capillaries. There are two main types of cell in the islets, distinguished as A-cells and B-cells according to the special staining reactions of the granules they contain. The cell

islets have been supposed to produce the internal secretion of the pancreas which is necessary for carbohydrate metabolism, but numerous researches have so far failed to elucidate their real function.

The walls of the pancreatic duct are thin, consisting of two coats, an external fibrous and an internal mucous; the latter is smooth, and furnished near its termination with a few scattered follicles.

Vessels and Nerves.—The arteries of the pancreas are derived from the lienal, and the pancreaticoduodenal branches of the hepatic and superior mesenteric. Its veins open into the

Alveolus

lienal and superior mesenteric veins. Its lymphatics are described on page 793. Its nerves are filaments from the lienal plexus.

Applied Anatomy.—Inflammation of the pancreas has of late years received considerable attention. It appears to be due to infection of the pancreatic ducts by microorganisms from the duodenum in cases of gastroduodenal catarrh, or from the biliary passages in which a gall-stone is lodged. Acute cases usually terminate fatally and are frequently of the hemorrhagic type; chronic inflammation of the pancreas produces few symptoms of disease unless it is extensive, when attacks of abdominal pain, loss of appetite, progressive weakness and wasting, and the passage of whitish fatty motions, are likely to follow. Extensive fibrosis of the pancreas also one of the commonest lesions found post mortem in cases of diabetes mellitus. Cysts of the pancreas are sometimes met with. They may be the result of traumatism, when they

FIG. 1015.—Section of pancreas of dog. $\times 250$.

generally contain blood, or they may be due to retention from obstruction of a duct, or from pressure on the main duct by a gall-stone. They may attain a large size, and cause symptoms by pressing on the stomach, Diaphragma, or common bile duct. They generally push their way forward between the stomach and transverse colon, and may then be felt as a definite tumor in the middle line of the upper part of the abdomen. The tumor is fixed and does not move with respiration. The treatment consists in opening the abdomen in the middle line, incising the cyst, evacuating its contents, and fixing its walls to the deeper layers of the abdominal wall. Drainage in the left loin, just below the last rib, can sometimes be established. When they are situated in the tail of the pancreas they have been removed. The pancreas is often the seat of cancer; this usually affects the head, and therefore speedily involves the common bile duct, leading to persistent jaundice; or it may press upon the portal vein, causing ascites, or involve the stomach, causing pyloric obstruction. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found in company with other viscera, in rare cases of diaphragmatic hernia.

THE UROGENITAL APPARATUS (APPARATUS UROGENITALIS; UROGENITAL ORGANS).

The urogenital apparatus consists of (a) the urinary organs for the secretion and discharge of the urine, and (b) the genital organs, which are concerned with the process of reproduction.

THE URINARY ORGANS.

The urinary organs comprise the kidneys, which secrete the urine, the ureters, or ducts, which convey urine to the urinary bladder, where it is for a time retained; and the urethra, through which it is discharged from the body.

The Kidneys (Renes).

The kidneys are situated in the posterior part of the abdomen, one on either side of the vertebral column, behind the peritoneum, and surrounded by a mass of fat

and loose areolar tissue. Their upper extremities are on a level with the upper border of the twelfth thoracic vertebra, their lower extremities on a level with the third lumbar. The right kidney is usually slightly lower than the left, probably on account of the vicinity of the liver. The long axis of each kidney is directed downward and lateralward; the transverse axis backward and lateralward.

Each kidney is about 11.25 cm. in length, 5 to 7.5 cm. in breadth, and rather more than 2.5 cm. in thickness. The left is somewhat longer, and narrower, than the right. The weight of the kidney in the adult male varies from 125 to 170 gm., in the adult female from 115 to 155 gm. The combined weight of the two kidneys in proportion to that of the body is about 1 to 240.

The kidney has a characteristic form, and presents for examination two surfaces, two borders, and an upper and lower extremity.

FIG. 1016.—The anterior surfaces of the kidneys, showing the areas of contact of neighboring viscera.

Relations.—The anterior surface (*facies anterior*) (Figs. 1012 and 1016) of each kidney is convex, and looks forward and lateralward. Its relations to adjacent viscera differ so completely on the two sides that separate descriptions are necessary.

Anterior Surface of Right Kidney.—A narrow portion at the upper extremity is in relation with the right suprarenal gland. A large area just below this and involving about three-fourths of the surface, lies in the renal impression on the inferior surface of the liver, and a narrow but somewhat variable area near the medial border is in contact with the descending part of the duodenum. The lower part of the anterior surface is in contact laterally with the right colic flexure, and medially, as a rule, with the small intestine. The areas in relation with the liver and small intestine are covered by peritoneum; the suprarenal, duodenal, and colic areas are devoid of peritoneum.

Anterior Surface of Left Kidney.—A small area along the upper part of the medial border is in relation with the left suprarenal gland, and close to the lateral border is a long strip in contact with the renal impression on the spleen. A somewhat quadrilateral field, about the middle of the anterior surface, marks the site of contact with the body of the pancreas, on the deep surface of which are the lienal vessels. Above this is a small triangular portion, between the suprarenal and splenic areas, in contact with the postero-inferior surface of the stomach. Below the pancreatic area the lateral part is in relation with the left colic flexure,

the medial with the small intestine. The areas in contact with the stomach and spleen are covered by the peritoneum of the omental bursa, while that in relation

C
V

FIG. 1017.—The posterior surfaces of the kidneys, showing areas of relation to the parietes.

to the small intestine is covered by the peritoneum of the general cavity; behind the latter are some branches of the left colic vessels. The suprarenal, pancreatic, and colic areas are devoid of peritoneum.

FIG. 1018.—The relations of the kidneys from behind.

The **Posterior Surface** (*facies posterior*) (Figs. 1017, 1018).—The posterior surface of each kidney is directed backward and medialward. It is imbedded in areolar

and fatty tissue and entirely devoid of peritoneal covering. It lies upon the Diaphragma, the medial and lateral lumbocostal arches, the Psoas major, the Quadratus lumborum, and the tendon of the Transversus abdominis, the subcostal, and one or two of the upper lumbar arteries, and the last thoracic, iliohypogastric, and ilioinguinal nerves. The right kidney rests upon the twelfth rib, the left usually on the eleventh and twelfth. The Diaphragma separates the kidney from the pleura, which dips down to form the phrenicocostal sinus, but frequently the muscular fibres of the Diaphragma are defective or absent over a triangular area immediately above the lateral lumbocostal arch, and when this is the case the perinephric areolar tissue is in contact with the diaphragmatic pleura.

Borders.—The **lateral border** (*margo lateralis; external border*) is convex, and is directed toward the postero-lateral wall of the abdomen. On the left side it is in contact at its upper part, with the spleen.

The **medial border** (*margo medialis; internal border*) is concave in the centre and convex toward either extremity; it is directed forward and a little downward. Its central part presents a deep longitudinal fissure, bounded by prominent overhanging anterior and posterior lips. This fissure is named the **hilus**, and transmits the vessels, nerves, and ureter. Above the hilus the medial border is in relation with the suprarenal gland; below the hilus, with the ureter.

Extremities.—The **superior extremity** (*extremitas superior*) is thick and rounded, and is nearer the median line than the lower; it is surmounted by the suprarenal gland, which covers also a small portion of the anterior surface.

The **inferior extremity** (*extremitas inferior*) is smaller and thinner than the superior and farther from the median line. It extends to within 5 cm. of the iliac crest.

The relative position of the main structures in the hilus is as follows: the vein is in front, the artery in the middle, and the ureter behind and directed downward. Frequently, however, branches of both artery and vein are placed behind the ureter.

Fixation of the Kidney (Figs. 1019, 1020).—The kidney and its vessels are imbedded in a mass of fatty tissue, termed the **adipose capsule**, which is thickest at the margins of the kidney and is prolonged through the hilus into the renal sinus. The kidney and the adipose capsule are enclosed in a sheath of fibrous tissue continuous with the subperitoneal fascia, and named the **renal fascia**. At the lateral border of the kidney the renal fascia splits into an anterior and a posterior layer. The anterior layer is carried medialward in front of the kidney and its vessels, and is continuous over

the aorta with the corresponding layer of the opposite side. The posterior layer extends medialward behind the kidney and blends with the fascia on the Quadratus lumborum and Psoas major, and through this fascia is attached to the vertebral column. Above the suprarenal gland the two layers of the renal fascia fuse,

and unite with the fascia of the Diaphragma; below they remain separate, and are gradually lost in the subperitoneal fascia of the iliac fossa. The renal fascia is connected to the fibrous tunic of the kidney by numerous trabeculae, which traverse the adipose capsule, and are strongest near the lower end of the organ. Behind the fascia renalis is a considerable quantity of fat, which constitutes the **paranephric body**. The kidney is held in position partly through the attachment of the renal fascia and partly by the apposition of the neighboring viscera.

FIG. 1020.—Transverse section, showing the relations of the capsule of the kidney. (After Gerota.)

General Structure of the Kidney.—The kidney is invested by a fibrous tunic, which forms a firm, smooth covering to the organ. The tunic can be easily stripped off, but in doing so numerous fine processes of connective tissue and small bloodvessels are torn through. Beneath this coat a thin wide-meshed net-work of unstriped muscular fibre forms an incomplete covering to the organ. When the capsule is stripped off, the surface of the kidney is found to be smooth and even and of a deep red color. In infants fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland. The kidney is dense in texture, but is easily lacerable by mechanical force. If a vertical section of the kidney be made from its convex to its concave border, and the loose tissue and fat removed from around the vessels and the excretory duct, it will be seen that the kidney consists of a central cavity surrounded at all parts but one by the proper kidney substance (Fig. 1021). This central cavity is called the **renal sinus**, and is lined by a prolongation of the fibrous tunic, which is continued around the lips of the hilus. Through the hilus the bloodvessels of the kidney and its excretory duct pass, and therefore these structures, upon entering or leaving the kidney, are contained within the sinus. The excretory duct or **ureter** begins by several short truncated branches termed **calices**, which unite to form two or three short tubes; these in turn expand into a wide funnel-shaped sac named the **renal pelvis**, from the neck of which the ureter issues. The calices and pelvis lie within the sinus; the bloodvessels of the kidney, after passing through the hilus, are also contained in the sinus, lying between its lining membrane and the excretory apparatus.

The kidney is composed of an internal **medullary** and an external **cortical substance**.

The **medullary substance** (*substantia medullaris*) consists of a series of red-colored striated conical masses, termed the **renal pyramids**, the bases of which are directed toward the circumference of the kidney, while their apices converge toward the renal sinus, where they form prominent papillae projecting into the interior of the calices; each calyx receives from one to three papillae.

The **cortical substance** (*substantia corticalis*) is reddish brown in color and soft and granular in consistence. It lies immediately beneath the fibrous tunic, arches over the bases of the pyramids, and dips in between adjacent pyramids toward the renal sinus. The parts dipping in between the pyramids are named the **renal columns** (Bertini), while the portions which connect the renal columns to each other and intervene between the bases of the pyramids and the fibrous tunic are called the **cortical arches** (indicated between A and A' in Fig. 1021). If the cortex be examined with a lens, it will be seen to consist of a series of lighter-colored, conical areas, termed the **radiate part**, and a darker-colored intervening substance, which from the complexity of its structure is named the **convoluted part**. The rays gradually taper toward the circumference of the kidney, and consist of a series of outward prolongations from the base of each renal pyramid.

The cortical and medullary substances, so dissimilar in appearance, are very similar in structure, being made up of renal tubules and bloodvessels, united and bound together by a connecting stroma.

Minute Anatomy.—The **renal tubules** (Fig. 1022), of which the kidney is for the most part made up, commence in the cortical substance, and after pursuing a very circuitous course through the cortical and medullary substances, finally end at the apices of the renal pyramids by open mouths, so that the fluid which they contain is emptied, through the calices, into the pelvis of the kidney. If the surface of one of the papillæ be examined with a lens, it will be seen to be studded over with minute openings, the orifices of the

FIG. 1021.—Vertical section of kidney.

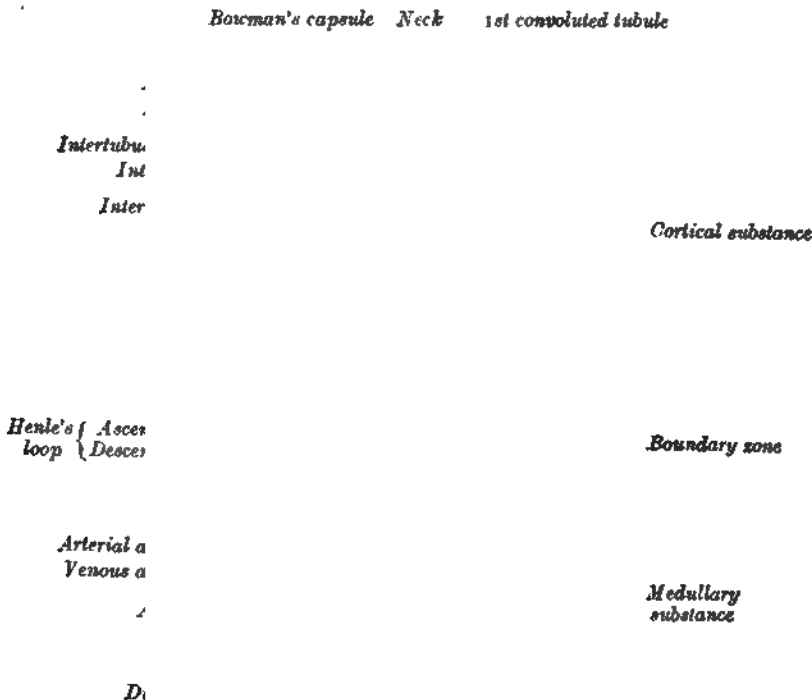

FIG. 1022.—Scheme of renal tubule and its vascular supply.

renal tubules, from sixteen to twenty in number, and if pressure be made on a fresh kidney, urine will be seen to exude from these orifices. The tubules commence in the convoluted part and renal columns as the **Malpighian bodies**, which are small rounded masses of a deep red color, varying in size, but of an average of about 0.2 mm. in diameter. Each of these little bodies is composed of two parts: a central glomerulus of vessels, called a **Malpighian tuft**, and a membranous envelope, the **Malpighian capsule** (*capsule of Bowman*), which is the small pouch-like commencement of a renal tubule.

The **Malpighian tuft** (*vascula glomerulus*) is a lobulated net-work of convoluted capillary bloodvessels, held together by scanty connective tissue. This capillary net-work is derived from a small arterial twig, the *afferent vessel*, which enters the capsule, generally at a point opposite to that at which the latter is connected with the tubule, and the resulting vein, the *efferent vessel*, emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (Fig. 1023). The **Malpighian** or **Bowman's capsule**, which surrounds the glomerulus, is formed of a hyaline membrane, supported by a small amount of connective tissue, which is continuous with the connective tissue of the tube. It is lined on its inner surface by a layer of squamous epithelial cells, which are reflected from the lining membrane on to the glomerulus, at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells, on a delicate supporting membrane (Fig. 1024). Thus between the glomerulus and the capsule a space is left, forming a cavity lined by a continuous layer of squamous cells; this cavity varies in size according to the state of secretion and the amount of fluid present in it. In the fetus and young subject the lining epithelial cells are polyhedral or even columnar.

FIG. 1023.—Distribution of bloodvessels in cortex of kidney

FIG. 1024.—Malpighian body.

The **renal tubules**, commencing in the Malpighian bodies, present, during their course, many changes in shape and direction, and are contained partly in the medullary and partly in the cortical substance. At their junction with the Malpighian capsule they exhibit a somewhat constricted portion, which is termed the **neck**. Beyond this the tubule becomes convoluted, and pursues a considerable course in the cortical substance constituting the **proximal convoluted tube**. After a time the convolutions disappear, and the tube approaches the medullary substance in a more or less spiral manner; this section of the tubule has been called the **spiral tube**. Throughout this portion of their course the renal tubules are contained entirely in the cortical substance, and present a fairly uniform calibre. They now enter the medullary substance, suddenly become much smaller, quite straight in direction, and dip down for a variable depth into the pyramids, constituting the **descending limb of Henle's loop**. Bending on themselves, they form what is termed the **loop of Henle**, and reascending, they become suddenly enlarged, forming the **ascending limb of Henle's loop**, and reënter the cortical substance. This portion of the tubule ascends for a short distance, when it again becomes dilated, irregular, and angular. This section is termed the **zigzag tubule**; it ends in a convoluted tube, which resembles the proximal convoluted tubule, and is called the **distal convoluted tubule**. This again terminates in a narrow **junctional tube**, which enters the straight or collecting tube.

The **straight** or **collecting tubes** commence in the radiate part of the cortex, where they receive the curved ends of the distal convoluted tubules. They unite at short intervals with one another, the resulting tubes presenting a considerable increase in calibre, so that a series of comparatively large tubes passes from the bases of the rays into the renal pyramids. In the medulla the tubes of each pyramid converge to join a central tube (*duct of Bellini*) which finally opens on the summit of one of the papillæ; the contents of the tube are therefore discharged into one of the calices.

Structure of the Renal Tubules—The renal tubules consist of a basement membrane lined with epithelium. The epithelium varies considerably in different sections of the tubule. In the neck

the epithelium is continuous with that lining the Malpighian capsule, and like it consists of flattened cells each containing an oval nucleus (Fig. 1026). The two convoluted tubules, the spiral and zigzag tubules and the ascending limb of Henle's loop, are lined by a type of epithelium which is histologically the same in all. The cells are somewhat columnar in shape and dovetail into one another of their lateral aspect. Each has a striated border next the lumen of the tube, its inner part is granular and its outer portion vertically striated. The nucleus is spherical and situated about the centre of the cell. In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat, clear epithelial plates, each with an oval nucleus (Fig. 1025). The nuclei alternate on opposite surfaces of the tubule so that the lumen remains fairly constant.

In the straight tube the epithelium is clear and cubical; in its papillary portion the cells are distinctly columnar and transparent (Fig. 1026).

The Renal Bloodvessels.—The kidney is plentifully supplied with blood (Fig. 1027) by the renal artery, a large offset of the abdominal aorta. Before it enters the kidney, each artery divides into four or five branches which at the hilus lie mainly between the renal vein and ureter, the vein being in front, the ureter behind; one branch usually lies behind the ureter. Each vessel gives off some small branches to the suprarenal glands, to the ureter, and to the surrounding cellular tissue and muscles. Frequently a second renal artery, termed the *inferior renal*, is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney, while occasionally an additional artery enters the upper part of the kidney. The branches of the renal artery, while in the sinus, give off a few twigs for the nutrition of the surrounding tissues, and end in the *arteriae propriae renales*, which enter the kidney proper in the renal columns. Two of these pass to each renal pyramid, and run along its sides for its entire length, giving off in their course the afferent vessels of the Malpighian bodies in the renal

columns. Having arrived at the bases of the pyramids, they form arterial arches or arcades which lie in the boundary zone between the bases of the pyramids and the cortical arches, and break up into two distinct sets of branches devoted to the supply of the remaining portions of the kidney.

The *first set*, the *interlobular arteries* (Fig. 1022), are given off at right angles from the side of the arterial arcade looking toward the cortical substance, and pass directly outward between

the medullary rays to reach the fibrous tunic, where they end in the capillary net-work of this part. These vessels do not anastomose with each other, but form what are called *end-arteries*. In their outward course they give off lateral branches; these are the *afferent vessels* for the Malpighian bodies (see page 1212); they enter the capsule, and end in the Malpighian tufts. From each tuft the corresponding *efferent vessel* arises, and, having made its egress from the capsule near to the point where the afferent vessel enters, breaks up into a number of branches, which form a dense *plexus* around the adjacent urinary tubes.

The **second set of branches** from the arterial arcades supply the renal pyramids, which they enter at their bases; and, passing straight through their substance to their apices, terminate in the venous plexuses found in that situation. They are called the *arteriae rectae*. The efferent vessels from the glomeruli nearest the medulla break up into leashes of straight vessels (*false arteriae rectae*) which pass down into the medulla and join the plexus of vessels there (Fig. 1022).

The **renal veins** arise from three sources, viz., the veins beneath the fibrous tunic, the plexuses around the convoluted tubules in the cortex, and the plexuses situated at the apices of the renal pyramids. The veins beneath the fibrous tunic (*venae stellatae*) are stellate in arrangement, and are derived from the capillary net-work, into which the terminal branches of the interlobular arteries break up. These join to form the *interlobular veins*, which pass inward between the rays, receive branches from the plexuses around the convoluted tubules, and, having arrived at the bases of the renal pyramids, join with the *venae rectae*, next to be described.

D

Branch of collecting tube, cut across, lined with cubical epithelium. *c*, *d*. Henle's loops cut across. *e*. Bloodvessels cut across. *D*. Connective tissue ground substance.

The *venae rectae* are branches from the plexuses at the apices of the medullary pyramids, formed by the terminations of the *arteriae rectae*. They run outward in a straight course between the tubes of the medullary substance, and joining, as above stated, the interlobular veins, form venous arcades; these in turn unite and form veins which pass along the sides of the pyramids (Fig. 1022).

These vessels, **venae propriae renales**, accompany the arteries of the same name, running along the entire length of the sides of the pyramids, and quit the kidney substance to enter the sinus. In this cavity they join the corresponding veins from the other pyramids to form the *renal vein*, which emerges from the kidney at the hilus and opens into the inferior vena cava: the left vein is longer than the right, and crosses in front of the abdominal aorta.

The **lymphatics** of the kidney are described on page 793.

Nerves of the Kidney.—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the coeliac plexus, the lower and outer part of the coeliac ganglion and aortic plexus, and from the lesser and lowest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testis in affections of the kidney. They accompany the renal artery and its branches, and are distributed to the bloodvessels and to the cells of the urinary tubules.

Connective Tissue (intertubular stroma).—Although the tubules and vessels are closely packed, a small amount of connective tissue, continuous with the fibrous tunic, binds them firmly together and supports the bloodvessels, lymphatics, and nerves.

Applied Anatomy.—Malformations of the kidney are not uncommon. There may be an entire absence of one kidney, but, according to Morris, the number of these cases is "excessively small" or there may be congenital atrophy of one kidney, when the kidney is very small, but usually healthy in structure. These cases are of great importance, and must be duly taken into

account when nephrectomy is contemplated. A more common malformation is where the two kidneys are fused together. They may be joined together only at their lower ends by means of a thick mass of renal tissue, so as to form a horseshoe-shaped body, or they may be completely united, forming a disk-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the middle line of the abdomen, but may be misplaced as well. In some mammals, *e. g.*, ox and bear, the kidney consists of a number of distinct lobules; this lobulated condition is characteristic of the kidney of the human fetus, and traces of it may persist in the adult. Sometimes the pelvis is duplicated, while a double ureter is not very uncommon. In some rare instances a third kidney may be present.

One or both kidneys may be misplaced as a congenital condition, and remain fixed in this abnormal position. They are then very often misshapen. They may be situated higher, though this is very uncommon, or lower than normal or removed farther from the vertebral column than usual; or they may be displaced into the iliac fossa, over the sacroiliac joint, on to the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may give rise to very serious trouble. The kidney may also be misplaced as a congenital condition, but may not be fixed; it is then known as a *floating kidney*. It is believed to be due to the fact that the kidney is completely enveloped by peritoneum which then passes backward to the vertebral column as a double layer, forming a mesonephron which permits of movement taking place. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in the tissues by which it is surrounded, moving with the capsule in the perinephric tissues. This condition is known as *movable kidney*, and is more common in the female than in the male. It occurs in badly nourished people, or in those who have become emaciated from any cause. It must not be confounded with the *floating kidney*, which is a congenital condition due to the development of a mesonephron. The two conditions cannot, however, be distinguished until the abdomen is opened or the kidney explored from the loin.

Injuries of the kidney are generally due to some severe crushing force, as from being run over by a heavy wagon or cart, or from the abdomen being compressed between the buffers of two railway carriages. When a laceration occurs on the posterior surface of the organ, infiltration of blood and urine takes place into the retroperitoneal connective tissue; this is often followed by suppuration, and death may ensue from septic poisoning. When the laceration is in front, the peritoneum may be torn and extravasation of blood and urine take place into the peritoneal cavity. Death may occur from hemorrhage or peritonitis. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and hydronephrosis follow. Sometimes the kidney may be bruised by blows in the loin, or by being compressed between the lower ribs and the ilium when the body is violently bent forward. This is followed by a little transient hematuria, which, however, speedily passes off.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephric abscess*. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighboring parts. The abscess tends to point externally in the groin or loin.

Tumors of the kidney, of which perhaps sarcoma is the most common, may be recognized by their position; by the resonant colon lying in front of them; and by their rounded outline not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded.

The *hypernephroma*, a benign or malignant tumor arising from the suprarenal gland, or from suprarenal "rests" or inclusions in the cortex or medulla of the kidney, is not infrequent. When occurring in children it is often associated with precocious growth of the body generally and of the hair and sexual organs in particular. Arising, as it often does, in the kidney, a hypernephroma may be indistinguishable from a true renal tumor so far as the physical signs and symptoms go; it is really, however, a tumor of the suprarenal gland substance.

The examination of the kidney should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forward; while the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation, sometimes with faintness.

The kidney may require exposure for exploration or the evacuation of pus (*nephrotomy*); it may be incised for the removal of stone (*nephrolithotomy*); it may be sutured when movable or floating (*nephrorrhaphy*); or it may be removed (*nephrectomy*). It may be exposed either by a lumbar or an abdominal incision; except in cases of very large tumors, a lumbar incision is best, as it has the advantages of not opening the peritoneum, and of affording admirable drainage. An oblique incision should be made, starting at the lateral border of the Sacrospinalis, 1.25 cm. below the last rib and directed downward and forward toward a point 2.5 cm. in front of the anterior superior spine of the ilium. The structures divided are the skin, the superficial fascia with the cutaneous nerves, the deep fascia, the posterior border of the Obliquus externus abdominis, and the outer border of the Latissimus dorsi; the Obliquus internus and the posterior aponeurosis of the Transversus abdominis; the lateral border of the Quadratus lumborum; the deep layer of the lumbodorsal fascia and the transversalis fascia. The fatty tissue around the

kidney is now exposed to view, and must be separated by the fingers, or a director, in order to reach the kidney. The operations of nephrolithotomy, for the removal of calculi from the kidney, and nephrotomy, or incision of the kidney for abscess, etc., are generally performed by the lumbar incision. This route is also generally chosen for nephrectomy, especially if the organ is thought to contain pus. The abdominal operation is best performed by an incision through the lateral part of the Rectus abdominis on the side of the kidney to be removed; the kidney is then reached from the lateral side of the colon, ascending or descending, as the case may be, and thus the vessels of the colon are not interfered with. The incision commencing just below the costal arch is made of varying length, according to the size of the kidney. The abdominal cavity having been opened, the intestines are drawn medialward and the peritoneum covering the kidney to the lateral side of the colon is incised, so that the fingers can be introduced behind the peritoneum. The kidney must now be enucleated, and the vessels firmly ligatured and divided, the ureter being tied separately. The particular advantage of the abdominal operation is that the condition of the other kidney can be ascertained by manual examination, before the removal of the diseased kidney is finally decided upon; and further, involvement of neighboring structure by a new-growth, rendering removal impossible, can only be discovered by the abdominal route.

Nephrorrhaphy is the name given to the operation for fixing a movable kidney. The kidney is reached by the lumbar incision, and its posterior surface denuded of its adipose capsule. Three stitches of medium thickness are passed through the transversalis fascia and muscles and through the cortical substance of the kidney, securing a good hold of it. When these sutures are tied, the kidney is tightly anchored in position; cases which are seen sometime afterward seem, however, to show that it does not always remain fixed.

The Ureters.

The **ureters** are the two tubes which convey the urine from the kidneys to the urinary bladder. Each commences within the sinus of the corresponding kidney as a number of short cup-shaped tubes, termed **calices**, which encircle the renal papillæ. Since a single calyx may enclose more than one papilla the calices are generally fewer in number than the pyramids—the former varying from seven to thirteen, the latter from eight to eighteen. The calices join to form two or three short tubes, and these unite to form a funnel-shaped dilatation, wide above and narrow below, named the **renal pelvis**, which is situated partly inside and partly outside the renal sinus. It is usually placed on a level with the spinous process of the first lumbar vertebra.

The **Ureter Proper** measures from 25 to 30 cm. in length, and is a thick-walled narrow cylindrical tube which is directly continuous near the lower end of the kidney with the tapering extremity of the renal pelvis. It runs downward and medialward in front of the Psoas major and, entering the pelvic cavity, finally opens into the fundus of the bladder.

The **abdominal part** (*pars abdominalis*) lies behind the peritoneum on the medial part of the Psoas major, and is crossed obliquely by the internal spermatic vessels. It enters the pelvic cavity by crossing either the termination of the common, or the commencement of the external, iliac vessels.

At its origin the **right** ureter is usually covered by the descending part of the duodenum, and in its course downward lies to the right of the inferior vena cava, and is crossed by the right colic and ileocolic vessels, while near the superior aperture of the pelvis it passes behind the lower part of the mesentery and the terminal part of the ileum. The **left** ureter is crossed by the left colic vessels, and near the superior aperture of the pelvis passes behind the sigmoid colon and its mesentery.

The **pelvic part** (*pars pelvina*) runs at first downward on the lateral wall of the pelvic cavity, along the anterior border of the greater sciatic notch and under cover of the peritoneum. It lies in front of the hypogastric artery medial to the obturator nerve and the umbilical, obturator, inferior vesical, and middle hemorrhoidal arteries. Opposite the lower part of the greater sciatic foramen it inclines medialward, and reaches the lateral angle of the bladder, where it is situated in front of the upper end of the seminal vesicle and at a distance of about 5 cm. from the opposite ureter; here the ductus deferens crosses to its medial side, and

the vesical veins surround it. Finally, the ureters run obliquely for about 2 cm. through the wall of the bladder and open by slit-like apertures into the cavity of the viscus at the lateral angles of the trigone. When the bladder is distended the openings of the ureters are about 5 cm. apart, but when it is empty and contracted the distance between them is diminished by one-half. Owing to their oblique course through the coats of the bladder, the upper and lower walls of the terminal portions of the ureters become closely applied to each other when the viscus is distended, and, acting as valves, prevent regurgitation of urine from the bladder.

In the **female**, the ureter forms, as it lies in relation to the wall of the pelvis, the posterior boundary of a shallow depression named the **ovarian fossa**, in which the ovary is situated. It then runs medialward and forward on the lateral aspect of the cervix uteri and upper part of the vagina to reach the fundus of the bladder. In this part of its course it is accompanied for about 2.5 cm. by the uterine artery, which then crosses in front of the ureter and ascends between the two layers of the broad ligament. The ureter is distant about 2 cm. from the side of the cervix of the uterus. The ureter is sometimes duplicated on one or both sides, and the two tubes may remain distinct as far as the fundus of the bladder. On rare occasions they open separately into the bladder cavity.

Structure (Fig. 1028).—The ureter is composed of three coats: **fibrous**, **muscular**, and **mucous coats**.

The **fibrous coat** (*tunica adventitia*) is continuous at one end with the fibrous tunic of the kidney on the floor of the sinus; while at the other it is lost in the fibrous structure of the bladder.

In the renal pelvis the **muscular coat** (*tunica muscularis*) consists of two layers, longitudinal and circular: the longitudinal fibres become lost upon the sides of the papillæ at the extremities of the calices; the circular fibres may be traced surrounding the medullary substance in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers: an external longitudinal, a middle circular, and an internal, less distinct than the other two, but having a general longitudinal direction. According to Köhler this internal layer is found only in the neighborhood of the bladder.

The **mucous coat** (*tunica mucosa*) is smooth, and presents a few longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, while it is prolonged over the papillæ of the kidney above. Its epithelium is of a transitional character, and resembles that found in the bladder (see Fig 1034). It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are somewhat flattened, with concavities on their deep surfaces into which the rounded ends of the cells of the second layer fit. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with rounded internal extremities which fit into the concavities of the cells of the first layer, and narrow external extremities which are wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement-membrane. Beneath the epithelium, and separating it from the muscular coats, is a dense layer of fibrous tissue containing many elastic fibres.

Vessels and Nerves.—The **arteries** supplying the ureter are branches from the renal, internal spermatic, hypogastric, and inferior vesical.

The **nerves** are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

FIG. 1028.—Transverse section of ureter.

Applied Anatomy.—Rupture of the ureter is not a common accident, but occasionally occurs. If it be torn completely across, the urine collects in the retroperitoneal tissues; if it be not completely divided, the lumen of the tube may become strictured and hydronephrosis or pyonephrosis result. The ureter may be accidentally wounded in some pelvic operations such as removal of the uterus; if this should happen the divided ends must be sutured together, or failing to accomplish this an attempt may be made to implant the upper end into the bladder or rectum. If this cannot be carried out the only alternative is to remove the kidney immediately.

Stones not uncommonly become impacted in the ureter. These may occur at any part, but most commonly either at the point where the tube is crossing the pelvic brim or at the termination, where it is passing obliquely through the muscular wall of the bladder. In the former case, an incision with its centre opposite, and 2.5 cm. internal to, the anterior superior iliac spine, dividing all the structures down to the peritoneum, enables the operator to reach the ureter by pushing the unopened peritoneum inward; the stone can then be felt in the ureter, the wall of which is incised, and the stone extracted, free drainage being provided for the escaping urine. When the stone is impacted at the vesical end of the tube a preliminary incision into the bladder is required, and by scratching through the mucous membrane overlying it the calculus can be removed.

The Urinary Bladder (*Vesica Urinaria*; **Bladder**) (Fig. 1029).

The **urinary bladder** is a musculomembranous sac which acts as a reservoir for the urine; and as its size, position, and relations vary according to the amount of fluid it contains, it is necessary to study it as it appears (a) when *empty*, and (b)

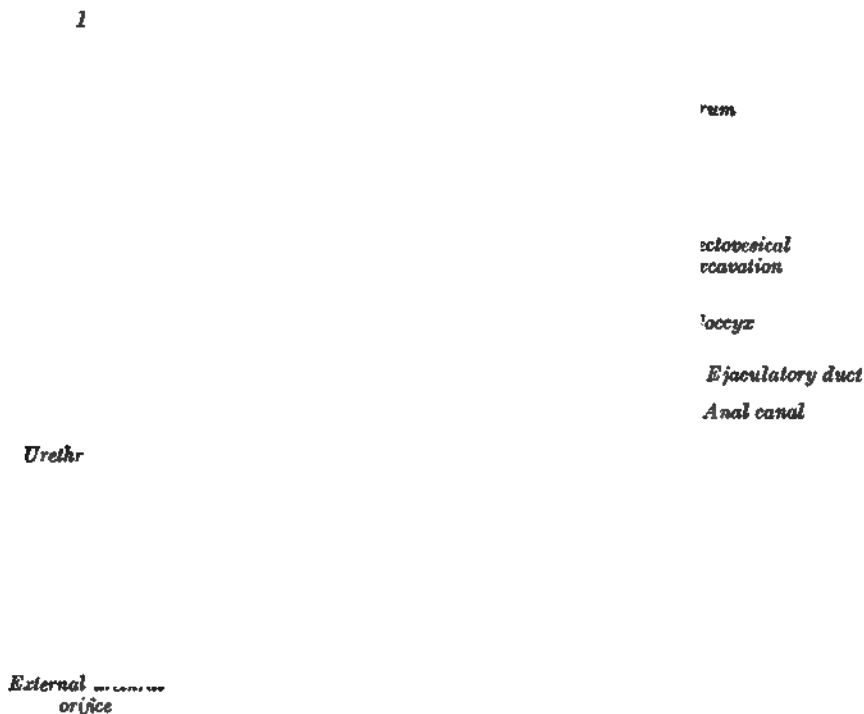

FIG. 1029.—Median sagittal section of male pelvis.

when *distended*. In both conditions the position of the bladder varies with the condition of the rectum, being pushed upward and forward when the rectum is distended.

The Empty Bladder.—When hardened *in situ*, the empty bladder has the form of a flattened tetrahedron, with its vertex tilted forward. It presents a fundus,

a vertex, a superior and an inferior surface. The **fundus** (Fig. 1041) is triangular in shape, and is directed downward and backward toward the rectum, from which it is separated by the rectovesical fascia, the vesiculæ seminales, and the terminal portions of the ductus deferentes. The **vertex** is directed forward toward the upper part of the symphysis pubis, and from it the middle umbilical ligament is continued upward on the back of the anterior abdominal wall to the umbilicus. The peritoneum is carried by it from the vertex of the bladder on to the abdominal wall to form the middle umbilical fold. The **superior surface** is triangular, bounded on either side by a lateral border which separates it from the inferior surface, and behind by a posterior border, represented by a line joining the two ureters, which intervenes between it and the fundus. The lateral borders extend from the ureters to the vertex, and from them the peritoneum is carried to the walls of the pelvis. On either side of the bladder the peritoneum shows a depression, named the **para-vesical fossa** (Fig. 963). The superior surface is directed upward, is covered by peritoneum, and is in relation with the sigmoid colon and some of the coils of the small intestine. When the bladder is empty and firmly contracted, this surface is convex and the lateral and posterior borders are rounded; whereas if the bladder be relaxed it is concave, and the interior of the viscus, as seen in a median sagittal section, presents the appearance of a V-shaped slit with a shorter posterior and a longer anterior limb—the apex of the V corresponding with the internal orifice of the urethra. The **inferior surface** is directed downward and is uncovered by peritoneum. It may be divided into a posterior or prostatic area and two infero-lateral surfaces. The prostatic area is somewhat triangular: it rests upon and is in direct continuity with the base of the prostate; and from it the urethra emerges. The infero-lateral portions of the inferior surface are directed downward and lateralward: in front, they are separated from the symphysis pubis by a mass of fatty tissue which is named the **retropubic pad**; behind, they are in contact with the fascia which covers the Levatores ani and Obturatores interni.

When the bladder is empty it is placed entirely within the pelvis, below the level of the obliterated hypogastric arteries, and below the level of those portions of the ductus deferentes which are in contact with the lateral wall of the pelvis; after they cross the ureters the ductus deferentes come into contact with the fundus of the bladder. As the viscus fills, its fundus, being more or less fixed, is only slightly depressed; while its superior surface gradually rises into the abdominal cavity, carrying with it its peritoneal covering, and at the same time rounding off the posterior and lateral borders.

The Distended Bladder.—When the bladder is moderately full it contains about 0.5 litre and assumes an oval form; the long diameter of the oval measures about 12 cm. and is directed upward and forward. In this condition it presents a postero-superior, an antero-inferior, and two lateral surfaces, a fundus and a summit. The **postero-superior surface** is directed upward and backward, and is covered by peritoneum: behind, it is separated from the rectum by the rectovesical excavation, while its anterior part is in contact with the coils of the small intestine. The **antero-inferior surface** is devoid of peritoneum, and rests, below, against the pubic bones, above which it is in contact with the back of the anterior abdominal wall. The lower parts of the lateral surfaces are destitute of peritoneum, and are in contact with the lateral walls of the pelvis. The line of peritoneal reflection from the lateral surface is raised to the level of the obliterated hypogastric artery. The **fundus** undergoes little alteration in position, being only slightly lowered. It exhibits, however, a narrow triangular area, which is separated from the rectum merely by the rectovesical fascia. This area is bounded below by the prostate, above by the rectovesical fold of peritoneum, and laterally by the ductus deferentes. The ductus deferentes frequently come in contact with each other above the prostate, and under such circumstances the lower part of the triangular area is obliterated.

ated. The line of reflection of the peritoneum from the rectum to the bladder appears to undergo little or no change when the latter is distended; it is situated about 10 cm. from the anus. The summit is directed upward and forward above the point of attachment of the middle umbilical ligament, and hence the peritoneum which follows the ligament, forms a pouch of varying depth between the summit of the bladder, and the anterior abdominal wall.

FIG. 1030.—Sagittal section through the pelvis of a newly born male child.

The Bladder in the Child (Figs. 1030, 1031).—In the newborn child the internal urethral orifice is at the level of the upper border of the symphysis pubis; the bladder therefore lies relatively at a much higher level in the infant than in the

FIG. 1031.—Sagittal section through the pelvis of a newly born female child.

adult. Its anterior surface "is in contact with about the lower two-thirds of that part of the abdominal wall which lies between the symphysis pubis and the umbilicus" (Symington¹). Its fundus is clothed with peritoneum as far as the level

¹ The Anatomy of the Child.

of the internal orifice of the urethra. Although the bladder of the infant is usually described as an abdominal organ, Symington has pointed out that only about one-half of it lies above the plane of the superior aperture of the pelvis. Disse maintains that the internal urethral orifice sinks rapidly during the first three years, and then more slowly until the ninth year, after which it remains stationary until puberty, when it again slowly descends and reaches its adult position.

The Female Bladder (Fig. 1032).—In the female, the bladder is in relation behind with the uterus and the upper part of the vagina. It is separated from the anterior surface of the body of the uterus by the vesicouterine excavation, but below the level of this excavation it is connected to the front of the cervix uteri and the upper part of the anterior wall of the vagina by areolar tissue. When the bladder is empty the uterus rests upon its superior surface. The female bladder is said by some to be more capacious than that of the male, but probably the opposite is the case.

FIG. 1032.—Median sagittal section of female pelvis.

Ligaments.—The bladder is connected to the pelvic wall by the fascia endopelvina. In front this fascial attachment is strengthened by a few muscular fibres, the **Pubovesicales**, which extend from the back of the pubic bones to the front of the bladder; behind, other muscular fibres run from the fundus of the bladder to the sides of the rectum, in the sacrogenital folds, and constitute the **Rectovesicales**.

The vertex of the bladder is joined to the umbilicus by the remains of the urachus which forms the **middle umbilical ligament**, a fibromuscular cord, broad at its attachment to the bladder but narrowing as it ascends.

From the superior surface of the bladder the peritoneum is carried off in a series of folds which are sometimes termed the **false ligaments of the bladder**. Anteriorly there are three folds: the **middle umbilical fold** on the middle umbilical ligament,

and two lateral umbilical folds on the obliterated hypogastric arteries. The reflections of the peritoneum on to the side walls of the pelvis form the lateral false ligaments, while the sacrogenital folds constitute posterior false ligaments.

Interior of the Bladder (Fig. 1033).—The mucous membrane lining the bladder is, over the greater part of the viscus, loosely attached to the muscular coat, and appears wrinkled or folded when the bladder is contracted; in the distended condition of the bladder the folds are effaced. Over a small triangular area, termed the *trigonum vesicae*, immediately above and behind the internal orifice of the urethra, the mucous membrane is firmly bound to the muscular coat, and is always smooth. The anterior angle of the *trigonum vesicae* is formed by the internal orifice of the urethra: its postero-lateral angles by the orifices of the ureters. Stretching behind the latter openings is a slightly curved ridge, the *torus uretericus*, forming the base of the trigone and produced by an underlying bundle of non-striped muscular

fibres. The lateral parts of this ridge extend beyond the openings of the ureters, and are named the *plicae uretericae*; they are produced by the terminal portions of the ureters as they traverse obliquely the bladder wall. When the bladder is illuminated the *torus uretericus* appears as a pale band and forms an important guide during the operation of introducing a catheter into the ureter.

The **orifices of the ureters** are placed at the postero-lateral angles of the *trigonum vesicae*, and are usually slit-like in form. In the contracted bladder they are about 2.5 cm. apart and about the same distance from the internal urethral orifice; in the distended viscus these measurements may be increased to about 5 cm.

The **internal urethral orifice** is placed at the apex of the *trigonum vesicae*, in the most dependent part of the bladder, and is usually somewhat crescentic in form; the mucous membrane immediately behind it presents a slight elevation, the *uvula vesicae*, caused by the middle lobe of the prostate.

Structure (Fig. 1034).—The bladder is composed of the four coats: **serous, muscular, sub-mucous, and mucous coats.**

The **serous coat** (*tunica serosa*) is a partial one, and is derived from the peritoneum. It invests the superior surface and the upper parts of the lateral surfaces, and is reflected from these on to the abdominal and pelvic walls.

The **muscular coat** (*tunica muscularis*) consists of three layers of unstriped muscular fibres: an external layer, composed of fibres having for the most part a longitudinal arrangement; a middle layer, in which the fibres are arranged, more or less, in a circular manner; and an internal layer, in which the fibres have a general longitudinal arrangement.

The fibres of the external layer arise from the posterior surface of the body of the pubis in both sexes (*musculi pubovesicales*), and in the male from the adjacent part of the prostate and its capsule. They pass, in a more or less longitudinal manner, up the inferior surface of the bladder, over its vertex, and then descend along its fundus to become attached to the prostate in the male, and to the front of the vagina in the female. At the sides of the bladder the fibres are arranged obliquely and intersect one another. This layer has been named the **Detrusor urinae muscle.**

The fibres of the middle circular layer are very thinly and irregularly scattered on the body of the organ, and, although to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Toward the lower part of the bladder, around the internal urethral orifice, they are disposed in a thick circular layer, forming the **Sphincter vesicae**, which is continuous with the muscular fibres of the prostate.

The **internal longitudinal layer** is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction. Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate, and are inserted by means of a fibrous process, into the middle lobe of that organ. They are the **muscles of the ureters**, described by Sir C. Bell, who supposed that during the contraction of the bladder they serve to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The **submucous coat** (*tela submucosa*) consists of a layer of areolar tissue, connecting together the muscular and mucous coats, and intimately united to the latter.

The **mucous coat** (*tunica mucosa*) is thin, smooth, and of a pale rose color. It is continuous above through the ureters with the lining membrane of the renal tubules, and below with that of the urethra. The loose texture of the submucous layer allows the mucous coat to be thrown into folds or *rugae* when the bladder is empty. Over the trigonum vesicae the mucous membrane is closely attached to the muscular coat, and is not thrown into folds, but is smooth and flat. The epithelium covering it is of the transitional variety, consisting of a superficial layer of polyhedral flattened cells, each with one, two, or three nuclei; beneath these is a stratum of large club-shaped cells, with their narrow extremities directed downward and wedged in between smaller spindle-shaped cells, containing oval nuclei (Fig. 1034). The epithelium varies according as the bladder is distended or contracted. In the former condition the superficial cells are flattened and those of the other layers are shortened; in the latter they present the appearance described above. There are no true glands in the mucous membrane of the bladder, though certain mucous follicles which exist, especially near the neck of the bladder, have been regarded as such.

Vessels and Nerves.—The arteries supplying the bladder are the superior, middle, and inferior vesical, derived from the anterior trunk of the hypogastric. The obturator and inferior gluteal arteries also supply small visceral branches to the bladder, and in the female additional branches are derived from the uterine and vaginal arteries.

The **veins** form a complicated plexus on the inferior surface, and fundus near the prostate, and end in the hypogastric veins.

The **lymphatics** are described on page 793.

The **nerves** of the bladder are (1) fine medullated fibres from the third and fourth sacral nerves, and (2) non-medullated fibres from the hypogastric plexus. They are connected with ganglia in the outer and submucous coats and are finally distributed, all as non-medullated fibres, to the muscular layer and epithelial lining of the viscus.

FIG. 1034.—Vertical section of bladder wall.

Applied Anatomy.—A defect of development, in which the bladder is implicated, is known under the name of *extroversion of the bladder*. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the fundus of the bladder presents on the abdominal surface, and is pushed forward by the pressure of the viscera within the abdomen, forming a red vascular tumor on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra, a condition known as *epispadias*. The pelvic bones are also arrested in development (see page 344).

The bladder may be ruptured by violence applied to the abdominal wall, when the viscus is distended, without any injury to the bony pelvis, or it may be torn in cases of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal: that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lembert's suture is resorted to, with a very considerable amount of success. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external incision.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder*. Between these muscular bundles the mucous membrane may bulge out, forming sacculi, constituting the *sacculated bladder*, and in these little pouches phosphatic concretions may collect, forming *encysted calculi*. The mucous membrane is very loosely attached, except over the trigone, to allow of the distension of the viscus.

Various forms of tumor have been found springing from the wall of the bladder. The commonest innocent tumor is the villous papilloma. Of the malignant tumors, epithelioma is the most common, but sarcoma is occasionally found in the bladder of children.

In doubtful cases the cystoscope proves a valuable aid in diagnosis. This instrument consists of a tube in which is fixed a small electric light, the wires of which run through the shaft of the instrument. Upon introducing this down the urethra, the bladder can be examined with the eye and a villous growth or other tumor, a calculus, or an ulcer can be detected; or the orifices of the ureters can be examined, and renal hematuria diagnosed, and it can be definitely settled from which kidney the blood comes. Again, the presence of minute tuberculous ulceration near the mouth of the ureter on the affected side may establish the diagnosis, not only of tuberculous kidney, but also of the side in which the disease is located. The cystoscope can be used to catheterize the ureter, for the purpose of obtaining a specimen of urine from either kidney, or to ascertain the condition of both kidneys where it is proposed to remove one. Ureteric bougies opaque to x-rays can be passed up and photographed.

Puncture of the bladder may be performed either above the symphysis pubis or through the rectum, in both cases without wounding the peritoneum. The former plan is generally to be preferred, since in puncture by the rectum a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvis cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a cannula in the rectum. In some cases, in performing this operation the rectovesical excavation of the peritoneum has been wounded, inducing fatal peritonitis. Puncture through the rectum, therefore, has been almost completely abandoned in favor of the suprapubic route.

Access to the bladder, for the purpose of removing calculi or an enlarged prostate, is almost always effected by the suprapubic route, the old perineal operation being now rarely resorted to. In the female, owing to the shortness of the urethra, and its ready dilatibility, calculi and foreign bodies and new growths, when of small size, may be removed by the urethral route.

Suprapubic cystotomy is performed by first injecting ten or twelve ounces of some weak antiseptic fluid into the bladder. Then, with or without distending the rectum, a vertical median incision, from 7 to 10 cm. in length, is made in the hypogastric region immediately above the symphysis, and extended between the *Pyramidales* and *Recti* until the *transversalis fascia* is reached. This is divided and some fatty tissue exposed (space of Retzius). Upon separating this, the inferior surface of the bladder will be exposed and will be recognized by its muscular fibres. A needle should be passed through its coat on either side of the spot selected for the opening, and two long pieces of silk inserted. The bladder is incised between these stays, which are held by an assistant and form a useful guide to the opening in the bladder when the fluid has escaped.

It is important that the bladder should be emptied by catheter as a routine measure in women, prior to operations on the lower part of the abdomen or pelvis. Neglect of this precaution has, not uncommonly, led to that viscus being opened by accident. Women especially are apt to acquire an atonic distension of the bladder, and the fact that some quantity of urine has been passed immediately before operation is no guarantee that the viscus is not distended. If the accident should occur, the bladder wall must be carefully sutured before the peritoneum is opened.

The Male Urethra (Urethra Virilis) (Fig. 1035).

The **male urethra** extends from the internal urethral orifice in the urinary bladder to the external urethral orifice at the end of the penis. It presents a double curve in the ordinary relaxed state of the penis (Fig. 1030). Its length varies from 17.5 to 20 cm.; and it is divided into three portions, the **prostatic**, **membranous**, and **cavernous**, the structure and relations of which are essentially different. Except during the passage of the urine or semen, the greater part of the urethral canal is a mere transverse cleft or slit, with its upper and under surfaces in contact; at the external orifice the slit is vertical, in the membranous portion irregular or stellate, and in the prostatic portion somewhat arched.

The **prostatic portion** (*pars prostatica*), the widest and most dilatable part of the canal, is about 3 cm. long. It runs almost vertically through the prostate from its base to its apex, lying nearer its anterior than its posterior surface; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest below, where it joins the membranous portion. A transverse section of the canal as it lies in the prostate is horse-shoe-shaped, with the convexity directed forward.

Upon the posterior wall or floor is a narrow longitudinal ridge, the **urethral crest** (*verumontanum*), formed by an elevation of the mucous membrane and its subjacent tissue. It is from 15 to 17 mm. in length, and about 3 mm. in height, and

contains, according to Kobelt, muscular and erectile tissue. When distended, it may serve to prevent the passage of the semen backward into the bladder. On either side of the crest is a slightly depressed fossa, the **prostatic sinus**, the floor of which is perforated by numerous apertures, the **orifices of the prostatic ducts** from the lateral lobes of the prostate; the ducts of the middle lobe open behind the crest. At the forepart of the urethral crest, below its summit, is a median elevation, the **colliculus seminalis**, upon or within the margins of which are the orifices of the prostatic utricle and the slit-like openings of the ejaculatory ducts. The **prostatic utricle** (*sinus pocularis*) forms a cul-de-sac about 6 mm. long, which runs upward and backward in the substance of the prostate behind the middle lobe. Its walls are composed of fibrous tissue, muscular fibres, and mucous

FIG. 1035.—The male urethra laid open on its anterior (upper) surface.

membrane, and numerous small glands open on its inner surface. It was called by Weber the *uterus masculinus*, from its being developed from the united lower ends of the atrophied Müllerian ducts, and therefore homologous with the uterus and vagina in the female.

The **membranous portion** (*pars membranacea*) is the shortest, least dilatable, and, with the exception of the external orifice, the narrowest part of the canal. It extends downward and forward, with a slight anterior concavity, between the apex of the prostate and the bulb of the urethra, perforating the urogenital diaphragm about 2.5 cm. below and behind the pubic symphysis. The hinder part of the urethral bulb lies in apposition with the inferior fascia of the urogenital diaphragm, but its upper portion diverges somewhat from this fascia: the anterior wall of the membranous urethra is thus prolonged for a short distance in front of the urogenital diaphragm; it measures about 2 cm. in length, while the posterior wall which is between the two fasciæ of the diaphragm is only 1.25 cm. long.

The membranous portion of the urethra is completely surrounded by the fibres of the Sphincter urethrae membranaceæ. In front of it the deep dorsal vein of the penis enters the pelvis between the transverse ligament of the pelvis and the arcuate pubic ligament; on either side near its termination are the bulbourethral glands.

The **cavernous portion** (*pars cavernosa; penile or spongy portion*) is the longest part of the urethra, and is contained in the corpus cavernosum urethrae. It is about 15 cm. long, and extends from the termination of the membranous portion to the external urethral orifice. Commencing below the inferior fasciæ of the urogenital diaphragm it passes forward and upward to the front of the symphysis pubis; and then, in the flaccid condition of the penis, it bends downward and forward. It is narrow, and of uniform size in the body of the penis, measuring about 6 mm. in diameter; it is dilated behind, within the bulb, and again anteriorly within the glans penis, where it forms the *fossa navicularis urethrae*.

The **external urethral orifice** (*orificium urethrae externum; meatus urinarius*) is the most contracted part of the urethra; it is a vertical slit, about 6 mm. long, bounded on either side by two small labia.

The lining membrane of the urethra, especially on the floor of the cavernous portion, presents the orifices of numerous mucous glands and follicles situated in the submucous tissue, and named the **urethral glands** (*Littre*). Besides these there are a number of small pit-like recesses, or *lacunæ*, of varying sizes. Their orifices are directed forward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunæ, larger than the rest, is situated on the upper surface of the fossa navicularis; it is called the *lacuna magna*. The bulbo-urethral glands open into the cavernous portion about 2.5 cm. in front of the inferior fascia of the urogenital diaphragm.

Structure.—The urethra is composed of mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The **mucous coat** forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally, with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra, viz., the bulbo-urethral glands and the prostate; and into the ductus deferentes and vesiculæ seminales, through the ejaculatory ducts. In the cavernous and membranous portions the mucous membrane is arranged in longitudinal folds when the tube is empty. Small papillæ are found upon it, near the external urethral orifice; its epithelial lining is of the columnar variety except near the external orifice, where it is squamous and stratified.

The **submucous tissue** consists of a vascular erectile layer; outside this is a layer of unstriated muscular fibres, arranged in a circular direction, which separates the mucous membrane and submucous tissue from the tissue of the corpus cavernosum urethrae.

Applied Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perineum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the

perineum and the history of the accident, will point to the nature of the injury. Rupture of the urethra is due in other cases to the perforation of a periurethral abscess. Extravasation of urine most frequently takes place into the perineum in front of the inferior fascia of the urogenital diaphragm, *i. e.*, under the fascia of Colles. Both these layers of fascia are attached firmly to the ischiopubic rami. It is clear, therefore, that when extravasation of fluid takes place between them, it cannot pass backward, because the two layers are continuous with each other around the Transversus perinaei muscles; it cannot extend laterally, on account of the connection of both these layers to the rami of the pubis and ischium; it cannot find its way into the pelvis, because the opening into this cavity is closed by the urogenital diaphragm, and, therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forward into the areolar tissue of the scrotum and penis, and thence on to the anterior wall of the abdomen.

Gonorrhoea is an acute and very prevalent inflammatory infection of the mucous membrane of the urethra. The causative organisms (gonococci) pass through the mucous membrane into the submucous tissue, and most serious complications and results may follow. In most cases the disease remains limited to the part of the urethra in front of the urogenital diaphragm, but in some (about 10 per cent.) the "posterior urethra" becomes involved in the process, leading to an inflammation of the openings of the prostatic follicles. Such a condition is apt to continue as a very chronic form of prostatitis, and in many cases the infection will spread along the ductus deferens, giving rise to epididymitis.

The anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatability, so that, excepting through the external urethral orifice, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The external orifice of the urethra is not so dilatable, and therefore may require slitting. A recognition of this dilatability caused Bigelow to very considerably modify the operation for crushing a stone in the bladder. In passing catheters, especially fine ones, the point of the instrument should be kept as far as possible along the upper wall of the canal, as otherwise it is very liable to enter one of the lacunae.

Stricture of the urethra is a disease of very common occurrence, and is generally situated in the cavernous part of the urethra, just in front of the membranous portion, but in a very considerable number of cases in the antescrotal part of the canal. The stricture usually results from the contraction of inflammatory products in the submucous tissue, the result, in the vast majority of all cases, of a prolonged gleet following gonorrhoea. Urethral stricture, however, follows rupture of that tube resulting from falls on the perineum, and in this variety is very dense, and is a most unsatisfactory condition with regard to treatment. Congenital stricture is also occasionally met with, and in such cases multiple strictures may be present throughout the whole length of the cavernous portion.

Congenital defects of the urethra occur occasionally. The one most frequently met with is where there is a cleft on the floor of the urethra owing to an arrest of union in the middle line. This is known as *hypospadias*, and the cleft may vary in extent. The simplest and by far the most common form is where the deficiency is confined to the glans penis. The urethra ends at the point where the extremity of the prepuce joins the body of the penis, in a small valve-like opening. The prepuce is also cleft on its under surface and forms a sort of hood over the glans. There is a depression on the glans in the position of the normal meatus. This condition produces no disability and requires no treatment. In more severe cases the cavernous portion of the urethra is cleft throughout its entire length, and the opening of the urethra is at the point of junction of the penis and scrotum. The under surface of the penis in the middle line presents a furrow lined by a moist mucous membrane, on either side of which is often more or less dense fibrous tissue stretching from the glans to the opening of the urethra, which prevents complete erection taking place. Great discomfort is induced during micturition, and sexual connection is impossible. The condition may be remedied by a series of plastic operations. The worst form of this condition is where the urethra is deficient as far back as the perineum, and the scrotum is cleft. The penis is small and bound down between the two halves of the scrotum, so as to resemble an hypertrophied clitoris. The testes are often retained. The condition of parts, therefore, very much resembles the external organs of generation of the female, and many children the victims of this malformation have been brought up as girls. The halves of the scrotum, deficient of testes, resemble the labia, the cleft between them looks like the orifice of the vagina, and the diminutive penis is taken for an enlarged clitoris. There is no remedy for this condition.

A much more uncommon form of malformation is where there is an apparent deficiency of the upper wall of the urethra; this is named *epispadias*. The deficiency may vary in extent; when it is complete the condition is associated with extroversion of the bladder. In less extensive cases, where there is no extroversion, there is an infundibuliform opening into the bladder. The penis is usually dwarfed and turned upward, so that the glans lies over the opening.

The Female Urethra (*Urethra Muliebris*) (Fig. 1032).

The female urethra is a narrow membranous canal, about 4 cm. long, extending from the internal to the external urethral orifice. It is placed behind the symphysis pubis, imbedded in the anterior wall of the vagina, and its direction is obliquely downward and forward; it is slightly curved with the concavity directed forward. Its diameter when undilated is about 6 mm. It perforates the fasciæ of the urogenital diaphragm, and its external orifice is situated directly in front of the vaginal opening and about 2.5 cm. behind the glans clitoridis. The lining membrane is thrown into longitudinal folds, one of which, placed along the floor of the canal, is termed the **urethral crest**. Many small urethral glands open into the urethra.

Structure.—The urethra consists of three coats: **muscular**, **erectile**, and **mucous**.

The **muscular coat** is continuous with that of the bladder; it extends the whole length of the tube, and consists of circular fibres. In addition to this, between the superior and inferior fasciæ of the urogenital diaphragm, the female urethra is surrounded by the *Sphincter urethræ membranaceæ*, as in the male.

A **thin layer of spongy erectile tissue**, containing a plexus of large veins, intermixed with bundles of unstriated muscular fibres, lies immediately beneath the mucous coat.

The **mucous coat** is pale; it is continuous externally with that of the vulva, and internally with that of the bladder. It is lined by stratified squamous epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

THE MALE GENITAL ORGANS (*ORGANA GENITALIA VIRILIA*).

The male genitals include the **testes**, the **ductus deferentes**, the **vesiculæ seminales**, the **ejaculatory ducts**, and the **penis**, together with the following accessory structures, viz., the **prostate** and the **bulbourethral glands**.

The Testes and Their Coverings (Fig. 1036).

The **testes** are two glandular organs, which secrete the semen; they are suspended in the scrotum by the spermatic cords. At an early period of fetal life the testes are contained in the abdominal cavity, behind the peritoneum. Before birth they descend to the inguinal canal, along which they pass with the spermatic cord, and, emerging at the subcutaneous inguinal ring, they descend into the scrotum, becoming invested in their course by coverings derived from the serous, muscular, and fibrous layers of the abdominal parietes, as well as by the scrotum.

The **coverings of the testes** are, the

Skin

Tunica vaginalis.

The **Scrotum** is a cutaneous pouch which contains the testes and parts of the spermatic cords. It is divided on its surface into two lateral portions by a ridge or **raphé**, which is continued forward to the under surface of the penis, and backward, along the middle line of the perineum to the anus. Of these two lateral portions the left hangs lower than the right, to correspond with the greater length of the left spermatic cord. Its external aspect varies under different circumstances: thus, under the influence of warmth, and in old and debilitated persons, it becomes elongated and flaccid; but, under the influence of cold, and in the young and robust, it is short, corrugated, and closely applied to the testes.

The scrotum consists of two layers, the **integument** and the **dartos tunic**.

The **Integument** is very thin, of a brownish color, and generally thrown into folds or rugæ. It is provided with sebaceous follicles, the secretion of which has a

peculiar odor, and is beset with thinly scattered, crisp hairs, the roots of which are seen through the skin.

The **Dartos Tunic** (*tunica dartos*) is a thin layer of non-striped muscular fibres, continuous, around the base of the scrotum, with the two layers of the superficial fascia of the groin and the perineum; it sends inward a septum, which divides the scrotal pouch into two cavities for the testes, and extends between the raphé and the under surface of the penis, as far as its root.

The dartos tunic is closely united to the skin externally, but connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility.

FIG. 1036.—Transverse section through the left side of the scrotum and the left testis. The sac of the tunica vaginalis is represented in a distended condition. (Diagrammatic.) (Dolépine.)

The **Intercrural Fascia** (*intercolumnar or external spermatic fascia*) is a thin membrane, prolonged downward around the surface of the cord and testis (see page 501). It is separated from the dartos tunic by loose areolar tissue.

The **Cremaster** consists of scattered bundles of muscular fibres connected together into a continuous covering by intermediate areolar tissue (see page 504).

The **Infundibuliform Fascia** (*tunica vaginalis communis* [*testis et funiculi spermatici*]) is a thin layer, which loosely invests the cord; it is a continuation downward of the transversalis fascia (see page 508).

The **Tunica Vaginalis** is described with the testes.

Vessels and Nerves.—The arteries supplying the coverings of the testes are: the superficial and deep external pudendal branches of the femoral, the superficial perineal branch of the internal pudendal, and the cremasteric branch from the inferior epigastric. The veins follow the course of the corresponding arteries. The lymphatics end in the inguinal lymph glands. The nerves are the ilioinguinal and lumboinguinal branches of the lumbar plexus, the two superficial perineal branches of the internal pudendal nerve, and the pudendal branch of the posterior femoral cutaneous nerve.

The **Inguinal Canal** (*canalis inguinalis*) is described on page 508.

The **Spermatic Cord** (*funiculus spermaticus*) extends from the abdominal inguinal ring, where the structures of which it is composed converge, to the back part of the testis. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first beneath the Obliquus internus, and upon the fascia

transversalis; but nearer the pubis, it rests upon the inguinal and lacunar ligaments, having the aponeurosis of the *Obliquus externus* in front of it, and the inguinal falx behind it. It then escapes at the subcutaneous ring, and descends nearly vertically into the scrotum. The left cord is rather longer than the right, consequently the left testis hangs somewhat lower than its fellow.

Structure of the Spermatic Cord.—The spermatic cord is composed of arteries, veins, lymphatics, nerves, and the excretory duct of the testis. These structures are connected together by areolar tissue, and invested by the layers brought down by the testis in its descent.

The **arteries of the cord** are: the internal and external spermatics; and the artery to the ductus deferens.

The **internal spermatic artery**, a branch of the abdominal aorta, escapes from the abdomen at the abdominal inguinal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the subcutaneous inguinal ring into the scrotum. It then descends to the testis, and, becoming tortuous, divides into several branches, two or three of which accompany the ductus deferens and supply the epididymis, anastomosing with the artery of the ductus deferens: the others supply the substance of the testis.

The **external spermatic artery** is a branch of the inferior epigastric artery. It accompanies the spermatic cord and supplies the coverings of the cord, anastomosing with the internal spermatic artery.

The **artery of the ductus deferens**, a branch of the superior vesical, is a long, slender vessel, which accompanies the ductus deferens, ramifying upon its coats, and anastomosing with the internal spermatic artery near the testis.

The **spermatic veins** emerge from the back of the testis, and receive tributaries from the epididymis: they unite and form a convoluted plexus, the **plexus pampiniformis**, which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the ductus deferens; below the subcutaneous inguinal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the abdominal inguinal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava, at an acute angle, and on the left side into the left renal vein, at a right angle.

The **lymphatic vessels** are described on page 794.

The **nerves** are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the ductus deferens.

Applied Anatomy.—The scrotum forms an admirable covering for the protection of the testes. These bodies, lying suspended and loose in the cavity of the scrotum and surrounded by serous membrane, are capable of great mobility, and can therefore easily slip about within the scrotum and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distension, and on account of the looseness and amount of subcutaneous tissue, the scrotum becomes greatly enlarged in cases of oedema, to which this part is especially liable as a result of its dependent position. The scrotum is occasionally the seat of epithelioma; this is no doubt due to the rugæ on its surface, which favor the lodgement of dirt, and this, producing irritation, is the exciting cause of the disease. The disease is very much less common than it used to be; this is probably due to the better hygienic conditions of the working classes. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue, large extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local blood-letting from this part is judged to be desirable. The muscular fibre in the dartos tunic causes contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and are of assistance in keeping the edges together, and covering the exposed parts.

The **Testes** are suspended in the scrotum by the spermatic cords, the left testis hanging somewhat lower than its fellow. The average dimensions of the testis are from 4 to 5 cm. in length, 2.5 cm. in breadth, and 3 cm. in the antero-posterior diameter; its weight varies from 10.5 to 14 gm. Each testis is of an oval form (Fig. 1037), compressed laterally, and having an oblique position in the scrotum; the upper extremity is directed forward and a little lateralward; the lower, backward and a little medialward; the anterior convex border looks forward and downward, the posterior or straight border, to which the cord is attached, backward and upward.

The anterior border and lateral surfaces, as well as both extremities of the organ,

are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying upon the lateral edge of this posterior border is a long, narrow, flattened body, named the **epididymis**.

The **epididymis** consists of a central portion or **body**; an upper enlarged extremity, the **head** (*globus major*); and a lower pointed extremity, the **tail** (*globus minor*), which is continuous with the ductus deferens, the **duct of the testis**. The head is intimately connected with the upper end of the testis by means of the efferent ductules of the gland; the tail is connected with the lower end by cellular tissue, and a reflection of the tunica vaginalis. The lateral surface, head and tail of the epididymis are free and covered by the serous membrane; the body is also completely invested by it, excepting along its posterior border; while between the body and the testis is a pouch, named the **sinus of the epididymis** (*digital fossa*). The epididymis is connected to the back of the testis by a fold of the serous membrane.

FIG. 1037.—The right testis, exposed by laying open the tunica vaginalis.

Appendages of the Testis and Epididymis.—On the upper extremity of the testis, just beneath the head of the epididymis, is a minute oval, sessile body, the **appendix of the testis** (*hydatid of Morgagni*); it is the remnant of the upper end of the Müllerian duct. On the head of the epididymis is a second small stalked appendage (sometimes duplicated); it is named the **appendix of the epididymis** (*pedunculated hydatid*), and is usually regarded as a detached efferent duct.

The testis is invested by three tunics: the **tunica vaginalis**, **tunica albuginea**, and **tunica vasculosa**.

The **Tunica Vaginalis** (*tunica vaginulis propria testis*) is the serous covering of the testis. It is a pouch of serous membrane, derived from the saccus vaginalis of the peritoneum, which in the fetus preceded the descent of the testis from the abdomen into the scrotum. After its descent, that portion of the pouch which extends from the abdominal inguinal ring to near the upper part of the gland becomes obliterated; the lower portion remains as a shut sac, which invests the surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a **visceral** and **parietal lamina**.

The **visceral lamina** (*lamina visceralis*) covers the greater part of the testis and epididymis, connecting the latter to the testis by means of a distinct fold. From

the posterior border of the gland it is reflected on to the internal surface of the scrotum.

The **parietal lamina** (*lamina parietalis*) is far more extensive than the visceral, extending upward for some distance in front and on the medial side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal laminæ constitutes the cavity of the tunica vaginalis.

The obliterated portion of the saccus vaginalis may generally be seen as a fibro-cellular thread lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia (page 1187). In other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.

The **Tunica Albuginea** is the fibrous covering of the testis. It is a dense membrane, of a bluish-white color, composed of bundles of white fibrous tissue which interlace in every direction. It is covered by the tunica vaginalis, except at the points of attachment of the epididymis to the testis, and along its posterior border, where the spermatic vessels enter the gland. It is applied to the tunica vasculosa over the glandular substance of the testis, and, at its posterior border, is reflected into the interior of the gland, forming an incomplete vertical septum, called the **mediastinum testis** (*corpus Highmori*).

The **mediastinum testis** extends from the upper to near the lower extremity of the gland, and is wider above than below. From its front and sides numerous imperfect septa (*trabeculae*) are given off, which radiate toward the surface of the organ, and are attached to the tunica albuginea. They divide the interior of the organ into a number of incomplete spaces which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the vessels and duct of the testis in their passage to and from the substance of the gland.

The **Tunica Vasculosa** is the vascular layer of the testis, consisting of a plexus of bloodvessels, held together by delicate areolar tissue. It clothes the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

Structure.—The glandular structure of the testis consists of numerous lobules. Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules (Fig. 1038) are conical in shape, the base being directed toward the circumference of the organ, the apex toward the mediastinum. Each lobule is contained in one of the intervals between the fibrous septa which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three, or more, minute convoluted tubes, the **tubuli seminiferi**. The tubules may be separately unravelled, by careful dissection under water, and may be seen to commence either by free cecal ends or by anastomotic loops. They are supported by loose connective tissue which contains here and there groups of "interstitial cells" containing yellow pigment granules. The total number of tubules is estimated by Lauth at 840, and the average length of each is 70 to 80 cm. Their diameter varies from 0.12 to 0.3 mm. The tubules are pale in color in early life, but in old age they acquire a deep yellow tinge from containing much fatty matter. Each tubule consists of a basement layer formed of laminated connective tissue containing numerous elastic fibres with flattened cells between the layers and covered externally by a layer of flattened epithelioid cells. Within the basement-membrane are epithelial cells arranged in several irregular layers, which are not always clearly separated, but which may be arranged in three different groups (Fig. 1039). Among these cells may be seen the **spermatozoa** in different

stages of development. (1) Lining the basement membrane and forming the outer zone is a layer of cubical cells, with small nuclei; some of these enlarge to become *spermatogonia*. The nucleus of some of the *spermatogonia* may be seen to be in process of indirect division (*karyokinesis*, page 34), and in consequence of this daughter cells are formed, which constitute the second zone. (2) Within this first layer is to be seen a number of larger polyhedral cells, with clear nuclei, arranged in two or three layers; these are the *intermediate cells* or *spermatocytes*. Most of these cells are in a condition of karyokinetic division, and the cells which result from this division form those of the next layer, the *spermatoblasts* or *spermatids*. (3) The third layer of cells consists of the *spermatoblasts* or *spermatids*, and each of these, without further subdivision, becomes a *spermatozoön*. The *spermatids* are small polyhedral cells, the nucleus of each of which contains half the usual number of chromosomes. In addition to these three layers of cells others are seen, which are termed the *supporting cells* (*cells of Sertoli*). They are elongated and columnar, and project inward from the basement membrane toward the lumen of the tube. As development of the spermatozoa proceeds the latter group themselves around the inner extremities of the supporting cells. The nuclear portion of the spermatid, which is partly imbedded in the supporting cell, is differentiated to form the head of the spermatozoön, while part of the cell protoplasm forms the middle piece and the tail is produced by an outgrowth from the double centriole of the cell. Ultimately the heads are liberated and the spermatozoa are set free. The structure of the spermatozoa is described on pages 80, 81.

In the apices of the lobules, the tubules become less convoluted, assume a nearly straight course, and unite together to form from twenty to thirty larger ducts, of about 0.5 mm. in diameter, and these, from their straight course, are called *tubuli recti* (Fig. 1038).

The *tubuli recti* enter the fibrous tissue of the mediastinum, and pass upward and backward, forming, in their ascent, a close net-work of anastomosing tubes which are merely channels in the fibrous stroma, lined by flattened epithelium, and having no proper walls; this constitutes the *rete testis*. At the upper end of the mediastinum, the vessels of the *rete testis* terminate in from twelve to fifteen or twenty ducts, the *ductuli efferentes*; they perforate the tunica albuginea, and carry the seminal fluid from the testis to the epididymis. Their course is at first straight; they then become enlarged, and exceedingly convoluted, and form a series of conical masses,

the *coni vasculosi*, which together constitute the head of the epididymis. Each cone consists of a single convoluted duct, from 15 to 20 cm. in length, the diameter of which gradually decreases from the testis to the epididymis. Opposite the bases of the cones the efferent vessels open at narrow intervals into a single duct, which constitutes, by its complex convolutions, the body and tail of the epididymis. When the convolutions of this tube are unravelled, it measures upward of 6 metres in length; it increases in diameter and thickness as it approaches the ductus

deferens. The convolutions are held together by fine areolar tissue, and by bands of fibrous tissue.

The tubuli recti have very thin walls; like the channels of the rete testis they are lined by a single layer of flattened epithelium. The ductuli efferentes and the tube of the epididymis have walls of considerable thickness, on account of the presence in them of muscular tissue, which is principally arranged in a circular manner. These tubes are lined by columnar ciliated epithelium (Fig. 1040).

Applied Anatomy.—The testis, developed in the lumbar region, may be arrested or delayed in its transit to the scrotum. It may be retained in the abdomen; or it may be arrested at the abdominal inguinal ring, or in the inguinal canal; or it may just pass out of the subcutaneous inguinal ring without finding its way to the bottom of the scrotum. When retained in the abdomen it gives rise to no symptoms, other than the absence of the testis from the scrotum; but when it is retained in the inguinal canal it is subjected to pressure and may become inflamed and painful. The retained testis is probably functionally useless; so that a man in whom both testes are retained (*anorchism*) is sterile, though he may not be impotent. The absence of one testis is termed *monorchism*. When a testis is retained in the inguinal canal it is often complicated with a congenital hernia, the funicular process of the peritoneum not being obliterated. In addition to the cases above described, where there is some arrest in the descent of the testis, this organ may descend through the inguinal canal, but may miss the scrotum and assume some abnormal position. The most common form is where the testis, emerging at the subcutaneous inguinal ring, slips down between the scrotum and thigh and comes to rest in the perineum. This is known as *perineal ectopia testis*. With all varieties of abnormality in the position of the testis, it is very common to find concurrently a congenital hernia, or, if a hernia be not actually present, the funicular process is usually patent, and almost invariably so if the testis is in the inguinal canal.

*Ciliated
epithelium*

*Spermatozoa
in lumen*

FIG. 1040.—Section of epididymis of guinea-pig. $\times 255$.

The testis, finally reaching the scrotum, may occupy an abnormal position in it. It may be inverted, so that its posterior or attached border is directed forward and the tunica vaginalis is situated behind. Should a hydrocele occur, and tapping be resorted to, the trocar may be thrust into the testis, if the operation is performed in the ordinary way, and care is not taken beforehand to ascertain the position of the gland.

A number of instances of torsion of the spermatic cord, resulting in acute strangulation of the testis, have been recorded. In some it has been attributed to a strain or twist, and in several patients the condition has been associated with a late descent of the organ. Symptoms of this condition closely simulate those of a strangulated hernia. In consequence of the torsion the circulation is partly arrested and the organ swells and becomes acutely painful, and the condition may be accompanied with shock and vomiting. Gangrene of the testis, however, rarely follows, and the condition, if left without operation, ends in atrophy of the organ. Torsion of the body of the testis also sometimes occurs within the tunica vaginalis in those cases in which a persistent mesorchium is present.

Fluid collections of a serous character are very frequently found in the scrotum. To these the term *hydrocele* is applied. The most common form is the ordinary *vaginal hydrocele*, in which the fluid is contained in the sac of the tunica vaginalis, which is separated, in its normal condition, from the peritoneal cavity by the whole extent of the inguinal canal. In another form, the *congenital hydrocele*, the fluid is in the sac of the tunica vaginalis, but this cavity communicates with the general peritoneal cavity, its tubular process remaining pervious. A third variety,

known as an *infantile hydrocele*, occurs in those cases where the tubular process becomes obliterated only at its upper part, at or near the abdominal inguinal ring. It resembles the vaginal hydrocele, except as regards its shape, the collection of fluid extending up the cord into the inguinal canal. Fourthly, the funicular process may become obliterated both at the abdominal inguinal ring and above the epididymis, leaving a central unobliterated portion, which may become distended with fluid, giving rise to a condition known as the *encysted hydrocele of the cord*.

Encysted hydrocele of the epididymis or *spermatocele* is the name given to a cyst found in connection with the head of the epididymis. Among its contents are found, in many instances, a varying number of spermatozoa, and it is probably a retention cyst of one of the tubules.

The testis frequently requires removal for malignant disease; in tuberculous disease; in cases of large *hernia testis*, and in some instances of incompletely descended or misplaced testes. The operation of castration was formerly performed for enlargement of the prostate, but has now been entirely abandoned in favor of the direct operation of the enlarged prostate. Castration is in most cases best carried out by the "high" operation, an incision being made through the skin and fascia in the region of the subcutaneous inguinal ring. The testis, with its deeper coverings, is then pushed up into the wound and separated from the scrotal tissues. The cord is then isolated, and an aneurism needle, armed with a ligature, passed through it, as high as it is thought necessary, and the cord tied and divided. In cases of malignant and tuberculous disease, it is desirable to open the inguinal canal and tie the cord as near the abdominal ring as possible. When removing the testis in this manner the tunica vaginalis is not opened and its folds of reflection to the scrotal tissues do not need division. The whole of the tunica vaginalis is thus removed with the cord and its coverings.

Acute inflammation of the testis, or *orchitis*, is common in gonorrhoea; a chronic fibrosing form of orchitis is frequent in syphilis, and leads to shrinkage and hardening of the testis. In *tabes dorsalis* the testis often becomes quite insensitive to pressure, which, in the healthy adult, readily produces a severe and peculiar sickening sensation.

The Ductus Deferens (Vas Deferens; Seminal Duct).

The *ductus deferens*, the excretory duct of the testis, is the continuation of the canal of the epididymis. Commencing at the lower part of the tail of the epididymis it is at first very tortuous, but gradually becoming less twisted it ascends along the posterior border of the testis and medial side of the epididymis, and, as a constituent of the spermatic cord, traverses the inguinal canal to the abdominal inguinal ring. Here it separates from the other structures of the cord, curves around the lateral side of the inferior epigastric artery, and ascends for about 2.5 cm. in front of the external iliac artery. It is next directed backward and slightly downward, and, crossing the external iliac vessels obliquely, enters the pelvic cavity, where it lies between the peritoneal membrane and the lateral wall of the pelvis, and descends on the medial side of the obliterated umbilical artery and the obturator nerve and vessels. It then crosses in front of the ureter, and, reaching the medial side of this tube, bends to form an acute angle, and runs medialward and slightly forward between the fundus of the bladder and the upper end of the seminal vesicle. Reaching the medial side of the seminal vesicle, it is directed downward and medialward in contact with it, gradually approaching the opposite ductus. Here it lies between the fundus of the bladder and the rectum, where it is enclosed, together with the seminal vesicle, in a sheath derived from the rectovesical portion of the fascia endopelvina. Lastly, it is directed downward to the base of the prostate, where it becomes greatly narrowed, and is joined at an acute angle by the duct of the seminal vesicle to form the ejaculatory duct, which traverses the prostate behind its middle lobe and opens into the prostatic portion of the urethra, close to the orifice of the prostatic utricle. The ductus deferens presents a hard and cord-like sensation to the fingers, and is of cylindrical form; its walls are dense, and its canal is extremely small. At the fundus of the bladder it becomes enlarged and tortuous, and this portion is termed the *ampulla*. A small triangular area of the fundus of the bladder, between the ductus deferentes laterally and the bottom of the rectovesical excavation of peritoneum above, is in contact with the rectum.

Ductuli Aberrantes.—A long narrow tube, the **ductulus aberrans inferior** (*vas aberrans of Haller*), is occasionally found connected with the lower part of the canal of the epididymis, or with the commencement of the ductus deferens. Its length varies from 3.5 to 35 cm., and it may become dilated toward its extremity; more commonly it retains the same diameter throughout. Its structure is similar to that of the ductus deferens. Occasionally it is found unconnected with the epididymis. A second tube, the **ductulus aberrans superior**, occurs in the head of the epididymis; it is connected with the rete testis.

Paradidymis (*organ of Giralde's*).—This term is applied to a small collection of convoluted tubules, situated in front of the lower part of the cord above the head of the epididymis. These tubes are lined with columnar ciliated epithelium, and probably represent the remains of a part of the Wolffian body.

Structure.—The ductus deferens consists of three coats: (1) an **external or areolar coat**; (2) a **muscular coat** which in the greater part of the tube consists of two layers of unstriped muscular fibre: an outer, longitudinal in direction, and an inner, circular; but in addition to these, at the commencement of the ductus, there is a third layer, consisting of longitudinal fibres, placed internal to the circular stratum, between it and the mucous membrane; (3) an **internal or mucous coat**, which is pale, and arranged in longitudinal folds. The mucous coat is lined by columnar epithelium which is non-ciliated throughout the greater part of the tube; a variable portion of the testicular end of the tube is lined by two strata of columnar cells and the cells of the superficial layer are ciliated.

The Vesiculæ Seminales (Seminal Vesicles) (Fig. 1041).

The **vesiculæ seminales** are two lobulated membranous pouches, placed between the fundus of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testes. Each sac is somewhat

FIG. 1041.—Fundus of the bladder with the vesiculæ seminales.

pyramidal in form, the broad end being directed backward, upward and lateralward. It is usually about 7.5 cm. long, but varies in size, not only in different individuals, but also in the same individual on the two sides. The **anterior surface** is in contact with the fundus of the bladder, extending from near the termination of the ureter to the base of the prostate. The **posterior surface** rests upon the rectum, from which it is separated by the rectovesical fascia. The **upper extremities** of the two vesicles diverge from each other, and are in relation with the ductus deferentes and the terminations of the ureters, and are partly covered by peritoneum. The **lower**

extremities are pointed, and converge toward the base of the prostate, where each joins with the corresponding ductus deferens to form the ejaculatory duct. Along the medial margin of each vesicle runs the ampulla of the ductus deferens.

Each vesicle consists of a single tube, coiled upon itself, and giving off several irregular cecal diverticula; the separate coils, as well as the diverticula, are connected together by fibrous tissue. When uncoiled, the tube is about the diameter of a quill, and varies in length from 10 to 15 cm.; it ends posteriorly in a cul-de-sac; its anterior extremity becomes constricted into a narrow straight duct, which joins with the corresponding ductus deferens to form the ejaculatory duct.

Structure.—The vesiculæ seminales are composed of three coats: an **external or areolar coat**; a **middle or muscular coat** thinner than in the ductus deferens and arranged in two layers, an outer longitudinal and inner circular; an **internal or mucous coat**, which is pale, of a whitish brown color, and presents a delicate reticular structure. The epithelium is columnar, and in the diverticula goblet cells are present, the secretion of which increases the bulk of the seminal fluid.

Vessels and Nerves.—The **arteries** supplying the vesiculæ seminales are derived from the middle and inferior vesical and middle hemorrhoidal. The **veins** and **lymphatics** accompany the arteries. The **nerves** are derived from the pelvic plexuses.

Applied Anatomy.—The vesiculæ seminales are often the seat of an extension of the disease in cases of tuberculosis of the testis, and should always be examined from the rectum, before deciding to perform castration in this affection. They also become affected in chronic posterior urethritis of gonorrhoeal origin.

The Ejaculatory Ducts (Ductus Ejaculatorii) (Fig. 1042).

The **ejaculatory ducts** are two in number, one on either side of the middle line. Each is formed by the union of the duct from the vesicula seminalis with the ductus deferens, and is about 2 cm. long.

They commence at the base of the prostate, and run forward and downward between its middle and lateral lobes, and along the sides of the prostatic utricle, to end by separate slit-like orifices close to or just within the margins of the utricle. The ducts diminish in size, and also converge, toward their terminations.

Structure. The coats of the ejaculatory ducts are extremely thin. They are: an **outer fibrous layer**, which is almost entirely lost after the entrance of the ducts into the prostate; a **layer of muscular fibres** consisting of a thin outer circular, and an inner longitudinal, layer; and **mucous membrane**.

FIG. 1042.—Vesiculæ seminales and ampullæ of ductus deferentes, seen from the front. The anterior walls of the left ampulla, left seminal vesicle, and prostatic urethra have been cut away.

The Penis.

The **penis** is a pendulous organ suspended from the front and sides of the pubic arch and containing the greater part of the urethra. In the flaccid condition it is cylindrical in shape, but when erect assumes the form of a triangular prism with rounded angles, one side of the prism forming the dorsum. It is composed of three cylindrical masses of cavernous tissue bound together by fibrous tissue and covered with skin. Two of the masses are lateral, and are known as the **corpora cavernosa penis**; the third is median, and is termed the **corpus cavernosum urethrae** (Figs. 1043, 1044).

The **Corpora Cavernosa Penis** form the greater part of the substance of the penis. For their anterior three-fourths they lie in intimate apposition with one another, but behind they diverge in the form of two tapering processes, known as the *crura*, which are firmly connected to the rami of the pubic arch. Traced from behind forward, each crus begins by a blunt-pointed process in front of the tuberosity of the ischium. Just before it meets its fellow it presents a slight enlargement, named by Kobelt the **bulb of the corpus cavernosum penis**. Beyond this point the crus undergoes a constriction and merges into the corpus cavernosum proper,

which retains a uniform diameter to its anterior end. Each corpus cavernosum penis ends abruptly in a rounded extremity some distance from the point of the penis.

The corpora cavernosa penis are surrounded by a strong fibrous envelope consisting of superficial and deep fibres. The superficial fibres are longitudinal in direction, and form a single tube which encloses both corpora; the deep fibres are arranged circularly around each corpus, and form by their junction in the median plane the **septum of the penis**. This is thick and complete behind, but is imperfect in front, where it consists of a series of vertical bands arranged like the teeth of a comb; it is therefore named the **septum pectiniforme**.

The **Corpus Cavernosum Urethrae** (*corpus spongiosum*) contains the urethra.

FIG. 1043.—The constituent cavernous cylinders of the penis. The glans and anterior part of the corpus cavernosum urethrae are detached from the corpora cavernosa penis and turned to one side.

FIG. 1044.—Transverse section of the penis.

Behind, it is expanded to form the urethral bulb, and lies in apposition with the inferior fascia of the urogenital diaphragm, from which it receives a fibrous investment. The urethra enters the bulb nearer to the upper than to the lower surface. On the latter there is a median sulcus, from which a thin fibrous septum projects into the substance of the bulb and divides it imperfectly into two lateral lobes or hemispheres.

The portion of the corpus cavernosum urethrae in front of the bulb lies in a groove on the under surface of the conjoined corpora cavernosa penis. It is cylindrical in form and tapers slightly from behind forward. Its anterior end is expanded in the form of an obtuse cone, flattened from above downward. This expansion, termed the **glans penis**, is moulded on the rounded ends of the corpora cavernosa

penis, extending farther on their upper than on their lower surfaces. At the summit of the glans is the slit-like vertical external urethral orifice. The circumference of the base of the glans forms a rounded projecting border, the **corona glandis**, overhanging a deep **retroglandular sulcus**, behind which is the **neck** of the penis.

For descriptive purposes it is convenient to divide the penis into three regions: the **root**, the **body**, and the **extremity**.

The **root** (*radix penis*) of the penis is triradiate in form, consisting of the diverging crura, one on either side, and the median urethral bulb. Each crus is covered by the Ischiocavernosus, while the bulb is surrounded by the Bulbocavernosus. The root of the penis lies in the perineum between the inferior fascia of the urogenital diaphragm and the fascia of Colles. In addition to being attached to the fasciæ and the pubic rami, it is bound to the front of the symphysis pubis by the fundiform and suspensory ligaments. The **fundiform ligament** springs from the front of the sheath of the Rectus abdominis and the linea alba; it splits into two fasciculi which encircle the root of the penis. The upper fibres of the **suspensory ligament** pass downward from the lower end of the linea alba, and the lower fibres from the symphysis pubis; together they form a strong fibrous band, which extends to the upper surface of the root, where it blends with the fascial sheath of the organ.

The **body** (*corpus penis*) extends from the root to the ends of the corpora cavernosa penis, and in it these corpora cavernosa are intimately bound to one another. A shallow groove which marks their junction on the upper surface lodges the deep dorsal vein of the penis, while a deeper and wider groove between them on the under surface contains the corpus cavernosum urethrae. The body is ensheathed by fascia, which is continuous above with the fascia of Scarpa, and below with the dartos tunic of the scrotum and the fascia of Colles.

The **extremity** is formed by the glans penis, the expanded anterior end of the corpus cavernosum urethrae. It is separated from the body by the constricted neck, which is overhung by the corona glandis.

The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and its absence of adipose tissue. At the root of the penis it is continuous with that over the pubes, scrotum, and perineum. At the neck it leaves the surface and becomes folded upon itself to form the **prepuce** or **foreskin**. The internal layer of the prepuce is directly continuous, along the line of the neck, with the integument over the glans. Immediately behind the external urethral orifice it forms a small secondary reduplication, attached along the bottom of a depressed median raphé, which extends from the meatus to the neck; this fold is termed the **frenulum** of the prepuce. The integument covering the glans is continuous with the urethral mucous membrane at the orifice; it is devoid of hairs, but projecting from its free surface are a number of small, highly sensitive papillæ. On the corona and neck numerous small glands, the **preputial glands**, have been described.¹ They secrete a sebaceous material of very peculiar odor, which probably contains casein, and readily undergoes decomposition.

The prepuce covers a variable amount of the glans, and is separated from it by a potential sac—the **preputial sac**—which presents two shallow fossæ, one on either side of the frenulum.

Structure of the Penis.—From the internal surface of the fibrous envelope of the corpora cavernosa penis, as well as from the sides of the septum, numerous bands or cords are given off, which cross the interior of these corpora cavernosa in all directions, subdividing them into a number of separate compartments, and giving the entire structure a spongy appearance (Fig. 1044). These bands and cords are called **trabeculæ**, and consist of white fibrous tissue, elastic fibres, and plain muscular fibres. In them are contained numerous arteries and nerves. The component fibres which form the trabeculæ are larger and stronger around the circumference than

¹ Stieda (Comptes-rendus du XII Congrès International de Médecine, Moscow, 1897) asserts that glands are never found on the corona glandis, and that what have hitherto been mistaken for glands are really large papillæ.

at the centres of the corpora cavernosa; they are also thicker behind than in front. The interspaces (cavernous spaces), on the contrary, are larger at the centre than at the circumference, their long diameters being directed transversely. They are filled with blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins.

The fibrous envelope of the corpus cavernosum urethrae is thinner, whiter in color, and more elastic than that of the corpora cavernosa penis. The trabeculae are more delicate, nearly uniform in size, and the meshes between them smaller than in the corpora cavernosa penis: their long diameters, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus cavernosum urethrae is formed partly of unstriated muscular fibres, and a layer of the same tissue immediately surrounds the canal of the urethra.

Vessels and Nerves.—The arteries bringing the blood to the cavernous spaces are the deep arteries of the penis and branches from the dorsal arteries of the penis, which perforate the fibrous capsule, along the upper surface, especially near the forepart of the organ. On entering the cavernous structure the arteries divide into branches, which are supported and enclosed by the trabeculae. Some of these arteries end in a capillary net-work, the branches of which open directly

into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller **helicine arteries**. They open into the spaces, and from them are also given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are most abundant in the back part of the corpora cavernosa (Fig. 1045).

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the dorsum of the organ to form the deep dorsal vein; others pass out on the upper surface of the corpora cavernosa and join the same vein; some emerge from the under surface of the corpora cavernosa penis and receiving branches from the corpus cavernosum urethrae, wind around the sides of the penis to end in the deep dorsal vein; but the greater number pass out at the root of the penis and join the prostatic plexus.

FIG. 1045.—Section of corpus cavernosum penis in a non-distended condition. (Cadiat.) a. Trabeculae of connective tissue, with many elastic fibres and bundles of plain muscular tissue, some of which are cut across (c). b. Blood sinuses.

The lymphatic vessels of the penis are described on page 794.

The nerves are derived from the pudendal nerve and the pelvic plexuses. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them end in peculiar end-bulbs (see page 1069).

Applied Anatomy.—The penis occasionally requires removal for malignant disease. Usually, removal of the antescrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the pubes and ischia. The former operation is performed by cutting through the corpora cavernosa penis from the dorsum, and then separating the corpus cavernosum urethrae from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which might otherwise take place. The vessels which require ligature are the deep and the dorsal arteries of the penis, and the artery of the septum. When the entire organ requires removal, the patient is placed in the lithotomy position, and an incision is made through the skin and subcutaneous tissue around the root of the penis, and carried down through the median line of the scrotum as far as the perineum. The two halves of the scrotum are then separated from each other, and a catheter having been introduced into the bladder as a guide, the corpus cavernosum urethrae below the urogenital diaphragm is separated from the corpora cavernosa penis and divided, the catheter having been withdrawn. The suspensory ligament is now severed and the crura separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perineum. The remainder of the wound is closed, free drainage being provided for.

The Prostate (Prostata; Prostate Gland).

The **prostate** is a firm, partly glandular and partly muscular body, which is placed immediately below the internal urethral orifice and around the commencement of the urethra. It is situated in the pelvic cavity, below the lower part of the symphysis pubis, above the superior fascia, of the urogenital diaphragm, and in front of the rectum, through which it may be distinctly felt, especially when enlarged. It is about the size of a chestnut and somewhat conical in shape, and presents for examination a **base**, an **apex**, an **anterior**, a **posterior**, and two **lateral surfaces**.

The **base** (*basis prostatae*) is directed upward, and is applied to the inferior surface of the bladder. The greater part of this surface is directly continuous with the bladder wall; the urethra penetrates it nearer its anterior than its posterior border.

The **apex** (*apex prostatae*) is directed downward, and is in contact with the superior fascia of the urogenital diaphragm.

Surfaces.—The **posterior surface** (*facies posterior*) is flattened from side to side and slightly convex from above downward; it is separated from the rectum by its sheath and some loose connective tissue, and is distant about 4 cm. from the anus. Near its upper border there is a depression through which the two ejaculatory ducts enter the prostate. This depression serves to divide the posterior surface into a lower larger and an upper smaller part. The upper smaller part constitutes the **middle lobe** of the prostate and intervenes between the ejaculatory ducts and the urethra; it varies greatly in size, and in some cases is destitute of glandular tissue. The lower larger portion sometimes presents a shallow median furrow, which imperfectly separates it into a **right** and a **left lateral lobe**: these form the main mass of the gland and are directly continuous with each other behind the urethra. In front of the urethra they are connected by a band which is named the **isthmus**: this consists of the same tissues as the capsule and is devoid of glandular substance.

The **anterior surface** (*facies anterior*) measures about 2.5 cm. from above downward but is narrow and convex from side to side. It is placed about 2 cm. behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the puboprostatic ligaments. The urethra emerges from this surface a little above and in front of the apex of the gland.

The **lateral surfaces** are prominent, and are covered by the anterior portions of the Levatores ani, which are, however, separated from the gland by a plexus of veins.

The prostate measures about 4 cm. transversely at the base, 2 cm. in its antero-posterior diameter, and 3 cm. in its vertical diameter. Its weight is about 8 gm. It is held in its position by the puboprostatic ligaments; by the superior fascia of the urogenital diaphragm, which invests the prostate and the commencement of the membranous portion of the urethra; and by the anterior portions of the Levatores ani, which pass backward from the pubis and embrace the sides of the prostate. These portions of the Levatores ani, from the support they afford to the prostate, are named the **Levatores prostatae**.

The prostate is perforated by the urethra and the ejaculatory ducts. The urethra usually lies along the junction of its anterior with its middle third. The ejaculatory ducts pass obliquely downward and forward through the posterior part of the prostate, and open into the prostatic portion of the urethra.

Structure (Fig. 1046).—The prostate is immediately enveloped by a thin but firm fibrous capsule, distinct from that derived from the fascia endopelvina, and separated from it by a plexus of veins. This capsule is firmly adherent to the prostate and is structurally continuous with the stroma of the gland, being composed of the same tissues, viz.: non-striated muscle and fibrous

tissue. The substance of the prostate is of a pale reddish-gray color, of great density, and not easily torn. It consists of glandular substance and muscular tissue.

The **muscular tissue** according to Kölliker, constitutes the proper stroma of the prostate; the connective tissue being very scanty, and simply forming between the muscular fibres, thin trabeculae, in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: immediately beneath the fibrous capsule is a dense layer, which forms an investing sheath for the gland; secondly, around the urethra, as it lies in the prostate, is another dense layer of circular fibres, continuous above with the internal layer of the muscular coat of the bladder, and blending below with the fibres surrounding the membranous portion of the urethra. Between these two layers strong bands of muscular tissue, which decussate freely, form meshes in which the glandular structure of the organ is imbedded. In that part of the gland which is situated in front of the urethra the muscular tissue is especially dense, and there is here little or no gland tissue; while in that part which is behind the urethra the muscular tissue presents a wide-meshed structure, which is densest at the base of the gland—that is, near the bladder—becoming looser and more sponge-like toward the apex of the organ.

FIG. 1046.—Transverse section of normal prostate through the middle of the urethral crest, from a subject aged nineteen years. (Taylor) *a.* Longitudinal section of ducts leading from the lobules of the prostatic glands. *b.* Urethral crest. *c.* Prostatic utricle. *d.* Urethra. *e.* Ejaculatory ducts. *f.* Arteries, veins, and venous sinuses in sheath of prostate. *g.* Nerve trunks in sheath. *h.* Point of origin of fibromuscular bands encircling urethra. *i.* Zone of striated voluntary muscle on superior surface.

The **glandular substance** is composed of numerous follicular pouches the lining of which frequently shows papillary elevations. The follicles open into elongated canals, which join to form from twelve to twenty small excretory ducts. They are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium which lines the canals and the terminal vesicles is of the columnar variety. The prostatic ducts open into the floor of the prostatic portion of the urethra, and are lined by two layers of epithelium, the inner layer consisting of columnar and the outer of small cubical cells. Small colloid masses, known as **amyloid bodies** are often found in the gland tubes.

Vessels and Nerves.—The **arteries** supplying the prostate are derived from the internal pudendal, inferior vesical, and middle hemorrhoidal. Its veins form a plexus around the sides and base of the gland; they receive in front the dorsal vein of the penis, and end in the hypogastric veins. The **nerves** are derived from the pelvic plexus.

Applied Anatomy.—By means of the finger introduced into the rectum, the surgeon detects enlargement or other disease of the prostate, he can feel the apex of the gland, which is the guide to Cook's operation for stricture; he is enabled also by the same means to direct the point of a catheter, when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel the surgeon may, in some cases, especially in boys, learn the position, as well as the size, of a

calculus in the bladder; and in the operation for its removal, if, as is not infrequently the case, it should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upward the fundus of the bladder from the rectum. The prostate is occasionally the seat of sup-puration, due to either gonorrhea or tuberculous disease. The gland is enveloped in a dense, unyielding capsule, which determines the course of the abscess, and also explains the great pain which is present in the acute form of the disease. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may burst into the rectum, or more rarely in the perineum. In advanced life the prostate sometimes becomes considerably enlarged and projects into the bladder so as to impede the passage of the urine. According to Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. In some cases the condition affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the middle lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the internal urethral orifice, preventing the passage of the urine; and the more the patient strains, the more completely will it block the opening into the urethra. In consequence of the enlargement of the prostate, a pouch is formed at the base of the bladder behind the projection, in which urine collects, and from which it cannot be entirely expelled. For this condition *prostatectomy* is sometimes done. The bladder is opened by an incision above the symphysis pubis, the mucous membrane of the post-prostatic pouch is scratched through, and the finger is then introduced into the space between the true capsule of the prostate and outer capsule formed by the fascia endopelvina. Separation in this plane is then carried out below and laterally until the apex of the gland is reached. The whole of the work is done with the finger, which is gradually swept around the sides until the anterior surface is reached and freed. The gland is then, by traction, displaced into the bladder and removed, usually carrying with it the greater portion of the mucous membrane of the prostatic urethra. Hemorrhage, which may be considerable at times, is checked by hot irrigations, and the bladder is temporarily drained. Very satisfactory results have followed this operation. The prostate can be reached from the perineum, and in some cases the enlarged gland has been removed by this route, but the perineal approach is not usually employed except in the case of abscess of or about the gland.

The Bulbourethral Glands (Glandulae Bulbourethrales; Cowper's Glands).

The **bulbourethral glands** are two small, rounded, and somewhat lobulated bodies, of a yellow color, about the size of peas, placed behind and lateral to the membranous portion of the urethra, between the two layers of the fascia of the urogenital diaphragm. They lie close above the bulb, and are enclosed by the transverse fibres of the Sphincter urethrae membranaceae. Their existence is said to be constant: they gradually diminish in size as age advances.

The excretory duct of each gland, nearly 2.5 cm. long, passes obliquely forward beneath the mucous membrane, and opens by a minute orifice on the floor of the cavernous portion of the urethra about 2.5 cm. in front of the urogenital diaphragm.

Structure.—Each gland is made up of several lobules, held together by a fibrous investment. Each lobule consists of a number of acini, lined by columnar epithelial cells, opening into one duct, which joins with the ducts of other lobules outside the gland to form the single excretory duct.

THE FEMALE GENITAL ORGANS (ORGANA GENITALIA MULIEBRIA).

The female genital organs consist of an internal and an external group. The **internal organs** are situated within the pelvis, and consist of the **ovaries**, the **uterine tubes**, the **uterus**, and the **vagina**. The **external organs** are placed below the urogenital diaphragm and below and in front of the pubic arch. They comprise the **mons pubis**, the **labia majora et minora pudendi**, the **clitoris**, the **bulbus vestibuli**, and the **greater vestibular glands**.

The Ovaries (Ovaria).

The **ovaries** are homologous with the testes in the male. They are two nodular bodies, situated one on either side of the uterus in relation to the lateral wall of the pelvis, and attached to the back of the broad ligament of the uterus, behind

and below the uterine tubes (Fig. 1047). The ovaries are of a grayish-pink color, and present either a smooth or a puckered uneven surface. They are each about 4 cm. in length, 2 cm. in width, and about 8 mm. in thickness, and weigh from 2 to 3.5 gm. Each ovary presents a lateral and a medial surface, an upper or tubal and a lower or uterine extremity, and an anterior or mesovarian and a posterior free border. It lies in a shallow depression, named the **ovarian fossa**, on the lateral wall of the pelvis; this fossa is bounded above by the external iliac vessels, in front by the obliterated umbilical artery, and behind by the ureter. The exact position of the ovary has been the subject of considerable difference of opinion, and the description here given applies to the ovary of the nulliparous woman. The ovary becomes displaced during the first pregnancy, and probably never again returns to its original position. In the erect posture the long axis of the ovary is vertical. The *tubal extremity* is near the external iliac vein; to it is attached the ovarian fimbria of the uterine tube and a fold of peritoneum, the **suspensory ligament of the ovary**, which is directed upward over the iliac vessels and contains the ovarian

Epoöphoron

FIG. 1047.—Uterus and right broad ligament, seen from behind. The broad ligament has been spread out and the ovary drawn downward.

vessels. The *uterine end* is directed downward toward the pelvic floor, it is usually narrower than the tubal, and is attached to the lateral angle of the uterus, immediately behind the uterine tube, by a rounded cord termed the **ligament of the ovary**, which lies within the broad ligament and contains some non-striped muscular fibres. The *lateral surface* is in contact with the parietal peritoneum, which lines the ovarian fossa; the *medial surface* is to a large extent covered by the fimbriated extremity of the uterine tube. The *mesovarian border* is straight and is directed toward the obliterated umbilical artery, and is attached to the back of the broad ligament by a short fold named the **mesovarium**. Between the two layers of this fold the bloodvessels and nerves pass to reach the hilus of the ovary. The *free border* is convex, and is directed toward the ureter. The uterine tube arches over the ovary, running upward in relation to its mesovarian border, then curving over its tubal pole, and finally passing downward on its free border and medial surface.

Epoöphoron (*parovarium*; *organ of Rosenmüller*) (Figs. 1047, 1048).—The epoöphoron lies in the mesosalpinx between the ovary and the uterine tube, and consists of a few short tubules (**ductuli transversi**) which converge toward the ovary

while their opposite ends open into a rudimentary duct, the *ductus longitudinalis epoöphori* (*duct of Gärtner*).

Paroöphoron.—The paroöphoron consists of a few scattered rudimentary tubules, best seen in the child, situated in the broad ligament between the epoöphoron and the uterus.

FIG. 1048.—Adult ovary, epoöphoron, and uterine tube. (From Farre, after Kobelt.) *a, e.* Epoöphoron formed from the upper part of the Wolffian body. *b* Remains of the uppermost tubes sometimes forming hydatids. *c.* Middle set of tubes. *d.* Some lower atrophied tubes. *e.* Atrophied remains of the Wolffian duct. *f.* The terminal bulb or hydatid. *A.* The uterine tube. *s.* Hydatid attached to the extremity. *i.* The ovary.

The ductuli transversi of the epoöphoron and the tubules of the paroöphoron are remnants of the tubules of the Wolffian body or mesonephros; the ductus longitudinalis epoöphori is a persistent portion of the Wolffian duct.

In the fetus, the ovaries are situated, like the testes, in the lumbar region, near the kidneys, but they gradually descend into the pelvis (page 187).

Structure (Fig. 1049).—The surface of the ovary is covered by a layer of columnar cells which constitutes the *germinal epithelium of Waldeyer*. This epithelium gives to the ovary a dull gray color as compared with the shining smoothness of the peritoneum; and the transition between the squamous epithelium of the peritoneum and the columnar cells which cover the ovary is usually marked by a line around the anterior border of the ovary. The ovary consists of a number of vesicular ovarian follicles imbedded in the meshes of a stroma or frame-work.

The stroma is a peculiar soft tissue, abundantly supplied with bloodvessels, consisting for the most part of spindle-shaped cells with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriated muscle cells, which, indeed, they most resemble; by others as connective-tissue cells. On the surface of the organ this tissue is much condensed, and forms a layer (*tunica albuginea*) composed of short connective-tissue fibres, with fusiform cells between them. The stroma of the ovary may contain interstitial cells resembling those of the testis.

Vesicular Ovarian Follicles (*Graafian follicles*).—Upon making a section of an ovary, numerous round transparent vesicles of various sizes are to be seen; they are the follicles, or ovisacs containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles, of uniform size, about 0.25 mm. in diameter. These are the follicles in their earliest condition, and the layer where they are found has been termed the *cortical layer*. They are especially numerous in the ovary of the young child. After puberty, and during the whole of the child-bearing period, large and mature, or almost mature follicles are also found in the cortical layer in small numbers, and also "corpora lutea," the remains of

FIG. 1049.—Section of the ovary. (After Schrön.) 1. Outer covering. 1'. Attached border. 2. Central stroma. 3. Peripheral stroma. 4. Bloodvessels. 5. follicles which have burst and are undergoing atrophy and absorption. Beneath this superficial stratum, other large and more or less mature follicles are found imbedded in the ovarian stroma. These increase in size as they recede from the surface toward a highly vascular stroma in the centre of the organ, termed the **medullary substance** (*zona vasculosa of Waldeyer*). This stroma forms the tissue of the hilus by which the ovary is attached, and through which the bloodvessels enter: it does not contain any follicles.

The larger follicles (Fig. 1050) consist of an external fibrovascular coat, connected with the surrounding stroma of the ovary by a net-work of bloodvessels; and an internal coat, which consists of several layers of nucleated cells, called the **membrana granulosa**.

At one part of the mature follicle the cells of the *membrana granulosa* are collected into a mass which projects into the cavity of the follicle. This is termed the **discus proligerus**, and in it the ovum is imbedded.¹ The follicle contains a transparent albuminous fluid.

The development and maturation of the follicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman's life, while their formation commences before birth. Before puberty the ovaries are small and the follicles contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the follicles; many, however, never attain full develop-

ment, but shrink and disappear. At puberty the ovaries enlarge and become more vascular, the follicles are developed in greater abundance, and their ova are capable of fecundation.

Discharge of the Ovum.—The follicles, after attaining a certain stage of development, gradually approach the surface of the ovary and burst; the ovum and fluid contents of the follicle are liberated on the exterior of the ovary, and carried into the uterine tube by currents set up by the movements of the cilia covering the mucous membrane of the fimbriae.

Corpus Luteum.—After the discharge of the ovum the lining of the follicle is thrown into folds, and vascular processes grow inward from the surrounding tissue. In this way the space is filled up and the corpus luteum formed. It consists at first of a radial arrangement of yellow cells with bloodvessels and lymphatic spaces, and later it merges with the surrounding stroma.

Vessels and Nerves.—The arteries of the ovaries and uterine tubes are the ovarian from the aorta. Each anastomoses freely in the mesosalpinx, with the uterine artery, gives some branches to the uterine tube, and others which traverse the mesovarium and enter the hilus of the ovary. The veins emerge from the hilus in the form of a plexus, the **pampiniform plexus**; the ovarian vein is formed from this plexus, and leaves the pelvis in company with the artery. The nerves are derived from the hypogastric or pelvic plexus, and from the ovarian plexus, the uterine tube receiving a branch from one of the uterine nerves.

Applied Anatomy.—The inflammations which affect the ovary are merely an extension of those from the tube. Ovarian new formations are of common occurrence, and are either solid or cystic; the former being the less common. The *ovarian cysts* in the majority of cases are cystadenomata which may assume enormous dimensions; in rarer instances they form from the tubules at the hilus of the ovary or those of the organ of Rosenmüller; in other instances a clear watery cyst forms between the layers of the broad ligament. An ovarian cyst, once diagnosed, should always be removed, as it is liable to become affected by suppuration, torsion of its pedicle, or other serious complications. The operation for its removal, badly termed *ovariotomy*, consists in opening the abdomen, and reducing the size of the cyst when large by tapping it before its withdrawal from the abdomen; the pedicle is then clamped with a large forceps, and the cyst is cut free. This pedicle must then be transfixed and securely ligatured by an interlocking ligature, which will not slip off. The pedicle consists of an elongated part of the broad ligament, including the uterine tube and ovarian artery, and a great number of large veins. Ovariectomy for a simple uncomplicated cyst presents no special difficulties, but, in cases where there are old adhesions implicating the small intestines, it may present very great difficulties.

FIG. 1050.—Section of vesicular ovarian follicle of cat. $\times 50$.

¹ For a description of the ovum, see page 77.

The Uterine Tube (Tuba Uterina [Fallopii]; Fallopian Tube; Oviduct).
(Figs. 1047, 1051).

The **uterine tubes** convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on either side, situated in the upper margin of the broad ligament, and extending from the superior angle of the uterus to the side of the pelvis. Each tube is about 10 cm. long, and is described as consisting of three portions: (1) the **isthmus**, or medial constricted third; (2) the **ampulla**, or intermediate dilated portion, which curves over the ovary; and (3) the **infundibulum**, with its **abdominal ostium**, surrounded by **fimbriæ**, one of which, the **ovarian fimbria**,

A

ary

f uterus

FIG. 1051.—Female pelvis and its contents, seen from above and in front.

is attached to the ovary. The uterine tube is directed lateralward as far as the uterine pole of the ovary, and then ascends along the mesovarian border of the ovary to the tubal pole, over which it arches; finally it turns downward and ends in relation to the free border and medial surface of the ovary. The uterine opening is minute, and will only admit a fine bristle; the abdominal opening is somewhat larger. In connection with the fimbriæ of the uterine tube, or with the broad ligament close to them, there are frequently one or more small pedunculated vesicles. These are termed the **appendices vesiculosæ** (*hydatids of Morgagni*).

Structure.—The uterine tube consists of three coats: **serous**, **muscular**, and **mucous**. The **external or serous coat** is peritoneal. The **middle or muscular coat** consists of an external longitudinal and an internal circular layer of non-striped muscular fibres continuous with those of the uterus. The **internal or mucous coat** is continuous with the mucous lining of the uterus, and, at the abdominal ostium of the tube, with the peritoneum. It is thrown into longitudinal folds, which in the ampulla are much more extensive than in the isthmus. The lining epithelium is columnar and ciliated. This form of epithelium is also found on the inner surface of the fimbriæ, while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

Applied Anatomy.—The majority of the diseases of the uterine tube are due to infection which have spread by way of the vagina and uterus, and the disease often does not stop at the uterine tube, but passes on to the peritoneum, giving rise to acute general peritonitis, or a localized condition termed *perimetritis* that may be acute or chronic. Perimetritis is often followed by various painful conditions, which are due to the peritoneal adhesions resulting from the

inflammation of the serous membrane, and which persist throughout life. Tubal inflammation (*salpingitis*) is usually the result of an infection either by the gonococcus or by septic organisms implanted at the time of labor or abortion. In many cases the fimbriated ends of the tubes become closed by adhesions, pus collects in the tubes, and a *pyosalpinx* results.

Fertilisation of the ovum is believed (page 82) to occur in the tube, and the fertilized ovum is then normally passed on into the uterus; the ovum, however, may adhere to an undergo development in the uterine tube, giving rise to the commonest variety of *ectopic gestation*. In such cases the amnion and chorion are formed, but a true decidua is never present; and the gestation usually ends by extrusion of the ovum through the abdominal ostium, although it is not uncommon for the tube to rupture into the peritoneal cavity, this being accompanied by severe hemorrhage, and needing surgical interference.

The Uterus (Womb) (Figs. 1047, 1051, 1052).

The uterus is a hollow, thick-walled, muscular organ situated deeply in the pelvic cavity between the bladder and rectum. Into its upper part the uterine tubes open, one on either side, while below, its cavity communicates with that of

FIG. 1052. Median sagittal section of female pelvis.

the vagina. When the ova are discharged from the ovaries they are carried to the uterine cavity through the uterine tubes. If an ovum be fertilized it imbeds itself in the uterine wall and is normally retained in the uterus until prenatal development is completed, the uterus undergoing changes in size and structure to accommodate itself to the needs of the growing embryo (see page 98). After parturition the uterus returns almost to its former condition, but certain traces of its enlargement remains. It is necessary, therefore, to describe as the type-form the adult virgin uterus, and then to consider the modifications which are effected as a result of pregnancy.

In the virgin state the uterus is flattened antero-posteriorly and is pyriform in shape, with the apex directed downward and backward. It lies between the bladder in front and the pelvic or sigmoid colon and rectum behind, and is completely within the pelvis, so that its base is below the level of the superior pelvic aperture. Its upper part is suspended by the broad and the round ligaments, while its lower portion is imbedded in the fibrous tissue of the pelvis.

The long axis of the uterus usually lies approximately in the axis of the superior pelvic aperture, but as the organ is freely movable its position varies with the state of distension of the bladder and rectum. Except when much displaced by a fully distended bladder, it forms a forward angle with the vagina, since the axis of the vagina corresponds to the axes of the cavity and inferior aperture of the pelvis.

The uterus measures about 7.5 cm. in length, 5 cm. in breadth, at its upper part, and nearly 2.5 cm. in thickness; it weighs from 30 to 40 gm. It is divisible into two portions. On the surface, about midway between the apex and base, is a slight constriction, known as the **isthmus**, and corresponding to this in the interior is a narrowing of the uterine cavity, the **internal orifice** of the uterus. The portion above the isthmus is termed the **body**, and that below, the **cervix**. The part of the body which lies above a plane passing through the points of entrance of the uterine tubes is known as the **fundus**.

Body (*corpus uteri*).—The body gradually narrows from the fundus to the isthmus.

The **vesical** or **anterior surface** (*facies vesicalis*) is flattened and covered by peritoneum, which is reflected on to the bladder to form the vesicouterine excavation. The surface lies in apposition with the bladder.

The **intestinal** or **posterior surface** (*facies intestinalis*) is convex transversely and is covered by peritoneum, which is continued down on to the cervix and vagina. It is in relation with the sigmoid colon, from which it is usually separated by some coils of small intestine.

The **fundus** (*fundus uteri*) is convex in all directions, and covered by peritoneum continuous with that on the vesical and intestinal surfaces. On it rest some coils of small intestine, and occasionally the distended sigmoid colon.

The **lateral margins** (*margo lateralis*) are slightly convex. At the upper end of each the uterine tube pierces the uterine wall. Below and in front of this point the round ligament of the uterus is fixed, while behind it is the attachment of the ligament of the ovary. These three structures lie within a fold of peritoneum which is reflected from the margin of the uterus to the wall of the pelvis, and is named the **broad ligament**.

Cervix (*cervix uteri*; *neck*).—The cervix is the lower constricted segment of the uterus. It is somewhat conical in shape, with its truncated apex directed downward and backward, but is slightly wider in the middle than either above or below. Owing to its relationships, it is less freely movable than the body, so that the latter may bend on it. The long axis of the cervix is therefore seldom in the same straight line as the long axis of the body. The long axis of the uterus as a whole presents the form of a curved line with its concavity forward, or in extreme cases may present an angular bend at the region of the isthmus.

The cervix projects through the anterior wall of the vagina, which divides it into an upper, supravaginal portion, and a lower, vaginal portion.

The **supravaginal portion** (*portio supravaginalis* [*cervicis*]) is separated in front from the bladder by fibrous tissue (**parametrium**), which extends also on to its sides and lateralward between the layers of the broad ligaments. The uterine arteries reach the margins of the cervix in this fibrous tissue, while on either side the ureter runs downward and forward in it at a distance of about 2 cm. from the cervix. *Posteriorly*, the supravaginal cervix is covered by peritoneum, which is prolonged

below on to the posterior vaginal wall, when it is reflected on to the rectum, forming the rectouterine excavation. It is in relation with the rectum, from which it may be separated by coils of small intestine.

The **vaginal portion** (*portio vaginalis [cervicis]*) of the cervix projects free into the anterior wall of the vagina between the anterior and posterior fornices. On its rounded extremity is a small, depressed, somewhat circular aperture, the **external orifice of the uterus**, through which the cavity of the cervix communicates with that of the vagina. The external orifice is bounded by two lips, an anterior and a posterior, of which the anterior is the shorter and thicker, although, on account of the slope of the cervix, it projects lower than the posterior. Normally, both lips are in contact with the posterior vaginal wall.

Interior of the Uterus (Fig. 1053).—The cavity of the uterus is small in comparison with the size of the organ.

The **Cavity of the Body** (*cavum uteri*) is a mere slit, flattened antero-posteriorly. It is triangular in shape, the base being formed by the internal surface of the fundus between the orifices of the uterine tubes, the apex by the internal orifice of the uterus through which the cavity of the body communicates with the canal of the cervix.

FIG. 1053.—Posterior half of uterus and upper part of vagina.

The **Canal of the Cervix** (*canalis cervicis uteri*) is somewhat fusiform, flattened from before backward, and broader at the middle than at either extremity. It communicates above through the internal orifice with the cavity of the body, and below through the external orifice with the vaginal cavity. The wall of the canal presents an anterior and a posterior longitudinal ridge, from each of which proceed a number of small oblique columns, the **palmate folds**, giving the appearance of branches from the stem of a tree; to this arrangement the name **arbor vitae uterina** is applied. The folds on the two

walls are not exactly opposed, but fit between one another so as to close the cervical canal.

The total length of the uterine cavity from the external orifice to the fundus is about 6.25 cm.

Ligaments.—The ligaments of the uterus are eight in number: one **anterior**; one **posterior**; two **lateral** or **broad**; two **uterosacral**; and two **round ligaments**.

The **anterior ligament** consists of the vesicouterine fold of peritoneum, which is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body.

The **posterior ligament** consists of the rectovaginal fold of peritoneum, which is reflected from the back of the posterior fornix of the vagina on to the front of the rectum. It forms the bottom of a deep pouch called the **rectouterine excavation**, which is bounded in front by the posterior wall of the uterus, the supravaginal cervix, and the posterior fornix of the vagina; behind, by the rectum; and laterally by two crescentic folds of peritoneum which pass backward from the cervix uteri on either side of the rectum to the posterior wall of the pelvis. These folds are named the **sacrogenital** or **rectouterine folds**. They contain a considerable amount of fibrous tissue and non-striped muscular fibres which are attached to the front of the sacrum and constitute the **uterosacral ligaments**.

The **two lateral** or **broad ligaments** (*ligamentum latum uteri*) pass from the sides of the uterus to the lateral walls of the pelvis. Together with the uterus they form

a septum across the female pelvis, dividing that cavity into two portions. In the anterior part is contained the bladder; in the posterior part the rectum, and in certain conditions some coils of the small intestine and a part of the sigmoid colon. Between the two layers of each broad ligament are contained: (1) the uterine tube superiorly; (2) the round ligament of the uterus; (3) the ovary and its ligament; (4) the epoöphoron and paroöphoron; (5) connective tissue; (6) unstriated muscular fibre; and (7) bloodvessels and nerves. The portion of the broad ligament which stretches from the uterine tube to the level of the ovary is known by the name of the *mesosalpinx*. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin, called the *infundibulopelvic ligament*.

The *round ligaments* (*ligamentum teres uteri*) are two flattened bands between 10 and 12 cm. in length, situated between the layers of the broad ligament in front of and below the uterine tubes. Commencing on either side at the lateral angle of the uterus, this ligament is directed forward, upward, and lateralward over the external iliac vessels. It then passes through the abdominal inguinal ring and along the inguinal canal to the labium majus, in which it becomes lost. The round ligaments consists principally of muscular tissue, prolonged from the uterus; also of some fibrous and areolar tissue, besides bloodvessels, lymphatics; and nerves, enclosed in a duplicature of peritoneum, which, in the fetus, is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the *canal of Nuck*. It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the *saccus vaginalis*, which precedes the descent of the testis.

In addition to the ligaments just described, there is a band named the *ligamentum transversalis colli* (Mackenrodt) on either side of the cervix uteri. It is attached to the side of the cervix uteri and to the vault and lateral fornix of the vagina, and is continuous externally with the fibrous tissue which surrounds the pelvic bloodvessels.

The form, size, and situation of the uterus vary at different periods of life and under different circumstances.

FIG. 1054.—Sagittal section through the pelvis of a newly born female child.

In the fetus the uterus is contained in the abdominal cavity, projecting beyond the superior aperture of the pelvis (Fig. 1054). The cervix is considerably larger than the body.

At puberty the uterus is pyriform in shape, and weighs from 14 to 17 gm. It has descended into the pelvis, the fundus being just below the level of the superior aperture of this cavity. The palmate folds are distinct, and extend to the upper part of the cavity of the organ.

The position of the uterus in the adult is liable to considerable variation, depending chiefly on the condition of the bladder and rectum. When the bladder is empty the entire uterus is directed forward, and is at the same time bent on itself at the junction of the body and cervix, so that the body lies upon the bladder. As the latter fills, the uterus gradually becomes more and more erect, until with a fully distended bladder the fundus may be directed backward toward the sacrum.

During menstruation the organ is enlarged, more vascular, and its surfaces rounder; the external orifice is rounded, its labia swollen, and the lining membrane of the body thickened, softer, and of a darker color. According to Sir J. Williams, at each recurrence of menstruation, a molecular disintegration of the mucous membrane takes place, which leads to its complete removal, only the bases of the glands imbedded in the muscle being left. At the cessation of menstruation, a fresh mucous membrane is formed by a proliferation of the remaining structures.

During pregnancy the uterus becomes enormously enlarged, and in the eighth month reaches the epigastric region. The increase in size is partly due to growth of preëxisting muscle, and partly to development of new fibres.

After parturition the uterus nearly regains its usual size, weighing about 42 gm.; but its cavity is larger than in the virgin state, its vessels are tortuous, and its muscular layers are more defined; the external orifice is more marked, and its edges present one or more fissures.

In old age the uterus becomes atrophied, and paler and denser in texture; a more distinct constriction separates the body and cervix. The internal orifice is frequently, and the external orifice occasionally, obliterated, while the lips almost entirely disappear.

Structure.—The uterus is composed of three coats: an **external** or **serous**, a **middle** or **muscular**, and an **internal** or **mucous**.

The **serous coat** (*tunica serosa*) is derived from the peritoneum; it invests the fundus and the whole of the intestinal surface of the uterus; but covers the vesical surface only as far as the junction of the body and cervix. In the lower fourth of the intestinal surface the peritoneum, though covering the uterus, is not closely connected with it, being separated from it by a layer of loose cellular tissue and some large veins.

The **muscular coat** (*tunica muscularis*) forms the chief bulk of the substance of the uterus. In the virgin it is dense, firm, of a grayish color, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the uterine tubes. It consists of bundles of unstriped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. The layers are three in number: external, middle, and internal. The external and middle layers constitute the muscular coat proper, while the inner layer is a greatly hypertrophied *muscularis mucosae*. During pregnancy the muscular tissue becomes more prominently developed, the fibres being greatly enlarged.

The external layer, placed beneath the peritoneum, is disposed as a thin plane on the vesical and intestinal surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each lateral angle of the uterus, are continued on to the uterine tube, the round ligament, and the ligament of the ovary: some passing at each side into the broad ligament, and others running backward from the cervix into the sacrouterine ligaments. The middle layer of fibres presents no regularity in its arrangement, being disposed longitudinally, obliquely, and transversely. It contains most bloodvessels. The internal or deep layer consists of circular fibres arranged in the form of two hollow cones, the apices of which surround the orifices of the uterine tubes, their bases intermingling with one another on the middle of the body of the uterus. At the internal orifice these circular fibres form a distinct sphincter.

The **mucous membrane** (*tunica mucosa*) (Fig. 1055) is smooth, and closely adherent to the subjacent tissue. It is continuous through the fimbriated extremity of the uterine tubes, with the peritoneum; and, through the external uterine orifice, with the lining of the vagina.

In the body of the uterus the mucous membrane is smooth, soft, of a pale red color, lined by columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles, arranged perpendicularly to the surface. The structure of the corium differs from that of ordinary mucous membranes, and consists of an embryonic nucleated and highly cellular form of connective tissue in which run numerous large lymphatics. In it are the tube-like **uterine glands**, lined by ciliated columnar epithelium. They are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged and elongated, presenting a contorted or waved appearance (see page 98).

In the cervix the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges, which diverge from an anterior and posterior longitudinal raphe. In the upper two-thirds of the canal, the mucous membrane is provided with numerous deep glandular follicles, which secrete a clear viscid alkaline mucus; and, in addition, extending through the whole length of the canal is a variable number of little cysts, presumably follicles which have become occluded and distended with retained secretion. They are called the **ovula Nabothi**. The mucous membrane covering the lower half of the cervical canal presents numerous papillæ. The epithelium of the upper two-thirds is cylindrical and ciliated, but below

this it loses its cilia, and gradually changes to stratified squamous epithelium close to the external orifice. On the vaginal surface of the cervix the epithelium is similar to that lining the vagina, viz., stratified squamous.

Ciliated epithelium

FIG. 1055.—Vertical section of mucous membrane of human uterus. (Sobotta.)

Vessels and Nerves.—The arteries of the uterus are the uterine, from the hypogastric; and the ovarian, from the abdominal aorta (Fig. 1056). They are remarkable for their tortuous

Branches to testis

FIG. 1056.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)

course in the substance of the organ, and for their frequent anastomoses. The termination of the ovarian artery meets that of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus, their disposition being circular. The veins are of

large size, and correspond with the arteries. They end in the uterine plexuses. In the impregnated uterus the arteries carry the blood to, and the veins convey it away from, the intervillous space of the placenta (see page 100). The **lymphatics** are described on page 795. The **nerves** are derived from the hypogastric and ovarian plexuses, and from the third and fourth sacral nerves.

Applied Anatomy.—A certain amount of anteversion and retroversion of the uterus can take place without the condition being regarded as pathological, but when the degree of flexion becomes considerable it must be regarded as a morbid condition. This is especially true of retroversion and retroflexion. The former is a falling back of the whole uterus, so that the cervix points upward toward the pubes, and the latter is a bending backward of the body, the cervix remaining in its normal position. The two conditions are usually combined. Prolapse of the uterus is another common infirmity. The organ sinks to an abnormally low level in the pelvis, and sometimes protrudes beyond the vulva. This is due to the supporting mechanism of the uterus being insufficient to sustain the strain thrown upon it.

The uterus may require removal in cases of malignant disease or for fibroid tumors. Carcinoma is the most common form of malignant disease of the uterus, though cases of sarcoma do occur. It may show itself either as a columnar carcinoma or as a squamous carcinoma; the former commencing either in the cervix or body of the uterus, the latter always commencing in the epithelial cells of the mucous covering of the vaginal surface of the cervix. Cancer of the body or of the cervix may be treated in the early stage, before fixation has taken place, by removal of the uterus, either through the vagina or by means of abdominal section, but if the body be much enlarged the former operation is impossible. Vaginal hysterectomy is performed by placing the patient in the lithotomy position and introducing a large duck-bill speculum. The cervix is then seized with a volsellum and pulled down as far as possible, and the mucous membrane of the vagina incised around the cervix and as near to it as the disease will allow, especially in front, where the ureters are in danger of being wounded. The rectouterine excavation is then opened sufficiently to allow of the introduction of the two forefingers, by means of which the opening is dilated laterally as far as the sacro-uterine ligaments. A somewhat similar proceeding is adopted in front, but here the bladder has to be separated from the wall of the uterus for about 2.5 cm. before the vesicouterine fold of peritoneum can be reached. This is done by carefully burrowing upward with a director and stripping the tissues off the uterine wall. When the vesicouterine pouch has been opened and the aperture dilated laterally, the uterus remains attached only by the broad ligaments, in which are contained the vessels that supply the uterus. Before division of the ligaments, these vessels have to be dealt with. The forefinger of the left hand is introduced into the rectouterine excavation, and an aneurism needle, armed with a long silk ligature, is inserted into the vesicouterine pouch, and is pushed through the broad ligament about 2.5 cm. above its lower level and at some distance from the uterus. One end of the ligature is now pulled through the anterior opening, and in this way we have the lowest 2.5 cm. of the broad ligament, in which is contained the uterine artery (Fig. 1056), enclosed in a ligature. This is tied tightly, and the operation is repeated on the other side. The broad ligament is then divided on either side, between the ligature and the uterus, to the extent to which it has been constricted. By traction on the volsellum which grasps the cervix, the uterus can be pulled considerably further down in the vagina, and a second 2.5 cm. of the broad ligament is treated in a similar way. This second ligature will embrace the pampiniform plexus of veins, and, when the broad ligament has been divided on either side, it will be found that a third ligature can be made to pass over the uterine tube and top of the broad ligament, after the uterus has been dragged down as far as possible. After the third ligature has been tied and the structures between it and the uterus divided, this organ will be freed from all its connections and can be removed from the vagina. The third ligature will contain the ovarian artery, between the ovary and the uterus, as it lies below the uterine tube. The vagina is then sponged out and lightly dressed with gauze; no sutures being used.

In the treatment of uterine fibroids which require operative interference, removal of the whole of the uterus, together with the tumors, through an abdominal incision gives the most satisfactory results; for, if the tumor is large, its size acts as a barrier to its safe delivery through the pelvis and genital passages. After the abdomen has been opened the uterine vessels are secured and the broad ligaments divided in a manner similar to that employed in vaginal hysterectomy, except that the proceeding is commenced from above. When the first two ligatures have been tied, and the broad ligament divided, it will be found that the uterus can be raised out of the pelvis. A transverse incision is now made through the peritoneum, where it is reflected from the front of the uterus on to the back of the bladder, and the serous membrane peeled from the surface of the uterus until the vagina is reached. The anterior wall of this canal is then cut across. The uterus is now turned forward and the peritoneum at the bottom of the rectouterine excavation incised transversely, and the posterior wall of the vagina cut across, until it meets the incision on the anterior wall. The uterus is now almost free, and is held only by the lower part of the broad ligament on either side, containing the uterine artery. A third ligature is made to encircle this as close to the uterus as possible, the position of the ureter

being always kept in mind, and, after having been tied, the structures are divided between the ligature and the uterus. The organ can now be removed. The vagina is plugged with gauze, and the external wound closed in the usual way. The vagina acts as a drain, and therefore the opening into it is not sutured.

Inflammation of the cellular tissue surrounding the cervix occasionally takes place. Laceration of the cervix by instruments or by the fetal head frequently occurs, opening up the cellular planes and so exposing them to any infection that may be present. An inflammatory mass forms in the cellular tissue between the layers of the broad ligament or of the uterosacral ligaments, and the condition is termed *pelvic cellulitis* or *parametritis*. This condition is usually confined to one side of the pelvis, forming a large inflammatory mass which pushes the uterus over to the opposite side. It does not always remain localized, however, but may spread widely, surrounding the rectum or the neck of the bladder, or mounting into the iliac fossa, or even to the perinephric cellular tissue. The condition may resolve or an abscess may form. In the former condition the cicatrization of the inflammatory products often produces displacements of the uterus toward the affected side of the pelvis, or stricture of the rectum when that viscus has been surrounded by the process. When suppuration ensues, the pus may burst into the bladder, vagina, or rectum, or it may present above the inguinal ligament, or it may mount to the anterior abdominal wall in front of the bladder or to the posterior abdominal wall between the iliac crest and last rib. The abscess may, moreover, make its way into the buttock by passing out of the pelvis through the greater sciatic foramen, or it may pass down between the fibres of the Levator ani and appear as a secondary ischiorectal abscess.

The Vagina (Fig. 1052).

The **vagina** extends from the vestibule to the uterus, and is situated behind the bladder and in front of the rectum; it is directed upward and backward, its axis forming with that of the uterus an angle of over 90°, opening forward. Its walls are ordinarily in contact, and the usual shape of its lower part on transverse section is that of an H, the transverse limb being slightly curved forward or backward, while the lateral limbs are somewhat convex toward the median line; its middle part has the appearance of a transverse slit. Its length is 6 to 7.5 cm. along its anterior wall, and 9 cm. along its posterior wall. It is constricted at its commencement, dilated in the middle, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short distance from the external orifice of the uterus, its attachment extending higher up on the posterior than on the anterior wall of the uterus. To the recess behind the cervix the term **posterior fornix** is applied, while the smaller recesses in front and at the sides are called the **anterior** and **lateral fornices**.

Relations.—The **anterior surface** of the vagina is in relation with the fundus of the bladder, and with the urethra. Its **posterior surface** is separated from the rectum by the rectouterine excavation in its upper fourth, and by the rectovesical fascia in its middle two-fourths; the lower fourth is separated from the anal canal by the perineal body. Its sides are enclosed between the Levatores ani muscles. As the terminal portions of the ureters pass forward and medialward to reach the fundus of the bladder, they run close to the lateral fornices of the vagina, and as they enter the bladder are slightly in front of the anterior fornix.

Structure.—The vagina consists of an **internal mucous lining** and a **muscular coat** separated by a layer of erectile tissue.

The **mucous membrane** (*tunica mucosa*) is continuous above with that lining the uterus. Its inner surface presents two longitudinal ridges, one on its anterior and one on its posterior wall. These ridges are called the **columns of the vagina** and from them numerous transverse ridges or rugæ extend outward on either side. These rugæ are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillæ; they are most numerous near the orifice of the vagina, especially before parturition. The epithelium covering the mucous membrane is of the stratified squamous variety. The submucous tissue is very loose, and contains numerous large veins which by their anastomoses form a plexus, together with smooth muscular fibres derived from the muscular coat; it is regarded by Gussenbauer as an erectile tissue. It contains a number of mucous crypts, but no true glands.

The **muscular coat** (*tunica muscularis*) consists of two layers: an external longitudinal, which is by far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the rectovesical fascia on either side. The two layers are not distinctly separable from each other, but are connected by oblique decussating fasciculi, which pass from the one layer to the

other. In addition to this, the vagina at its lower end is surrounded by a band of striped muscular fibres, the **Bulbocavernosus** (see page 520).

External to the muscular coat is a layer of connective tissue, containing a large plexus of bloodvessels.

The **erectile tissue** consists of a layer of loose connective tissue, situated between the mucous membrane and the muscular coat; imbedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres, derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

The External Genital Organs (*Partes Genitales Externae Muliebres*) (Fig. 1057).

The external genital organs of the female are: the **mons pubis**, the **labia majora et minora pedundi**, the **clitoris**, the **vestibule of the vagina**, the **bulb of the vestibule**, and the **greater vestibular glands**. The term **pudendum** or **vulva**, as generally applied, includes all these parts.

Hymen

FIG. 1057.—External genital organs of female. The labia minora have been drawn apart.

The **Mons Pubis** (*commissura labiorum anterior*; *mons Veneris*), the rounded eminence in front of the pubic symphysis, is formed by a collection of fatty tissue beneath the integument. It becomes covered with hair at the time of puberty.

The **Labia Majora** (*labia majora pudendi*) are two prominent longitudinal cutaneous folds which extend downward and backward from the mons pubis and form the lateral boundaries of a fissure or cleft, the **pudendal cleft** or **rima**, into which the vagina and urethra open. Each labium has two surfaces, an outer, pigmented and covered with strong, crisp hairs; and an inner, smooth and beset with large sebaceous follicles. Between the two there is a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos tunic of the scrotum, besides vessels,

nerves, and glands. The labia are thicker in front, where they form by their meeting the **anterior labial commissure**. Posteriorly they are not really joined, but appear to become lost in the neighboring integument, ending close to, and nearly parallel with, each other. Together with the connecting skin between them, they form the **posterior labial commissure** or posterior boundary of the pudendum. The interval between the posterior commissure and the anus, from 2.5 to 3 cm. in length, constitutes the **perineum**. The labia majora correspond to the scrotum in the male.

The **Labia Minora** (*labia minora pudendi; nymphae*) are two small cutaneous folds, situated between the labia majora, and extending from the clitoris obliquely downward, lateralward, and backward for about 4 cm. on either side of the orifice of the vagina, between which and the labia majora they end; in the virgin the posterior ends of the labia minora are usually joined across the middle line by a fold of skin, named the **frenulum of the labia** or **fourchette**. Anteriorly, each labium minus divides into two portions: the upper division passes above the clitoris to meet its fellow of the opposite side, forming a fold which overhangs the glans clitoridis, and is named the **preputium clitoridis**; the lower division passes beneath the clitoris and becomes united to its under surface, forming, with its fellow of the opposite side, the **frenulum of the clitoris**. On the opposed surfaces of the labia minora are numerous sebaceous follicles.

The **Clitoris** is an erectile structure, homologous with the penis. It is situated beneath the anterior labial commissure, partially hidden between the anterior ends of the labia minora. It consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane, united together along their medial surfaces by an incomplete fibrous pectiniform septum; each corpus is connected to the rami of the pubis and ischium by a crus; the **free extremity** (*glans clitoridis*) is a small rounded tubercle, consisting of spongy erectile tissue, and highly sensitive. The clitoris is provided like the penis, with a suspensory ligament, and with two small muscles, the Ischiocavernosi, which are inserted into the crura of the clitoris.

The **Vestibule** (*vestibulum vaginae*).—The cleft between the labia minora and behind the glans clitoridis is named the **vestibule of the vagina**: in it are seen the urethral and vaginal orifices and the openings of the ducts of the greater vestibular glands.

The **external urethral orifice** (*orificium urethrae externum; urinary meatus*) is placed about 2.5 cm. behind the glans clitoridis and immediately in front of that of the vagina; it usually assumes the form of a short, sagittal cleft with slightly raised margins.

The **vaginal orifice** is a median slit below and behind the opening of the urethra; its size varies inversely with that of the **hymen**.

The **hymen** is a thin fold of mucous membrane situated at the orifice of the vagina; the inner surfaces of the fold are normally in contact with each other, and the vaginal orifice appears as a cleft between them. The hymen varies much in shape. When stretched, its commonest form is that of a ring, generally broadest posteriorly; sometimes it is represented by a semilunar fold, with its concave margin turned toward the pubes. Occasionally it is cribriform, or its free margin forms a membranous fringe. It may be entirely absent, or may form a complete septum across the lower end of the vagina; the latter condition is known as an **imperforate hymen**. It may persist after copulation, so that it cannot be considered as a test of virginity. When the hymen has been ruptured, small rounded elevations known as the **carunculae hymeneales** are found as its remains. Between the hymen and the frenulum of the labia is a shallow depression, named the **navicular fossa**.

The **Bulb of the Vestibule** (*bulbus vestibuli; vaginal bulb*) is the homologue of the bulb and adjoining part of the corpus cavernosum urethrae of the male, and

consists of two elongated masses of erectile tissue, placed one on either side of the vaginal orifice and united to each other in front by a narrow median band termed the **pars intermedia**. Each lateral mass measures a little over 2.5 cm. in length. Their posterior ends are expanded and are in contact with the greater vestibular glands; their anterior ends are tapered and joined to one another by the **pars intermedia**; their deep surfaces are in contact with the inferior fascia of the urogenital diaphragm; superficially they are covered by the **Bulbocavernosus**.

The **Greater Vestibular Glands** (*glandula vestibularis major* [Bartholini]; *Bartholin's glands*) are the homologues of the bulbo-urethral glands in the male. They consist of two small, roundish bodies of a reddish-yellow color, situated one on either side of the vaginal orifice in contact with the posterior end of each lateral mass of the bulb of the vestibule. Each gland opens by means of a duct, about 2 cm. long, immediately lateral to the hymen, in the groove between it and the labium minus.

The Mammae (Mammary Gland; Breasts).

The **mammae** secrete the milk, and are accessory glands of the generative system. They exist in the male as well as in the female; but in the former only in the rudimentary state, unless their growth is excited by peculiar circumstances. In the female they are two large hemispherical eminences lying within the superficial fascia and situated on the front and sides of the chest; each extends from the second rib above to the sixth rib below, and from the side of the sternum to near the mid-axillary line. Their weight and dimensions differ at different periods of life, and in different individuals. Before puberty they are of small size, but enlarge as the generative organs become more completely developed. They increase during pregnancy and especially after delivery, and become atrophied in old age. The left mamma is generally a little larger than the right. The deep surface of each is nearly circular, flattened, or slightly concave, and has its long diameter directed upward and lateralward toward the axilla; it is separated from the fascia covering the *Pectoralis major*, *Serratus anterior*, and *Obliquus externus abdominis* by loose connective tissue. The subcutaneous surface of the mamma is convex, and presents, just below the centre, a small conical prominence, the **papilla**.

The **Mammary Papilla** or **Nipple** (*papilla mammae*) is a cylindrical or conical eminence situated about the level of the fourth intercostal space. It is capable of undergoing a sort of erection from mechanical excitement, a change mainly due to the contraction of its muscular fibres. It is of a pink or brownish hue, its surface wrinkled and provided with secondary papillae; and it is perforated by from fifteen to twenty orifices, the apertures of the lactiferous ducts. The base of the mammary papilla is surrounded by an **areola**. In the virgin the areola is of a delicate rosy hue; about the second month after impregnation it enlarges and acquires a darker tinge, and as pregnancy advances it may assume a dark brown or even black color. This color diminishes as soon as lactation is over, but is never entirely lost throughout life. These changes in the color of the areola are of importance in forming a conclusion in a case of suspected first pregnancy. Near the base of the papilla, and upon the surface of the areola, are numerous large sebaceous glands, the **areolar glands**, which become much enlarged during lactation, and present the appearance of small tubercles beneath the skin. These glands secrete a peculiar fatty substance, which serves as a protection to the integument of the papilla during the act of sucking. The mammary papilla consists of numerous vessels, intermixed with plain muscular fibres, which are principally arranged in a circular manner around the base: some few fibres radiating from base to apex.

Structure (Figs. 1058, 1059).—The mamma consists of gland tissue; of fibrous tissue, connecting its lobes; and of fatty tissue in the intervals between the lobes. The gland tissue, when freed from fibrous tissue and fat, is of a pale reddish color, firm in texture, flattened from before

backward and thicker in the centre than at the circumference. The subcutaneous surface of the mamma presents numerous irregular processes which project toward the skin and are joined to it by bands of connective tissue. It consists of numerous lobes, and these are composed of lobules, connected together by areolar tissue, bloodvessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli, which open into the smallest branches of the lactiferous ducts; these ducts unite to form larger ducts, and these end in a single canal, corresponding with

Lobule

FIG. 1058.—Dissection of the lower half of the mamma during the period of lactation. (Luschka.)

one of the chief subdivisions of the gland. The number of excretory ducts varies from fifteen to twenty; they are termed the *tubuli lactiferi*. They converge toward the areola, beneath which they form dilatations or *ampullae*, which serve as reservoirs for the milk, and, at the base of the papilla, become contracted, and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue containing longitudinal and transverse elastic fibres; muscular fibres are entirely absent; they are lined by columnar epithelium resting on a basement-membrane. The epithelium of the mamma differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or suckling, the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge, and the cells undergo rapid multiplication. At the commencement of lactation, the cells in the centre of the alveolus undergo fatty degeneration, and are eliminated in the first milk, as *colostrum corpuscles*. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells, with spherical nuclei, lining the basement membrane. The cells, during the state of activity of the gland, are capable of forming, in their interior, oil globules, which are then ejected into the lumen of the alveolus, and constitute the milk globules. When the acini are distended by the accumulation of the secretion the lining epithelium becomes flattened.

The *fibrous tissue* invests the entire surface of the mamma, and sends down septa between its lobes, connecting them together.

The *fatty tissue* covers the surface of the gland, and occupies the interval between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and papilla.

Alveoli

Fat

Duct

FIG. 1059.—Section of portion of mamma.

Vessels and Nerves.—The **arteries** supplying the mammae are derived from the thoracic branches of the axillary, the intercostals, and the internal mammary. The **veins** describe an anastomotic circle around the base of the papilla, called by Haller the *circulus venosus*. From this, large branches transmit the blood to the circumference of the gland, and end in the axillary and internal mammary veins. The **lymphatics** are described on page 797. The **nerves** are derived from the anterior and lateral cutaneous branches of the fourth, fifth, and sixth thoracic nerves.

Applied Anatomy.—The ducts descending from the mammary papilla radiate through the gland, and when an incision is made into the breast the scalpel should be directed radially, from the centre to the periphery, so that it may not pass across the ducts. A milk duct may become obstructed and distended, forming a tumor known as a *galactocoele*. *Abscess* frequently occurs about the mamma, and most often in women who are lactating, especially those who have cracks or fissures about the papilla. The abscess may lie between the septa, in the gland tissue itself; or it may lie beneath the skin by the side of the papilla and superficial to the mamma or it may form beneath it, between the mamma and the deep fascia. Free incision, radiating from the papilla, is required in such cases.

Cystic formation of many different kinds is commonly seen in the mamma; in some cases it is due to dilatation of the larger ducts or of the lymph spaces throughout the gland; in others the cysts occur in new growths of the mamma, or as the result of obstruction of the smaller ducts by chronic inflammatory processes.

Malignant growths are seen more often in the mamma than in any other organ; they are of great variety, but the commonest is the spheroidal-celled cancer, the cells of which are intermingled with a varying amount of fibrous tissue. A hard contracting tumor mass results, which drags on the fibrous septa between the lobes so that fixation or retraction of the papilla ensues, and sooner or later the malignant infiltration invades the surrounding gland tissues, the skin, the deep fascia and Pectorales, and even the chest wall and pleura. The lymph glands beneath the Pectorales and those situated toward the apex of the axilla become early involved with secondary malignant deposit, and later the supraclavicular glands enlarge. In other cases the mediastinal glands may be involved, when the disease is situated on the medial side of the papilla.

The operation for removal of a mamma affected with malignant disease should be an extensive procedure, with the object of extirpating all fascial planes and lymphatic structures that may be infected. The incision commences below, over the upper part of the sheath of the Rectus, encloses the mamma by an ellipse, and is then continued on toward the apex of the axilla. The skin is reflected on both sides of the incision; anteriorly, until the sternum is reached, and posteriorly to the posterior boundary of the axilla. The origin of the sternal portion of the Pectoralis major is then divided and turned outward. The Pectoralis minor is next seen, and its origin is then divided in a similar manner. The whole of the muscular and fascial planes of the front of the chest are thus separated *en masse*, carrying with them the mamma and the skin covering it. The insertions of the two Pectorales have next to be divided, and finally the axillary lymph glands and fat are removed from the axillary vessels in one piece with the mass of tissue already detached. This is done by first freely exposing the whole length of the axillary vein and then, with a blunt instrument, peeling the structures off the vein from above downward, from the point where they are crossed by the Subclavius muscle to the lower border of the axilla. In this part of the operation many branches of both vein and artery require ligature. The only thing which then remains to be divided is the deep fascia along the posterior axillary wall. The wound is then closed, drainage is provided, and firm pressure is applied with the dressings. It will be noted that the clavicular portion of the Pectoralis major is left intact, as it is of considerable service for the subsequent movements of the arm, the utility of which is but slightly impaired.

THE DUCTLESS GLANDS.

There are certain organs which are very similar to secreting glands, but differ from them in one essential particular, viz., they do not possess any ducts by which their secretion is discharged. These organs are known as **ductless glands**. They are capable of *internal secretion*—that is to say, of forming, from materials brought to them in the blood, substances which have a certain influence upon the nutritive and other changes going on in the body. This secretion is carried into the blood stream, either directly by the veins or indirectly through the medium of the lymphatics.

These glands include the **thyroid** and the **parathyroids**, the **thymus**, the **spleen**, the **suprarenal glands**, and the **glomus caroticum** and **glomus coccygeum**, which will

be described in this section. They also include the **lymph glands**, which have already been described in the section on Angiology; and the **pineal gland** and **hypophysis cerebri** described in the section on Neurology.

THE THYROID GLAND (GLANDULA THYREODEA; THYROID BODY).
(Fig. 1060).

The **thyroid gland** is a highly vascular organ, situated at the front and sides of the neck; it consists of right and left lobes connected across the middle line by a narrow portion, the **isthmus**. Its weight is somewhat variable, but is usually about 30 grams. It is slightly heavier in the female, in whom it becomes enlarged during menstruation and pregnancy.

FIG. 1060.—The thyroid gland and its relations.

The **lobes** (*lobuli gl. thyroideae*) are conical in shape, the apex of each being directed upward and lateralward as far as the junction of the middle with the lower third of the thyroid cartilage; the base looks downward, and is on a level with the fifth or sixth tracheal ring. Each lobe is about 5 cm. long; its greatest width is about 3 cm., and its thickness about 2 cm. The **lateral** or **superficial surface** is convex, and covered by the skin, the superficial and deep fasciæ, the Sternocleidomastoideus, the superior belly of the Omohyoideus, the Sternohyoideus and Sternothyroideus, and beneath the last muscle by the pretracheal layer of the deep fascia, which forms a capsule for the gland. The **deep** or **medial surface** is moulded over the underlying structures, viz., the thyroid and cricoid cartilages, the trachea, the Constrictor pharyngis inferior and posterior part of the Cricothyroideus, the œsophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent nerves. The **anterior border** is thin, and inclines obliquely from above downward toward the middle line of the neck, while the

posterior border is thick and overlaps the common carotid artery, and, as a rule, the parathyroids.

The **isthmus** (*isthmus gl. thyroidea*) connects together the lower thirds of the lobes; it measures about 1.25 cm. in breadth, and the same in depth, and usually covers the second and third rings of the trachea. Its situation and size present, however, many variations. In the middle line of the neck it is covered by the skin and fascia, and close to the middle line, on either side, by the *Sternothyroideus*. Across its upper border runs an anastomotic branch uniting the two superior thyroid arteries; at its lower border are the inferior thyroid veins. Sometimes the isthmus is altogether wanting.

A third lobe, of conical shape, called the **pyramidal lobe**, frequently *arises* from the upper part of the isthmus, or from the adjacent portion of either lobe, but most commonly the left, and ascends as far as the hyoid bone. It is occasionally quite detached, or may be divided into two or more parts.

A fibrous or muscular band is sometimes found attached, above, to the body of the hyoid bone, and below to the isthmus of the gland, or its pyramidal lobe. When muscular, it is termed the **Levator glandulae thyroideae**.

Small detached portions of thyroid tissue are sometimes found in the vicinity of the lateral lobes or above the isthmus; they are called **accessory thyroid glands** (*glandulae thyroideae accessoriae*).

Colloid material

*Colloid in
lymphatic vessel*

*Cubical
epithelium*

FIG. 1061.—Section of thyroid gland of sheep. $\times 160$.

Structure.—The thyroid gland is invested by a thin capsule of connective tissue, which projects into its substance and imperfectly divides it into masses of irregular form and size. When the organ is cut into, it is of a brownish-red color, and is seen to be made up of a number of closed vesicles, containing a yellow glairy fluid, and separated from each other by intermediate connective tissue (Fig. 1061).

The vesicles of the thyroid of the adult animal are generally closed spherical sacs; but in some young animals, *e. g.*, young dogs, the vesicles are more or less tubular and branched. This appearance is supposed to be due to the mode of growth of the gland, and merely indicates that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of cubical epithelium. There does not appear to be a basement-membrane, so that the epithelial cells are in direct contact with the connective-tissue reticulum which supports the acini. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semifluid, slightly yellowish, colloid material; red corpuscles are found in it in various stages of disintegration and decolorization, the yellow tinge being probably due to the hemoglobin, which is thus set free from the colored corpuscles. The colloid material contains an iodine compound, *iodothylin*, and is readily stained by eosin. It passes out between the cubical cells and is absorbed into the blood or lymph.

Vessels and Nerves.—The arteries supplying the thyroid gland are the superior and inferior thyroids and sometimes an additional branch (*thyroidea ima*) from the innominate artery or the arch of the aorta, which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The veins form a plexus on the surface of the

gland and on the front of the trachea; from this plexus the superior, middle, and inferior thyroid veins arise; the superior and middle end in the internal jugular, the inferior in the innominate vein. The capillary bloodvessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymphatics, which surround a greater or smaller part of the circumference of the vesicle. The **lymphatic vessels** run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a net-work in the capsule of the gland; they may contain colloid material. They end in the thoracic and right lymphatic trunks. The **nerves** are derived from the middle and inferior cervical ganglia of the sympathetic.

Applied Anatomy.—An enlargement of the thyroid gland is called a goitre. The swelling may take the form of a diffuse hypertrophy of the whole gland, giving rise to the *parenchymatous goitre*, this being mainly due to the hypertrophy of the thyroid follicles themselves; in other cases a *fibroid* form of goitre is produced owing to the increase in the interstitial connective tissue; in others, again, the vascular changes may preponderate, and many large pulsating vessels may be present. Much more commonly, however, the enlargement is due to adenomatous new growth in the substance of the thyroid; these tumors are always innocent, and tend to destroy life only by pressure on the air passages. A single tumor is the rule, but in some instances a very large number may be present. They tend to show marked mucoid degeneration, and so become converted into cyst-adenomata, and finally into what appear to be simple cysts. These tumors may attain an enormous size and may involve practically the whole gland. Malignant tumor-growth more rarely attacks the organ.

When, in spite of treatment, a goitre continues to grow, and especially when there are commencing symptoms of tracheal pressure, operative interference becomes necessary. This is not difficult, if an encapsulated tumor is to be dealt with, provided the anatomical layers covering it are remembered. In such a case it is necessary to make an incision suited to the size and situation of the tumor, and having divided the deep cervical fascia, to retract the Sternocleidomastoideus or divide it if necessary. The Sternohyoideus and Sternothyroideus next require division, or in some cases their fibres may be separated and drawn asunder, and beneath is found the ensheathing capsule derived from the pretracheal fascia; this requires division, and exposes the true capsule of the thyroid gland. In the case of an adenoma or cyst, this true capsule then needs incision before the tumor can be effectually shelled out, and this is usually accomplished with very little hemorrhage, and without any of the main vessels of the gland requiring ligature.

Partial extirpation of the thyroid, viz., the removal of one lateral lobe with division of the isthmus, may be required in cases of parenchymatous goitre, and in the diffuse form of adenomatous disease. It is a more radical proceeding, and carries with it a much greater risk from hemorrhage; there is also a danger of wounding the recurrent nerve. The whole gland must never be removed, as such a procedure is followed by the development of myxedema. In hemithyroidectomy a free incision is indicated—dividing muscles, if necessary—to expose the true gland capsule, but at the same time avoiding injury to the large vessels which lie beneath it. The superior and inferior pedicles containing the respective thyroid arteries are then isolated and clamped on either side and divided between the clamps. The half gland is then turned over toward the middle line, and the isthmus ligatured and divided. Some venous bleeding is apt to occur from connections with the tracheal veins, and must be stopped. The pedicles are then securely ligatured and the wound closed. In dealing with the inferior thyroid artery, the position of the recurrent nerve must be borne in mind, so as not to ligature or divide it. Temporary aphonia, not uncommonly follows from bruising of the nerve, and if nothing more serious has occurred soon passes off.

THE PARATHYROID GLANDS.

The **parathyroid glands** are small brownish-red bodies, situated as a rule between the posterior borders of the lateral lobes of the thyroid gland and its capsule. They differ from it in structure, being composed of masses of cells arranged in a more or less columnar fashion with numerous intervening capillaries. They measure on an average about 6 mm. in length, and from 3 to 4 mm. in breadth, and usually present the appearance of flattened oval disks. They are divided, according to their situation, into **superior** and **inferior**. The superior, usually two in number, are the more constant in position, and are situated, one on either side, at the level of the lower border of the cricoid cartilage, behind the junction of the pharynx and œsophagus. The inferior, also usually two in number, may be applied to the lower edge of the lateral lobes, or placed at some little distance below the thyroid gland, or found in relation to one of the inferior thyroid veins.¹

¹ Consult an article "Concerning the Parathyroid Glands," by D. A. Welsh, *Journal of Anatomy and Physiology*, vol. xxxii.

In man, they number four as a rule; fewer than four were found in less than 1 per cent. of over a thousand persons (Pepere¹), but more than four in over 33 per cent. of 122 bodies examined by Civalleri. In addition, numerous minute islands of parathyroid tissue may be found scattered in the connective tissue and fat of the neck around the parathyroid glands proper, and quite distinct from them.

Structure.—Microscopically the parathyroids consist of intercommunicating columns of cells supported by connective tissue containing a rich supply of blood capillaries. Most of the cells are clear, but some, larger in size, contain oxyphil granules. Vesicles containing colloid have been described as occurring in the parathyroid, but the observation has not been confirmed.

Applied Anatomy.—No doubt the parathyroid glands produce an internal secretion essential to the well-being of the human economy; but it is still a matter of dispute what symptoms of disease are produced by their removal and suppression of their secretion. Pepere believes that they show signs of exceptional activity during pregnancy, and that parathyroid insufficiency is a main factor in the production of tetany in infants and adults, of eclampsia, and of certain sorts of fits.

THE THYMUS (THYMUS GLANDS) (Fig. 1062).

The thymus is a temporary organ, attaining its largest size at the time of puberty (Hammar), when it ceases to grow, gradually dwindles, and almost disappears. If examined when its growth is most active, it will be found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the thorax, partly in the neck, and extending from the fourth costal cartilage upward, as high as the lower border of the thyroid gland. It is covered by the sternum, and by the origins of the Sternohyoidei and Sternothyreoides.

FIG. 1062.—The thymus of a full-term fetus, exposed *in situ*.

Below, it rests upon the pericardium, being separated from the aortic arch and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sternohyoidei and Sternothyreoides. The two lobes generally differ in size; they are occasionally united, so as to form a single mass; and sometimes separated by an intermediate lobe. The thymus is of a pinkish-gray color, soft, and lobulated on its surfaces. It is about 5 cm. in length, 4 cm. in breadth below, and about 6 mm. in thickness. At birth it weighs about 15 grams.

Structure.—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue; the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from that of a pin's head to that of a small pea, and are made up of a number of small nodules or follicles, which are irregular in shape and are more or less fused together, especially toward the interior of the gland. Each follicle is from 1 to 2 mm.

¹ Consult *Le Ghiandole paratiroidee*, by A. Pepere, Turin, 1906.

in diameter and consists of a medullary and a cortical portion, and these differ in many essential particulars from each other. The **cortical portion** is mainly composed of lymphoid cells, supported by a network of finely branched cells, which is continuous with a similar network in the medullary portion. This network forms an adventitia to the bloodvessels. In the **medullary portion** the reticulum is coarser than in the cortex, the lymphoid cells are relatively fewer in number, and there are found peculiar nest-like bodies, the concentric corpuscles of Hassall. These concentric corpuscles are composed of a central mass, consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells (Fig. 1063). They are the remains of the epithelial tubes which grow out from the third branchial pouches of the embryo to form the thymus.

FIG. 1063. —Minuta structure of thymus. Follicle of injected thymus from calf, four days old, slightly diagrammatic, magnified about 50 diameters. The large vessels are disposed in two rings, one of which surrounds the follicle, the other lies just within the margin of the medulla. (Watney.) A and B. From thymus of camel, examined without addition of any reagent. Magnified about 400 diameters. A. Large colorless cell, containing small oval masses of hemoglobin. Similar cells are found in the lymph glands, spleen, and medulla of bone. B. Colored blood corpuscles.

Each follicle is surrounded by a vascular plexus, from which vessels pass into the interior, and radiate from the periphery toward the centre, forming a second zone just within the margin of the medullary portion. In the centre of the medullary portion there are very few vessels, and they are of minute size.

Watney has made the important observation that hemoglobin is found in the thymus, either in cysts or in cells situated near to, or forming part of, the concentric corpuscles. This hemoglobin occurs as granules or as circular masses exactly resembling colored blood corpuscles. He has also discovered, in the lymph issuing from the thymus, similar cells to those found in the gland, and, like them, containing hemoglobin in the form of either granules or masses. From these facts he arrives at the conclusion that the gland is one source of the colored blood corpuscles. More recently Schaffer has observed actual nucleated red-blood corpuscles in the thymus.

Vessels and Nerves.—The **arteries** supplying the thymus are derived from the internal mammary, and from the superior and inferior thyroids. The **veins** end in the left innominate vein, and in the thyroid veins. The **lymphatics** are described on page 779. The **nerves** are exceedingly minute; they are derived from the vagi and sympathetic. Branches from the descending hypoglossi and phrenic reach the investing capsule, but do not penetrate into the substance of the gland.

Applied Anatomy.—Sudden death—*thymus death*—with heart-failure, and with or without acute respiratory embarrassment, has been recorded in a number of infants and children]in whom the thymus was considerably enlarged and the lymphatic tissues throughout the body showed general hypertrophy, but who showed no other evidence of disease. Such deaths have often occurred during the administration of anesthetics, particularly chloroform. How far the enlarged thymus was responsible for the death of these patients, and, if it was responsible, how far its action was mechanical, are points that have been much disputed. Short of producing this sudden death, it appears that thymic enlargement may cause attacks of respiratory stridor, or noisy and difficult breathing, and spasmodic attacks of asthma—*thymic asthma*—which may be frequently repeated and may even result in death. Primary tumors of the thymus are rare forms of mediastinal new growth, and are usually dermoids or lymphosarcomas.

THE SPLEEN (LIEN). 1742

The **spleen** is situated principally in the left hypochondriac region, but its superior extremity extends into the epigastric region; it lies between the fundus of the stomach and the Diaphragma. It is the largest of the ductless glands, and is of an oblong, flattened form, soft, of very friable consistence, highly vascular, and of a dark purplish color.

Relations.—The **diaphragmatic surface** (*facies diaphragmatica; external or phrenic surface*) is convex, smooth, and is directed upward, backward, and to the left, except at its upper end, where it is directed slightly medialward. It is in relation with the under surface of the Diaphragma, which separates it from the ninth, tenth, and eleventh ribs of the left side, and the intervening lower border of the left lung and pleura.

The **visceral surface** (Fig. 1064) is divided by a ridge into an **anterior or gastric** and a **posterior or renal portion**.

Vein
leaving
hilus

FIG. 1064.—The visceral surface of the spleen.

The **gastric surface** (*facies gastrica*), which is directed forward, upward, and medialward, is broad and concave, and is in contact with the posterior wall of the stomach; and below this with the tail of the pancreas. It presents near its medial border a long fissure, termed the hilus. This is pierced by several irregular apertures, for the entrance and exit of vessels and nerves.

The **renal surface** (*facies renalis*) is directed medialward and downward. It is somewhat flattened, is considerably narrower than the gastric surface, and is in relation with the upper part of the anterior surface of the left kidney and occasionally with the left suprarenal gland.

The **superior extremity** (*extremitas superior*) is directed toward the vertebral column, where it lies on a level with the eleventh thoracic vertebra. The **lower extremity** or **colic surface** (*extremitas inferior*) is flat, triangular in shape, and rests upon the left flexure of the colon and the phrenicocolic ligament, and is generally in contact with the tail of the pancreas. The **anterior border** (*margo anterior*) is free, sharp, and thin, and is often notched, especially below; it separates the diaphragmatic from the gastric surface. The **posterior border** (*margo posterior*), more rounded and blunter than the anterior, separates the renal from the diaphragmatic surface; it corresponds to the lower border of the eleventh rib and lies between the Diaphragma and left kidney. The intermediate margin is the ridge which separates the renal and gastric surfaces. The **inferior border** (*internal border*) separates the diaphragmatic from the colic surface.

The spleen is almost entirely surrounded by peritoneum, which is firmly adherent to its capsule. It is held in position by two folds of this membrane. One, the **phrenicolienal ligament**, is derived from the peritoneum, where the wall of the general peritoneal cavity comes into contact with the omental bursa between the left kidney and the spleen; the lienal vessels pass between its two layers (Fig. 965). The other fold, the **gastrolienal ligament**, is also formed of two layers, derived from the general peritoneal cavity and the omental bursa respectively, where they meet between the spleen and stomach (Fig. 965); the short gastric and left gastroepiploic branches of the lienal artery run between its two layers. The lower end of the spleen is supported by the phrenicocolic ligament (see page 1157).

The size and weight of the spleen are liable to very extreme variations at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult*, it is usually about 12 cm. in length, 7 cm. in breadth, and 3 or 4 cm. in thickness, and weighs about 200 grams. *At birth*, its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as 1 to 350; while in the adult it varies from 1 to 320 and 400. *In old age*, the organ not only diminishes in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and after digestion, and varies according to the state of nutrition of the body, being large in highly fed, and small in starved animals. In malarial fever it becomes much enlarged, weighing occasionally as much as 9 kilos.

Frequently in the neighborhood of the spleen, and especially in the gastrolienal ligament and greater omentum, small nodules of splenic tissue may be found, either isolated or connected to the spleen by thin bands of splenic tissue. They are known as **accessory spleens** (*lien accessorius*; *supernumerary spleen*). They vary in size from that of a pea to that of a plum.

Structure.—The spleen is invested by two coats: an **external serous** and an **internal fibroelastic coat**.

The **external** or **serous coat** (*tunica serosa*) is derived from the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibroelastic coat. It invests the entire organ, except at the hilus and along the lines of reflection of the phrenicolienal and gastrolienal ligaments.

The **fibroelastic coat** (*tunica albuginea*) invests the organ, and at the hilus is reflected inward upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibroelastic coat, numerous small fibrous bands, **trabeculae** (Fig. 1065), are given off in all directions; these uniting, constitute the frame-work of the spleen. The spleen therefore consists of a number of small spaces or **areolae**, formed by the trabeculae; in these areolae is contained the **splenic pulp**.

The fibroelastic coat, the sheaths of the vessels, and the trabeculae, are composed of white and yellow elastic fibrous tissues, the latter predominating. It is owing to the presence of the elastic tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents of this tunic, there is found in man a small amount of non-striped muscular fibre; and in some mammalia, *e. g.*, dog, pig, and cat, a large amount, so that the trabeculae appear to consist chiefly of muscular tissue.

The **splenic pulp** (*pulpa lienis*) is a soft mass of a dark reddish-brown color, resembling grumous blood; it consists of a fine reticulum of fibres, continuous with those of the trabeculae, to which are applied flat, branching cells. The meshes of the reticulum are filled with blood, in which, however, the white corpuscles are found to be in larger proportion than they are in ordinary blood. Large rounded cells, termed **splenic cells**, are also seen; these are capable of amoeboid movement, and often contain pigment and red-blood corpuscles in their interior. The cells of the reticulum each possess a round or oval nucleus, and like the splenic cells, they may contain pigment granules in their cytoplasm; they do not stain deeply with carmine, and in this respect differ from the cells of the Malpighian bodies. In the young spleen, giant cells may also be found, each containing numerous nuclei or one compound nucleus. Nucleated red-blood corpuscles have also been found in the spleen of young animals.

Bloodvessels of the Spleen.—The **lienal artery** is remarkable for its large size in proportion to the size of the organ, and also for its tortuous course. It divides into six or more branches, which enter the hilus of the spleen and ramify throughout its substance (Fig. 1066), receiving

sheaths from an involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ, from within outward, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells. Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

FIG. 1065.—Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its tributaries.

The arterioles supported by the minute trabeculae, traverse the pulp in all directions in bundles (*pencils*) of straight vessels. Their trabecular sheaths gradually undergo a transformation, become much thickened, and converted into adenoid tissue; the bundles of connective tissue becoming looser and their fibrils more delicate, and containing in their interstices an abundance of lymph corpuscles (W. Müller).

FIG. 1066.—Transverse section of the human spleen, showing the distribution of the splenic artery and its branches.

The altered coat of the arterioles, consisting of adenoid tissue, presents here and there thickenings of a spheroidal shape, the **lymphatic nodules** (*Malpighian bodies of the spleen*). These bodies vary in size from about 0.25 mm. to 1 mm. in diameter. They are merely local expansions or hyperplasie of the adenoid tissue, of which the external coat of the smaller arteries of the spleen

is formed. They are most frequently found surrounding the arteriole, which thus seems to tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. In transverse sections, the artery, in the majority of cases, is found in an excentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of a semiopaque whitish

Trabecula

*Lymphatic
nodule*

Spleen pulp

FIG. 1067.—Transverse section of a portion of the spleen.

color in the dark substance of the pulp. In minute structure they resemble the adenoid tissue of lymph glands, consisting of a delicate reticulum, in the meshes of which lie ordinary lymphoid cells (Fig. 1067). The reticulum is made up of extremely fine fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at its periphery. The cells which it encloses are possessed of amoeboid movement. When treated with carmine they become deeply stained, and can be easily distinguished from those of the pulp.

*Continuous
processes of
retic cells*

*Small
artery* —

Branching cell

FIG. 1068.—Section of the spleen, showing the termination of the small bloodvessels.

The arterioles end by opening freely into the splenic pulp; their walls become much attenuated, they lose their tubular character, and the endothelial cells become altered, presenting a branched appearance, and acquiring processes which are directly connected with the processes of the reticular cells of the pulp (Fig. 1068). In this manner the vessels end, and the blood flowing through them finds its way into the interstices of the reticulated tissue of the splenic pulp. Thus

the blood passing through the spleen is brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins, which begin much in the same way as the arteries end. The connective-tissue corpuscles of the pulp arrange themselves in rows, in such a way as to form an elongated space or sinus. They become elongated and spindle-shaped, and overlap each other at their extremities, and thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surfaces of these cells are seen delicate transverse lines or markings, which are due to minute elastic fibrillæ arranged in a circular manner around the sinus. Thus the channel obtains an external investment, and gradually becomes converted into a small vein, which after a short course acquires a coat of ordinary connective tissue, lined by a layer of flattened epithelial cells which are continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones; these do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form six or more branches, which emerge from the hilus, and, uniting, constitute the lienal vein, the largest radicle of the portal vein.

The veins are remarkable for their numerous anastomoses, while the arteries hardly anastomose at all.

The lymphatics are described on page 793.

The nerves are derived from the coeliac plexus and are chiefly non-medullated. They are distributed to the bloodvessels and to the smooth muscle of the capsule and trabeculæ.

Applied Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be ruptured by direct or indirect violence; torn by a broken rib; or injured by a punctured or gunshot wound. When the organ is enlarged, the chance of rupture is increased. The great risk is hemorrhage, owing to the vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due, in a great measure, to the contractile power of the capsule, which narrows the wound and prevents the escape of blood. In cases where the diagnosis is clear, and the symptoms indicate danger to life, laparotomy must be performed, and if the hemorrhage cannot be stayed by ordinary surgical methods, the spleen must be removed.

The spleen may become enormously enlarged in certain diseased conditions, such as ague, leukemia, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma, as a part of a general blood-disease. In these cases the tumor may fill a considerable part of the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine new growth.

The spleen is sometimes the seat of cystic tumors, especially hydatids, and of abscess. These cases require treatment by incision and drainage; and in abscess great care must be taken, if there are no adhesions between the spleen and abdominal wall, to prevent the escape of any of the pus into the peritoneal cavity. If possible the operation should be performed in two stages. Sarcoma and carcinoma are occasionally found in the spleen, but very rarely as primary diseases.

Extirpation of the spleen has been performed for wounds or injuries, in floating spleen, in simple hypertrophy, in leukemic enlargement (but the operation is now considered unjustifiable in this condition), and in the case of enlargement due to certain obscure parasitic infections met with in hot climates. The incision is best made in the left semilunar line; the spleen is isolated from its surroundings and delivered from the abdomen; the pedicle is then transfixed and ligatured in two portions.

THE SUPRARENAL GLANDS (GLANDULÆ SUPRARENALIS; ADRENAL CAPSULE) (Figs. 1069, 1070).

The suprarenal glands are two small flattened bodies of a yellowish color, situated at the back part of the abdomen, behind the peritoneum, and immediately above and in front of the upper end of each kidney; hence their name. The right one is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left is more semilunar, usually larger, and placed at a higher level than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected: their usual size is from 3 to 5 cm. in length, rather less in width, and from 4 to 6 mm. in thickness. Their average weight is from 1.5 to 2.5 gm. each.

Relations.—The relations of the suprarenal glands differ on the two sides of the body.

The right suprarenal is situated behind the inferior vena cava and right lobe of the liver, and in front of the Diaphragma and upper end of the right kidney. It is roughly triangular in shape; its base, directed downward, is in contact with the medial and anterior aspects of the upper end

of the right kidney. It presents two surfaces for examination, an anterior and a posterior. The *anterior surface* looks forward and lateralward, and has two areas: a medial, narrow, and non-peritoneal, which lies behind the inferior vena cava; and a lateral, somewhat triangular, in contact with the liver. The upper part of the latter surface is devoid of peritoneum, and is in relation with the bare area of the liver near its lower and medial angle, while its inferior portion is covered by peritoneum, reflected on to it from the inferior layer of the coronary ligament; occasionally the duodenum overlaps the inferior portion. A little below the apex, and near the anterior border of the gland, is a short furrow termed the *hilus*, from which the suprarenal vein emerges to join the inferior vena cava. The *posterior surface* is divided into upper and lower parts by a curved ridge: the upper, slightly convex, rests upon the Diaphragma; the lower, concave, is in contact with the upper end and the adjacent part of the anterior surface of the kidney.

FIG. 1069.—Suprarenal glands viewed from the front.

The *left suprarenal*, slightly larger than the right, is crescentic in shape, its concavity being adapted to the medial border of the upper part of the left kidney. It presents a medial border, which is convex, and a lateral, which is concave; its upper end is narrow, and its lower rounded. Its *anterior surface* has two areas: an upper one, covered by the peritoneum of the omental bursa, which separates it from the cardiac end of the stomach, and sometimes from the superior extremity of the spleen; and a lower one, which is in contact with the pancreas and lienal artery, and is therefore not covered by the peritoneum. On the anterior surface, near its lower end, is a furrow or *hilus*, directed downward and forward, from which the suprarenal vein emerges. Its *posterior surface* presents a vertical ridge, which divides it into two areas; the lateral area rests on the kidney, the medial and smaller on the left crus of the Diaphragma.

FIG. 1070.—Suprarenal glands viewed from behind.

The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous capsule, which is difficult to remove on account of the numerous fibrous processes and vessels entering the organ through the furrows on its anterior surface and base.

Small *accessory suprarenals* (*glandulae suprarenales accessoriae*) are often to be found in the connective tissue around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure.—On section, the suprarenal gland is seen to consist of two portions (Fig. 1071): an *external or cortical* and an *internal or medullary*. The former constitutes the chief part of the organ, and is of a deep yellow color; the medullary substance is soft, pulpy, and of a dark red or brown color.

The **cortical portion** (*substantia corticalis*) consists of a fine connective-tissue net-work, in which is imbedded the glandular epithelium. The epithelial cells are polyhedral in shape and possess rounded nuclei; many of the cells contain coarse granules, others lipid globules. Owing to differences in the arrangement of the cells, three distinct zones can be made out: (1) the **zona glomerulosa**, situated beneath the capsule, consists of cells arranged in rounded groups, with here and there indications of an alveolar structure; the cells of this zone are very granular, and stain deeply. (2) The **zona fasciculata**, continuous with the zona glomerulosa, is composed of columns of cells arranged in a radial manner; these cells contain finer granules and in many instances globules of lipid material. (3) The **zona reticularis**, in contact with the medulla, consists of cylindrical masses of cells irregularly arranged; these cells often contain pigment granules which give this zone a darker appearance than the rest of the cortex.

The **medullary portion** (*substantia medullaris*) is extremely vascular, and is composed of a loose mesh-work of connective tissue surrounding a large plexus of sinusoidal venous spaces and containing non-striped muscular fibres. In addition to the veins, multinucleated masses of protoplasm are scattered throughout the medulla as well as many irregular-shaped cells containing pigment. The cell protoplasm has an especial affinity for chromic salts, which stain it a brown color. Such cells are therefore termed **chromaffin cells** (see page 133). This portion of the gland is richly supplied with non-medullated nerve fibres, and here and there sympathetic ganglia are found.

Medulla

Ganglion

FIG. 1071.—Section of a part of a suprarenal gland. (Magnified.)

Vessels and Nerves.—The **arteries** supplying the suprarenal glands are numerous and of comparatively large size; they are derived from the aorta, the inferior phrenic, and the renal. They subdivide into minute branches previous to entering the cortical part of the gland, where they break up into capillaries which end in the venous plexus of the medullary portion.

The **suprarenal vein** returns the blood from the medullary venous plexus and receives several branches from the cortical substance; it emerges from the hilus of the gland and on the right side opens into the inferior vena cava, on the left into the renal vein.

The **lymphatics** end in the lumbar glands.

The **nerves** are exceedingly numerous, and are derived from the coeliac and renal plexuses, and, according to Bergmann, from the phrenic and vagus nerves. They enter the lower and medial part of the capsule, traverse the cortex, and end around the cells of the medulla. They have numerous small ganglia developed upon them in the medullary portion of the gland.

In connection with the development of the medulla from the sympathochromaffin tissue, it is to be noted that this portion of the gland secretes a substance, **adrenalin**, which has a powerful influence on those muscular tissues which are supplied by sympathetic fibres.

Applied Anatomy.—The suprarenal **cortex** is derived from the coelomic epithelium of the Wolffian ridge, and is connected with the sexual glands; it is related to growth and development in some way, and is often found to be hypertrophied in patients with chronic kidney disease and high blood-pressure. The **medulla**, on the other hand, is neuro-ectodermal in origin, and

closely connected with the sympathetic nervous system. When the suprarenal medulla is destroyed by tuberculosis, to which the glands are prone, or by the pressure of a new growth, the secretion of adrenalin becomes inadequate, and Addison's disease develops. Patients with Addison's disease become pigmented in various parts of the body, possibly from irritation of the sympathetic, and complain of great weakness, lack of energy, nausea, and severe attacks of vomiting. Their blood-pressure is low, the whole nervous system is depressed, and death follows after a period of months or years, usually from asthenia. Tumors derived from the suprarenal itself, or from misplaced suprarenal "rests" occurring in such organs as the kidney or liver, may be either benign or malignant, and are classed together under the name "hypernephroma." In children the malignant hypernephroma is often associated with obesity and precocity. The benign hypernephroma, or suprarenal adenoma, appears to produce no symptoms except those due to its slow enlargement.

THE CAROTID SKEINS (GLOMERA CAROTICA; CAROTID GLANDS; CAROTID BODIES.)

The **carotid skeins**, two in number, are situated one on either side of the neck, behind the common carotid artery at its point of bifurcation into the external and internal carotid trunks. They are reddish brown in color and oval in shape, the long diameter measuring about 5 mm.

FIG. 1072.—Section of part of human glomus caroticum. (Schaper.) Highly magnified. Numerous bloodvessels are seen in section among the gland cells.

Each is invested by a fibrous capsule and consists largely of spherical or irregular masses of cells (Fig. 1072), the masses being more or less isolated from one another by septa which extend inward from the deep surface of the capsule. The cells are polyhedral in shape, and each contains a large nucleus imbedded in finely granular protoplasm, which is stained yellow by chromic salts. Numerous nerve fibres, derived from the sympathetic plexus on the carotid artery, are distributed throughout the organ, and a net-work of large sinusoidal capillaries ramifies among the cells.

THE COCCYGEAL SKEIN (GLOMUS COCCYGEUM; COCCYGEAL GLAND OR BODY; LUSCHKA'S GLAND).

The **coccygeal skein** is placed in front of, or immediately below, the tip of the coccyx. It is about 2.5 mm. in diameter and is irregularly oval in shape; several smaller nodules are found around or near the main mass.

It consists of irregular masses of round or polyhedral cells (Fig. 1073), the cells of each mass being grouped around a dilated sinusoidal capillary vessel. Each cell

contains a large round or oval nucleus, the protoplasm surrounding which is clear, and is not stained by chromic salts.¹

FIG. 1073.—Section of an irregular nodule of the *glomus coccygeum*. (Sertoli.) $\times 85$. The section shows the fibrous covering of the nodule, the bloodvessels within it, and the epithelial cells of which it is constituted.

Besides the ductless glands mentioned, reference may be made to a pair of small bodies, the **aortic bodies of Zuckerkandl**. These are found in the embryo, and persist until shortly after birth; they lie one on either side of the abdominal aorta between the superior mesenteric and common iliac arteries (see page 133). They consist essentially of masses of polygonal or cuboidal chromaffin cells imbedded in a wide-meshed capillary plexus.

SURFACE ANATOMY AND SURFACE MARKINGS.

SURFACE ANATOMY OF THE HEAD AND NECK.

Bones (Fig. 1074).—Various bony surfaces and prominences on the skull can be easily identified by palpation. The **external occipital protuberance** is situated behind, in the middle line, at the junction of the skin of the neck with that of the head. The **superior nuchal line** runs lateralward from it on either side, while extending downward from it is the **median nuchal crest**, situated deeply at the bottom of the nuchal furrow. Above the superior nuchal lines the vault of the cranium

FIG. 1074.—Side view of head, showing surface relations of bones.

is thinly covered with soft structures, so that the form of this part of the head is almost that of the upper portion of the occipital, the parietal, and the frontal bones. The superior nuchal line can be followed lateralward to the mastoid portion of the temporal bone, from which the **mastoid process** projects downward and forward behind the ear. The anterior and posterior borders, the apex, and the external surface of this process are all available for superficial examination the anterior border lies immediately behind the concha, and the apex is on a level

with the lobule of the auricula. About 1 cm. below and in front of the apex of the mastoid process, the **transverse process of the atlas** can be distinguished. In front of the ear the **zygomatic arch** can be felt throughout its entire length; its posterior end is narrow and is situated a little above the level of the tragus; its anterior end is broad and is continued into the zygomatic bone. The lower border of the arch is more distinct than the upper, which is obscured by the attachment of the temporal fascia. In front, and behind, the upper border of the arch can be followed into the **superior temporal line**. In front, this line begins at the zygomatic process of the frontal bone as a curved ridge which runs at first forward and upward on the frontal bone, and then curving backward separates the forehead from the temporal fossa. It can then be traced across the parietal bone, where, though less marked, it can generally be recognized. Finally, it curves downward, and forward, and passing above the external acoustic meatus, ends in the posterior root of the zygomatic arch. Near the line of the greatest transverse diameter of the head are the **parietal eminences**, one on either side of the middle line; further forward, on the forehead, are the **frontal eminences**, which vary in prominence in different individuals and are frequently unsymmetrical. Below the frontal eminences the **superciliary arches**, which indicate the position of the frontal sinuses, can be recognized; as a rule they are small in the female and absent in children. In some cases the prominence of the superciliary arches is related to the size of the frontal sinuses, but frequently there is no such relationship. Situated between, and connecting the superciliary ridges, is a smooth, somewhat triangular area, the **glabella**, below which the **nasion** (*frontonasal suture*) can be felt as a slight depression at the root of the nose.

Below the nasion the **nasal bones**, scantily covered by soft tissues, can be traced to their junction with the nasal cartilages, and on either side of the nasal bone the complete outline of the **orbital margin** can be made out. At the junction of the medial and intermediate thirds of the supraorbital margin the **supraorbital notch**, when present, can be felt; close to the medial end of the infraorbital margin is a little tubercle which serves as a guide to the position of the lacrimal sac. Below and lateral to the orbit, on either side, is the **zygomatic bone** forming the prominence of the cheek; its posterior margin is easily palpable, and on it just above the level of the lateral palpebral commissure is the **zygomatic tubercle**. A slight depression, about 1 cm. above this tubercle, indicates the position of the **zygomaticofrontal suture**. Directly below the orbit a considerable part of the anterior surface of the maxilla and the whole of its alveolar process can be palpated. The outline of the **mandible** can be recognized throughout practically its entire extent; in front of the tragus and below the zygomatic arch is the condyle, and from this the posterior border of the ramus can be followed to the angle; from the angle to the symphysis the lower rounded border of the mandible can be easily traced; the lower part of the anterior border of the ramus and the alveolar process can be made out without difficulty. In the receding angle below the chin is the **hyoid bone**, and the finger can be carried along the bone to the tip of the greater cornu, which is on a level with the angle of the mandible: the greater cornu is most readily appreciated by making pressure on one side, when the cornu of the opposite side will be rendered prominent and can be felt distinctly beneath the skin.

Joints and Muscles.—The **temporomandibular articulation** is quite superficial, and is situated below the posterior end of the zygomatic arch, in front of the external acoustic meatus. Its position can be ascertained by defining the condyle of the mandible; when the mouth opens, the condyle advances out of the mandibular fossa on to the articular tubercle, and a depression is felt in the situation of the joint.

The outlines of the muscles of the head and face cannot be traced on the surface except in the case of the Masseter and Temporalis. The muscles of the scalp

are so thin that the outline of the bone is perceptible beneath them. Those of the face are small, covered by soft skin, and often by a considerable layer of fat, and their outlines are therefore concealed; they serve, however, to round off and smooth prominent borders, and to fill up what would otherwise be unsightly angular depressions. Thus the *Orbicularis oculi* rounds off the prominent margin of the orbit, and the *Procerus* fills in the sharp depression below the glabella. In like manner the labial muscles converging to the lips, and assisted by the superimposed fat, fill up the sunken hollow of the lower part of the face. When in action the facial muscles produce the various expressions, and in addition through the skin into numerous folds and wrinkles. The *Masseter* imparts fulness to the hinder part of the cheek; if firmly contracted, as when the teeth are clenched, its quadrilateral outline is plainly visible; the anterior border forms a prominent vertical ridge, behind which is a considerable fulness especially marked at the

FIG. 1075.—Anterolateral view of head and neck.

lower part of the muscle. The *Temporalis* is fan-shaped and fills the temporal fossa, substituting for the concavity a somewhat convex swelling, the anterior part of which, on account of the absence of hair on the overlying skin, is more marked than the posterior, and stands out in strong relief when the muscle is in action.

In the neck, the *Platysma* when contracted throws the skin into oblique ridges parallel with the fasciculi of the muscle. The *Sternocleidomastoideus* has the most important influence on the surface form of the neck (Figs. 1075, 1076). When the muscle is at rest its anterior border forms an oblique rounded edge ending below in the sharp outline of the sternal head; the posterior border is only distinct for about 2 or 3 cm. above the middle of the clavicle. During contraction, the sternal head stands out as a sharply defined ridge, while the clavicular head is flatter and less prominent; between the two heads is a slight depression: the fleshy middle portion

of the muscle appears as an oblique elevation with a thick, rounded, anterior border, best marked in its lower part. The sternal heads of the two muscles are separated by a V-shaped depression, in which are the *Sternohyoideus* and *Sternothyroideus*.

Above the hyoid bone, near the middle line, the anterior belly of the *Digastricus* produces a slight convexity.

The anterior border of the *Trapezius* presents as a faint ridge running from the superior nuchal line, downward and forward to the junction of the intermediate and lateral thirds of the clavicle. Between the *Sternocleidomastoideus* and the *Trapezius* is the posterior triangle of the neck, the lower part of which appears as a shallow concavity—the *supraclavicular fossa*. In this fossa, the inferior belly of the *Omohyoideus*, when in action, presents as a rounded cord-like elevation a little above, and almost parallel to, the clavicle.

FIG. 1076.—Front view of neck.

Arteries.—The positions of several of the larger arteries can be ascertained from their pulsations.

The *subclavian artery* can be felt by making pressure downward, backward, and medialward behind the clavicular head of the *Sternocleidomastoideus*; its *transverse cervical branch* may be detected parallel to, and about a finger's breadth above, the clavicle. The *common and external carotid arteries* can be recognized immediately beneath the anterior edge of the *Sternocleidomastoideus*. The *external maxillary artery* can be traced over the border of the mandible just in front of the anterior border of the *Masseter*, then about 1 cm. lateral to the angle of the mouth, and finally as it runs up the side of the nose. The pulsation of the *occipital artery* can be distinguished about 3 or 4 cm. lateral to the external occipital protuberance; that of the *posterior auricular* in the groove between the mastoid process and the auricle. The course of the *superficial temporal artery* can be readily followed across the posterior end of the zygomatic arch to a point about 3 to 5 cm. above this, where it divides into its frontal and parietal branches; the pulsation of the frontal branch is frequently visible on the side of the forehead. The *supraorbital artery* can usually be detected immediately above the supraorbital notch or foramen.

— SURFACE MARKINGS OF SPECIAL REGIONS OF HEAD AND NECK.

The Cranium.—Scalp.—The soft parts covering the upper surface of the skull form the scalp and comprise the following layers (Fig. 1077): (1) *skin*, (2) *subcutaneous tissue*, (3) *Occipitalis frontalis* and *galea aponeurotica*, (4) *subaponeurotic tissue*, (5) *pericranium*. The subcutaneous tissue consists of a close mesh-work of fibres, the meshes of which contain fatty tissue; the fibres bind the skin and galea aponeurotica firmly together, so that when the Occipitalis or the Frontalis is in action the skin moves with the aponeurosis. The subaponeurotic tissue, which intervenes between the galea aponeurotica and the pericranium, is much looser in texture, and permits the movement of the aponeurosis over the underlying bones.

FIG. 1077.—Diagrammatic section of scalp.

Bony Landmarks (Fig. 1074).—In addition to the bony points already described which can be determined by palpation, the following are utilized for surface markings:

Auricular Point.—The centre of the orifice of the external acoustic meatus.

Preauricular Point.—A point on the posterior root of the zygomatic arch immediately in front of the external acoustic meatus.

Asterion.—The point of meeting of the lambdoidal, mastoöccipital, and masto-parietal sutures; it lies 4 cm. behind and 12 mm. above the level of the auricular point.

Pterion.—The point where the great wing of the sphenoid joins the sphenoidal angle of the parietal; it is situated 35 mm. behind, and 12 mm. above, the level of the frontozygomatic suture.

Inion.—The external occipital protuberance.

Lambda.—The point of meeting of the lambdoidal and sagittal sutures; it is in the middle line about 6.5 cm. above the inion.

Bregma.—The meeting-point of the coronal and sagittal sutures; it lies at the point of intersection of the middle line of the scalp with a line drawn vertically upward through the preauricular point.

A line passing through the inferior margin of the orbit and the auricular point is known as **Reid's base line**. The lambdoidal suture can be indicated on either

side by the upper two-thirds of a line from the lambda to the tip of the mastoid process. The **sagittal suture** is in the line joining the lambda to the bregma. The position of the **coronal suture** on either side is sufficiently represented by a line joining the bregma to the centre of the zygomatic arch.

The floor of the middle fossa of the skull is at the level of the posterior three-fourths of the upper border of the zygomatic arch; the articular eminence of the temporal bone is opposite the foramen spinosum and the semilunar ganglion.

FIG. 1078.—Drawing of a cast by Cunningham to illustrate the relations of the brain to the skull.

Brain (Figs. 1078, 1079).—The general outline of the **cerebral hemisphere**, on either side, may be mapped out on the surface in the following manner. Starting from the nasion, a line drawn along the middle of the scalp to the inion represents the superior border. The line of the lower margin behind is that of the transverse sinus (see page 1282), or more roughly a line convex upward from the inion to the posterior root of the zygomatic process of the temporal bone; thence along the posterior two-thirds of the upper border of the zygomatic arch where the line turns up to the pterion; the front part of the lower margin extends from the pterion to the glabella about 1 cm. above the supraorbital margin. The **cerebellum** is so deeply situated that there is no reliable surface marking for it; a point 4 cm. behind and 1.5 cm. below the level of the auricular point is situated directly over it.

The relations of the principal fissures and gyri of the cerebral hemispheres to the surface of the scalp are of considerable practical importance, and several methods of indicating them have been devised. Necessarily these methods can

only be regarded as approximately correct, yet they are all sufficiently accurate for surgical purposes. The **longitudinal fissure** corresponds to the medial line of the scalp between the nasion and inion. In order to mark out the **lateral cerebral (Sylvian) fissure** a point, termed the Sylvian point, which practically corresponds to the pterion, is defined 35 mm. behind and 12 mm. above the level of the frontozygomatic suture; this point marks the spot where the lateral fissure divides. Another method of defining the Sylvian point is to divide the distance between the nasion and inion into four equal parts; from the junction of the third and fourth parts (reckoning from the front) draw a line to the frontozygomatic suture; from the junction of the first and second parts a line to the auricular point. These two lines intersect at the Sylvian point and the portion of the first line behind this point overlies the posterior ramus of the lateral cerebral fissure. The position

FIG. 1079.—Relations of the brain and middle meningeal artery to the surface of the skull. 1. Nasion. 2. Inion. 3. Lambda. 4. Lateral cerebral fissure. 5. Central sulcus. A.A. Reid's base line. B. Point for trephining the anterior branch of the middle meningeal artery. C. Suprameatal triangle. D. Sigmoid bend of the transverse sinus. E. Point for trephining over the straight portion of the transverse sinus, exposing dura mater of both cerebrum and cerebellum. Outline of cerebral hemisphere indicated in blue; course of middle meningeal artery in red.

of the posterior ramus can otherwise be obtained by joining the Sylvian point to a point 2 cm. below the summit of the parietal eminence. The anterior ascending ramus can be marked out by drawing a line upward at right angles to the line of the posterior ramus for 2 cm. and the anterior horizontal ramus by a line of the same length drawn horizontally forward—both from the Sylvian point. To define the **central sulcus (fissure of Rolando)** two points are taken; one is situated 1.25 cm. behind the centre of the line joining the nasion and inion; the second is at the intersection of the line of the posterior ramus of the lateral cerebral fissure with a line through the preauricular point at right angles to Reid's base line. The upper 9 cm. of the line joining these two points overlies the central sulcus and forms an angle, opening forward, of about 70° with the middle line of the scalp. An alternative method is to draw two perpendicular lines from Reid's base line to the top of the head; one from the preauricular point and the other from the posterior

border of the mastoid process at its root. A line from the upper end of the posterior line to the point where the anterior intersects the line of the posterior ramus of the lateral fissure indicates the position of the central sulcus. The **precentral** and **postcentral sulci** are practically parallel to the central sulcus; they are situated respectively about 15 mm. in front of, and behind, it. The **superior frontal sulcus** can be mapped out by a line drawn from the junction of the upper and middle thirds of the precentral sulcus, in a direction parallel with the longitudinal sulcus, to a point midway between the middle line of the forehead and the temporal line, 4 cm. above the supraorbital notch. The **inferior frontal sulcus** begins at the junction of the middle and lower thirds of the precentral sulcus, and follows the course of the superior temporal line.

The horizontal limb of the **intraparietal sulcus** begins from the junction of the lower with the middle third of the postcentral sulcus and curves backward parallel to the longitudinal fissure, midway between it and the parietal eminence; it then curves downward to end midway between the lambda and the parietal eminence. The external part of the **parietooccipital fissure** runs lateralward at right angles to the longitudinal fissure for about 2.5 cm. from a point 5 mm. in front of the lambda. If the line of the posterior ramus of the lateral cerebral fissure be continued back to the longitudinal fissure, the last 2.5 cm. of it will indicate the position of the parietooccipital fissure.

The **lateral ventricle** may be circumscribed by a quadrilateral figure. The upper limit is a horizontal line 5 cm. above the zygomatic arch; this defines the roof of the ventricle. The lower limit is a horizontal line 1 cm. above the zygomatic arch; it indicates the level of the end of the inferior horn. Two vertical lines, one through the junction of the anterior and middle thirds of the zygomatic arch, and the other 5 cm. behind the tip of the mastoid process, indicate the extent of the anterior horn in front and the posterior horn behind.

Vessels.—The line of the anterior division of the **middle meningeal artery** is equidistant from the frontozygomatic suture and the zygomatic arch; it is obtained by joining up the following points: (1) 2.5 cm., (2) 4 cm., and (3) 5 cm. from these two landmarks. The posterior division can be reached 2.5 cm. above the auricular point.

The position of the **transverse sinus** is obtained by taking two lines: the first from the inion to a point 2.5 cm. behind the auricular point; the second from the anterior end of the first to the tip of the mastoid process. The second line corresponds roughly to the line of reflection of the skin of the auricula behind, and its upper two-thirds represents the sigmoid part of the sinus. The first part of the sinus has a slight upward convexity, and its highest point is about 4 cm. behind and 1 cm. above the level of the auricular point. The width of the sinus is about 1 cm.

The Face.—Air Sinuses (Fig. 1080).—The frontal and maxillary sinuses vary so greatly in form and size that their surface markings must be regarded as only roughly approximate. To mark out the position of the **frontal sinus** three points are taken: (1) the nasion, (2) a point in the middle line 3 cm. above the nasion, (3) a point at the junction of the lateral and intermediate thirds of the supraorbital margin. By joining these a triangular field is described which overlies the greater part of the sinus. The outline of the **maxillary sinus** is irregularly quadrilateral and is obtained by joining up the following points: (1) the lacrimal tubercle, (2) a point on the zygomatic bone at the level of the inferior and lateral margins of the orbit, (3) and (4) points on the alveolar process above the last molar and the second premolar teeth respectively.

External Maxillary Artery.—The course of this artery on the face may be indicated by a line starting from the lower border of the mandible at the anterior margin of the Masseter, and running at first forward and upward to a point 1 cm. lateral

to the angle of the mouth, thence to the ala of the nose and upward to the medial commissure of the eye (Fig. 1081).

Trigeminal Nerve.—Terminal branches of this nerve, viz., the supraorbital branch of the ophthalmic, the infraorbital of the maxillary, and the mental of the mandibular emerge from corresponding foramina on the face (Fig. 1081). The supraorbital foramen is situated at the junction of the medial and intermediate thirds of the supraorbital margin. A line drawn from this foramen to the lower border of the mandible, through the interval between the two lower premolar teeth, passes over the infraorbital and mental foramina; the former lies about 1 cm. below the margin of the orbit, while the latter varies in position according to the age of the individual; in the adult it is midway between the upper and lower borders of the mandible, in the child it is nearer the lower border, while in the edentulous jaw of old age it is close to the upper margin.

Frontal sinus

*Line of nasolacrimal
duct*

Maxillary sinus

FIG. 1080.—Outline of bones of face, showing position of air sinuses.

FIG. 1081.—Outline of side of face, showing chief surface markings.

The position of the sphenopalatine ganglion is indicated from the side by a point on the upper border of the zygomatic arch, 6 mm. from the margin of the zygomatic bone.

Parotid Gland (Fig. 1081).—The upper border of the parotid gland corresponds to the posterior two-thirds of the lower border of the zygomatic arch; the posterior border to the front of the external acoustic meatus, the mastoid process, and the anterior border of Sternocleidomastoideus. The inferior border is indicated by a line from the tip of the mastoid process to the junction of the body and greater cornu of the hyoid bone. In front, the anterior border extends for a variable distance on the superficial surface of the Masseter. The surface marking for the **parotid duct** is a line drawn across the face about a finger's breadth below the zygomatic arch, i. e., from the lower margin of the concha to midway between the red margin

of the lip and the ala of the nose; the duct ends opposite the second upper molar tooth and measures about 5 cm. in length.

The Nose.—The outlines of the nasal bones and the cartilages forming the external nose can be easily felt. The mobile portion of the nasal septum, formed by the medial crura of the greater alar cartilages and the skin, is easily distinguished between the nares. When the head is tilted back and a speculum introduced through the naris, the floor of the nasal cavity, the lower part of the nasal septum, and the anterior ends of the middle and inferior nasal conchæ can be examined. The opening of the nasolacrimal duct, which lies under cover of the front of the inferior nasal concha, is situated about 2.5 cm. behind the naris and 2 cm. above the level of the floor of the nasal cavity.

FIG 1082.—The mouth cavity. The cheeks have been slit transversely and the tongue pulled forward

The Mouth.—The orifice of the mouth is bounded by the lips, which are covered externally by the whitish skin and internally by the red mucous membrane. The size of the orifice varies considerably in different individuals, but seems to bear a close relationship to the size and prominence of the teeth; its angles usually correspond to the lateral borders of the canine teeth. Running down the centre of the outer surface of the upper lip is a shallow groove—the **philtrum**. If the lips be everted there can be seen, in the middle line of each, a small fold of mucous membrane—the **frenulum**—passing from the lip to the gum. By pulling the angle of the

mouth outward the mucous membrane of the cheek can be inspected, and on this, opposite the second molar tooth of the maxilla, is the little papilla which marks the orifice of the parotid duct.

In the floor of the mouth is the *tongue* (Fig. 1082). Its upper surface is convex and is marked along the middle line by a shallow sulcus; the anterior two-thirds are rough and studded with papillæ; the posterior third is smooth and tuberculated. The division between the anterior two-thirds and the posterior third is marked by a V-shaped furrow, the *sulcus terminalis*, which is situated immediately behind the line of the vallate papillæ.

FIG. 1083.—The mouth cavity. The apex of the tongue is turned upward, and on the right side a superficial dissection of its under surface has been made.

On the under surface of the tongue (Fig. 1083) the mucous membrane is smooth and devoid of papillæ. In the middle line, the mucous membrane extends to the floor of the mouth as a distinct fold—the *frenulum*—the free edge of which runs forward to the *symphysis menti*. Sometimes the *ranine vein* can be seen immediately beneath the mucous membrane, a little lateral to the *frenulum*. Close to the attachment of the *frenulum* to the floor of the mouth, the slit-like orifice of the *submaxillary duct* is visible on either side. Running backward and lateralward from the orifice of the *submaxillary duct* is the *plica sublingualis*, produced by the projection of the *sublingual gland* which lies immediately beneath the mucous membrane. The *plica* serves also to indicate the line of the *submaxillary duct* and of the *lingual nerve*. At the back of the mouth is the *isthmus faucium*, bounded above by the *palatine velum*, from the free margin of which the *uvula* projects downward in the middle line. On either side of the *isthmus* are the two *palatine arches*, the anterior formed by the *Glossopalatinus* and the posterior by the *Pharyn-*

gopalatinus. Between the two arches of either side is the palatine **tonsil**, above which is the small supratonsillar recess; the position of the tonsil corresponds to the angle of the mandible. When the mouth is opened widely, a tense band—the pterygomandibular raphé—can be seen and felt lateral to the glossopalatine arch. Its lower end is attached to the mandible behind the last molar tooth, and immediately below and in front of this the **lingual nerve** can be felt; the upper

FIG. 1084.—Front of nasal part of pharynx, as seen with the laryngoscope.

end of the ligament can be traced to the pterygoid hamulus. About 1 cm. in front of the hamulus and 1 cm. medial to the last molar tooth of the maxilla is the greater palatine foramen through which the descending palatine vessels and the anterior palatine nerve emerge. Behind the last molar tooth of the maxilla the coronoid process of the mandible is palpable.

FIG. 1085.—Laryngoscopic view of interior of larynx

By tilting the head well back a portion of the posterior pharyngeal wall, corresponding to the site of the second and third cervical vertebræ, can be seen through the isthmus faucium. On introducing the finger the anterior surfaces of the upper cervical vertebræ can be felt through the thin muscular wall of the pharynx; if the finger be hooked round the palatine velum, the choanæ can be distinguished in front, and the pharyngeal ostium of the auditory tube on either side. The level of the choanæ is that of the atlas, while the palatine velum is opposite the body of the axis.

With the laryngoscope many other structures can be seen. In the nasal part of the pharynx (Fig. 1084), the choanæ, the nasal septum, the nasal conchæ, and the pharyngeal ostia of the auditory tubes can all be examined. Further down, the base of the tongue, the anterior surface of the epiglottis with the glossoepiglottic and pharyngoepiglottic folds bounding the valleculæ, and the pyriform sinuses, are readily distinguished. Beyond these is the entrance to the larynx, bounded on either side by the aryepiglottic folds, in each of which are two rounded eminences corresponding to the corniculate and cuneiform cartilages.

Within the larynx (Fig. 1085) on either side are the ventricular and vocal folds (false and true vocal cords) with the ventricle between them. Still deeper are seen the cricoid cartilage and the anterior parts of some of the cartilaginous rings of the trachea, and sometimes, during deep inspiration, the bifurcation of the trachea.

The Eye.—The palpebral fissure is elliptical in shape, and varies in form in different individuals and in different races of mankind; normally it is oblique, in a direction upward and lateralward, so that the lateral commissure is on a slightly higher level than the medial. When the eyes are directed forward as in ordinary vision the upper part of the cornea is covered by the upper eyelid and its lower margin corresponds to the level of the free margin of the lower eyelid, so that usually the lower three-fourths are exposed.

At the medial commissure (Fig. 1086) are the caruncula lacrimalis and the plica semilunaris. When the lids are everted, the tarsal glands appear as a series of nearly straight parallel rows of light yellow granules. On the margins of the lids about 5 mm. from the medial commissure are two small openings—the **lacrimal puncta**; in the natural condition they are in contact with the conjunctiva of the bulb of the eye, so that it is necessary to evert the eyelids to expose them. The position of the lacrimal sac is indicated by a little tubercle which can be plainly felt on the lower margin of the orbit; the sac lies immediately above and medial to the tubercle. If the eyelids be drawn lateralward so as to tighten the skin at the medial commissure a prominent core can be felt beneath the tightened skin; this is the medial palpebral ligament, which lies over the junction of the upper with the lower two-thirds of the sac, thus forming a useful guide to its situation. The direction of the nasolacrimal duct is indicated by a line from the lacrimal sac to the first molar tooth of the maxilla; the length of the duct is about 12 or 13 mm.

On looking into the eye, the **iris** with its opening, the **pupil**, and the front of the lens can be examined, but for investigation of the **retina** an ophthalmoscope is necessary. With this the **lens**, the vessels of the **retina** the **optic disk**, and the **macula lutea** can all be inspected (Fig. 1087).

On the lateral surface of the nasal part of the frontal bone the pulley of the **Obliquus superior** can be easily reached by pushing the finger backward along the roof of the orbit; the tendon of the muscle can be traced for a short distance backward and lateralward from the pulley.

Optic disc

Macula lutea

Retina

FIG. 1087.—The interior of the posterior half of the left eyeball.

The Ear.—The various prominences and fossæ of the auricula (see page 1044) are visible (Fig. 1088). The opening of the **external acoustic meatus** is exposed by drawing the tragus forward; at the orifice are a few short crisp hairs which serve to prevent the entrance of dust or of small insects; beyond this the secretion of the **ceruminous glands** serves to catch any small particles which may find their way into the meatus. The interior of the meatus can be examined through a speculum. At the line of junction of its bony and cartilaginous portions an obtuse angle is formed which projects into the antero-inferior wall and produces a narrowing of the lumen in this situation. The cartilaginous part, however, is connected to the bony part by fibrous tissue which renders the outer part of the meatus very movable, and therefore by drawing the auricula upward, backward, and slightly outward, the canal is rendered almost straight. In children the meatus is very short, and this should be remembered in introducing the speculum.

FIG. 1088.—The auricula or pinna.
Lateral surface.

Through the speculum the greater part of the **tympanic membrane** (Fig. 1089) is visible. It is a pearly-gray membrane slightly glistening in the adult, placed obliquely so as to form with the floor of the meatus an angle of about 55° . At birth it is more horizontal and situated in almost the same plane as the base of the skull. The membrane is concave outward, and the point of deepest concavity—the **umbo**—is slightly below the centre. Running upward and slightly forward from the umbo is a reddish-yellow streak produced by the manubrium of the malleus. This streak ends above just below the roof of the meatus at a small white rounded prominence which is caused by the lateral process of the malleus projecting against the membrane. The anterior and posterior **malleolar folds** extend from the prominence to the circumference of the membrane and enclose the **pars flaccida**. Behind the streak caused by the manubrium of the malleus a second streak, shorter and very faint, can be distinguished; this is the **long crus**

of the **incus**. A narrow triangular patch extending downward and forward from the umbo reflects the light more brightly than any other part, and is usually described as the **cone of light**.

FIG. 1090.—Left temporal bone showing surface markings for the tympanic antrum (red), transverse sinus (blue), and facial nerve (yellow).

Tympanic Antrum.—The site of the tympanic antrum is indicated by the **supra-meatal triangle** (Fig. 1090). This triangle is bounded above by the posterior root of the zygomatic arch; behind by a vertical line from the posterior border of the external acoustic meatus; in front and below by the upper margin of the meatus.

The Neck (Fig. 1091). **Larynx and Trachea.**—In the receding angle below the chin, the **hyoid bone** (page 1276), situated opposite the fourth cervical vertebra, can easily be made out. A finger's breadth below it is the laryngeal prominence of the

thyroid cartilage; the space intervening between the hyoid bone and the thyroid cartilage is occupied by the **hyothyroid membrane**. The outlines of the thyroid cartilage are readily palpated; below its lower border is a depression corresponding to the middle **cricothyroid ligament**. The level of the vocal folds corresponds to the middle of the anterior margin of the thyroid cartilage. The anterior part of the cricoid cartilage forms an important landmark on the front of the neck; it lies opposite the sixth cervical vertebra, and indicates the junctions of pharynx with œsophagus, the larynx with trachea. Below the cricoid cartilage the **trachea** can be felt, though it is only in thin subjects that the separate rings can be distinguished; as a rule there are seven or eight rings above the jugular notch of the sternum, and of these the second, third, and fourth are covered by the isthmus of the thyroid gland.

FIG. 1091.—Side of neck, showing chief surface markings.

Muscles.—The posterior belly of **Digastricus** is marked out by a line from the tip of the mastoid process to the junction of the greater cornu and body of the hyoid bone; a line from this latter point to a point just lateral to the symphysis menti indicates the position of the anterior belly. The line of **Omothyroideus** begins at the lower border of the hyoid bone, curves downward and lateralward to cross **Sternocleidomastoideus** at the junction of its middle and lower thirds, *i. e.*, opposite the cricoid cartilage, and then runs more horizontally to the acromial end of the clavicle.

Arteries.—The position of the **common carotid artery** in the neck is indicated by a line drawn from the upper part of the sternal end of the clavicle to a point midway between the tip of the mastoid process and the angle of the mandible. From the clavicle to the upper border of the thyroid cartilage this line overlies the common carotid artery, beyond this it is over the external carotid. The **external carotid artery** may otherwise be marked out by the upper part of a line from the side of the cricoid cartilage to the front of the external acoustic meatus, arching the line slightly forward.

The points of origin of the main branches of the external carotid in the neck are all related to the tip of the greater cornu of the hyoid bone as follows: (1) the **superior thyroid**, immediately below it; (2) the **lingual**, on a level with it; (3) the **facial**, and (4) the **occipital** a little above and behind it.

The **subclavian artery** is indicated on the surface by a curved line, convex upward, from the sternoclavicular articulation to the middle of the clavicle. The highest point of the convexity is from 1 to 3 cm. above the clavicle.

Veins.—The surface marking for the **internal jugular vein** is slightly lateral and parallel to that for the common carotid artery. The position of the **external jugular vein** is marked out by a line from the angle of the mandible to the middle of the clavicle. A point on this line about 4 cm. above the clavicle indicates the spot where the vein pierces the deep fascia. The line of the **anterior jugular vein** begins close to the symphysis menti, runs downward parallel with and a little to one side of the middle line and, at a variable distance above the jugular notch, turns lateralward to the external jugular.

Nerves.—The **facial nerve** at its exit from the stylomastoid foramen is situated about 2.5 cm. from the surface, opposite the middle of the anterior border of the mastoid process; a horizontal line from this point to the ramus of the mandible overlies the stem of the nerve. To mark the site of the **accessory nerve** a line is drawn from the angle of the mandible to a point on the anterior border of Sternocleidomastoideus about 3 to 4 cm. below the apex of the mastoid process, or to the midpoint of the posterior border of the muscle; the line is continued across the posterior triangle to Trapezius.

The cutaneous branches of the cervical plexus as they emerge from the posterior border of Sternocleidomastoideus may be indicated as follows: the **lesser occipital** begins immediately above the midpoint of the border and runs along the border to the scalp; the **great auricular** and **cervical cutaneous** both start from the middle of the border, the former running upward toward the lobule of the auricula, the latter crossing Sternocleidomastoideus at right angles to its long axis; the **supra-clavicular** nerves emerge from immediately below the middle of the posterior border and run down over the clavicle. The **phrenic nerve** begins at the level of the middle of the thyroid cartilage and runs behind the clavicle about midway between the anterior and posterior borders of Sternocleidomastoideus.

The upper border of the **brachial plexus** is indicated by a line from the side of the cricoid cartilage to the middle of the clavicle.

Submaxillary Gland.—On either side of the neck the superficial portion of the submaxillary gland, as it lies partly under cover of the mandible, can be palpated.

SURFACE ANATOMY OF THE BACK.

Bones.—The only subcutaneous parts of the vertebral column are the apices of the spinous processes. These are distinguishable at the bottom of a furrow which runs down the middle line of the back from the external occipital protuberance to the middle of the sacrum. In the **cervical region** the furrow is broad and ends below in a conspicuous projection caused by the spinous processes of the seventh cervical and first thoracic vertebræ. Above this, the spinous process of the sixth cervical vertebra sometimes forms a projection; the other cervical spinous processes are sunken, but that of the axis can be felt. In the **thoracic region** the furrow is shallow and during stooping disappears, and then the spinous processes become more or less visible; the markings produced by them are small and close together. In the **lumbar region** the furrow is deep and the situations of the spinous processes are frequently indicated by little pits or depressions, especially when the muscles in the loins are well-developed. In the **sacral region** the furrow is shallower, presenting a flattened area which ends below at the most prominent part of the dorsal surface of the sacrum, *i. e.*, the spinous process of the third sacral vertebra. At the bottom of the sacral furrow the irregular dorsal surface of the bone may be felt, and below this, in the deep groove running to the anus, the **coccyx**.

The only other portions of the vertebral column which can be felt from the surface are the transverse processes of the first, sixth, and seventh cervical vertebræ.

Muscles.—The muscles proper of the back are so obscured by those of the upper extremity (Fig. 1092) that they have very little influence on surface form. The **Splendi** by their divergence serve to broaden out the upper part of the back of the neck and produce a fulness in this situation. In the loin the **Sacrospinales**, bound

FIG. 1092.—Surface anatomy of the back.

down by the lumbodorsal fascia, form rounded vertical eminences which determine the depth of the spinal furrow and taper below to a point on the dorsal surface of the sacrum. The continuations of the **Sacrospinales** in the lower thoracic region form flattened planes which are gradually lost on passing upward.

SURFACE MARKINGS OF THE BACK.

Bony Landmarks.—In order to identify any particular spinous process it is customary to count from the prominence caused by the seventh cervical and first

thoracic; of these the latter is the more prominent. The root of the spine of the scapula is on a level with the tip of the spinous process of the third thoracic vertebra, and the inferior angle with that of the seventh. The highest point of the iliac crest is on a level with the spinous process of the fourth lumbar, and the posterior superior iliac spine with that of the second sacral.

The transverse process of the atlas is about 1 cm. below and in front of the apex of the mastoid process. The transverse process of the sixth cervical vertebra is opposite the cricoid cartilage; below it is the transverse process of the seventh and occasionally a cervical rib.

FIG. 1095.—Scheme showing the relations of the regions of attachment of the spinal nerves to the vertebral spinous processes. (After Reid.)

Medulla Spinalis.—The position of the lower end of the medulla spinalis varies slightly with the movements of the vertebral column, but, in the adult, in the upright posture it is usually at the level of the spinous process of the second lumbar vertebra (Fig. 1093); at birth it lies at the level of the fourth lumbar.

The **subdural** and **subarachnoid cavities** end below opposite the spinous process of the third sacral vertebra (Fig. 1094).

Spinal Nerves (Fig. 1095).—The table on page 1293, after Macalister, shows the relations which the places of attachment of the nerves to the medulla spinalis present to the bodies and spinous processes of the vertebræ.

SURFACE ANATOMY OF THE THORAX.

Bones.—The skeleton of the thorax is to a very considerable extent covered by muscles, so that in the strongly developed muscular subject it is for the most part concealed. In the emaciated subject, however, the ribs, especially in the lower and lateral regions, stand out as prominent ridges with the sunken intercostal spaces between them.

In the middle line, in front, the superficial surface of the **sternum** can be felt throughout its entire length at the bottom of a furrow, the sternal furrow, situated between the *Pectorales majores*. These muscles overlap the anterior surface somewhat, so that the whole width of the sternum is not subcutaneous, and this overlapping is greatest opposite the middle of the bone; the furrow, therefore, is wide at its upper and lower parts but narrow in the middle. At the upper border of the manubrium sterni is the **jugular notch**: the lateral parts of this notch are obscured by the tendinous origins of the *Sternocleidomastoidei*, which appear as oblique cords narrowing and deepening the notch. Lower down on the subcutaneous surface is a well-defined transverse ridge, the **sternal angle**; it denotes the junction of the manubrium and body. From the middle of the sternum the sternal furrow spreads out and ends at the junction of the body with the xiphoid process. Immediately below this is the **infrasternal notch**; between the sternal ends of the seventh costal cartilages, and below the notch, is a triangular depression, the epigastric fossa, in which the **xiphoid process** can be felt.

On either side of the sternum the costal cartilages and ribs on the front of the thorax are partly obscured by the *Pectoralis major*, through which, however, they can be felt as ridges with yielding intervals between them corresponding to the intercostal spaces. Of these spaces, that between the second and third ribs is the widest, the next two are somewhat narrower, and the remainder, with the exception of the last two, are comparatively narrow.

Below the lower border of the *Pectoralis major* on the front of the chest, the broad flat outlines of the ribs as they descend, and the more rounded outlines of the costal cartilages, are often visible. The lower boundary of the front of the thorax, which is most plainly seen by bending the body backward, is formed by the xiphoid process, the cartilages of the seventh, eighth, ninth, and tenth ribs, and the ends of the cartilages of the eleventh and twelfth ribs.

On either side of the thorax, from the axilla downward, the flattened external surfaces of the ribs may be defined. Although covered by muscles, all the ribs, with the exception of the first, can generally be followed without difficulty over the front and sides of the thorax. The first rib being almost completely covered by the clavicle can only be distinguished in a small portion of its extent.

At the back, the angles of the ribs lie on a slightly marked oblique line on either side of, and some distance from, the spinous processes of the vertebræ. The line diverges somewhat as it descends, and lateral to it is a broad convex surface caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

Muscles.—The surface muscles covering the thorax belong to the musculature of the upper extremity (Figs. 1096, 1100), and will be described in that section (page 1319). There is, however, an area of practical importance bounded by these muscles. It is limited above by the lower border of *Trapezius*, below by the upper border of *Latissimus dorsi*, and laterally by the vertebral border of the scapula; the

bone is partly formed by *Trapezius major*. If the scapula be drawn forward by forcing the arm across the chest and the trunk bent forward, parts of the scull and seventh rib and the interspace between them become subcutaneous and available for palpation. The space is therefore known as the **triangle of palpation**.

FIG. 1006.—The left side of the thorax.

Mamma. The size of the mamma is subject to great variations. In the adult nulliparous female, it extends vertically from the second to the sixth rib, and transversely from the side of the sternum to the midaxillary line. In the male and in the nulliparous female the **mammary papilla** is situated in the fourth interspace about 6 or 10 cm. from the middle line, or 2 cm. from the costochondral junction.

SURFACE MARKINGS OF THE THORAX.

Bony Landmarks. The second costal cartilage corresponding to the sternal angle is so readily found that it is used as a starting-point from which to count the ribs. The lower border of the Pectoralis major at its attachment corresponds to the fifth rib; the uppermost visible digitation of Serratus anterior indicates the sixth rib.

The jugular notch is in the same horizontal plane as the lower border of the body of the second thoracic vertebra; the sternal angle is at the level of the fifth thoracic vertebra, while the junction between the body and xiphoid process of the sternum corresponds to the fibrocartilage between the ninth and tenth thoracic vertebrae.

The influence of the obliquity of the ribs on horizontal levels in the thorax is well shown by the following line. "If a horizontal line be drawn around the body at the level of the inferior angle of the scapula, while the arms are at the sides, the

line would cut the sternum in front between the fourth and fifth ribs, the fifth rib, in the nipple line, and the ninth rib at the vertebral column." (Treves).

Diaphragma.—The shape and variations of the Diaphragma as seen by skiagraphy have already been described (page 497).

Surface Lines.—For clinical purposes, and for convenience of description, the surface of the thorax has been mapped out by arbitrary lines (Fig. 1101). On the front of the thorax the most important vertical lines are the **midsternal**, the middle line of the sternum; and the **mammary**, which runs vertically downward from a point midway between the centre of the jugular notch and the tip of the acromion. This latter line, if prolonged, is practically continuous with the lateral line on the front of the abdomen. Other vertical lines on the front of the thorax are the **lateral sternal** along the sternal margin, and the **parasternal** midway between the lateral sternal and the mammary.

On either side of the thorax the **anterior** and **posterior axillary lines** are drawn vertically from the corresponding axillary folds; the **midaxillary line** runs downward from the apex of the axilla.

On the posterior surface of the thorax the **scapular line** is drawn vertically through the inferior angle of the scapula.

FIG. 1097.—Front of thorax, showing surface relations of bones, lungs (purple), pleura (blue), and heart (red outline). *P.* Pulmonary valve. *A.* Aortic valve. *B.* Bicuspid valve. *T.* Tricuspid valve.

Pleuræ (Figs. 1097, 1098).—The lines of reflection of the pleuræ can be indicated on the surface. On the *right* side the line begins at the sternoclavicular articulation and runs downward and medialward to the midpoint of the junction between the manubrium and body of the sternum. It then follows the midsternal line to the lower end of the body of the sternum or on to the xiphoid process, where it turns lateralward and downward across the seventh sternocostal articulation. It crosses the eighth costochondral junction in the mammary line, the tenth rib in the mid-axillary line, and is prolonged thence to the spinous process of the twelfth thoracic vertebra.

On the *left* side, beginning at the sternoclavicular articulation, it reaches the midpoint of the junction between the manubrium and body of the sternum, and extends down the midsternal line in contact with that of the opposite side to the level of the fourth costal cartilage. It then diverges lateralward and is continued downward slightly lateral to the sternal border, as far as the sixth costal cartilage. Running downward and lateralward from this point it crosses the seventh costal cartilage, and from this onward it is similar to the line on the right side, but at a slightly lower level.

Lungs (Figs. 1097, 1098).—The **apex** of the lung is situated in the neck above the medial third of the clavicle. The height to which it rises above the clavicle varies very considerably, but is generally about 2.5 cm. It may, however, extend as high as 4 or 5 cm., or, on the other hand, may scarcely project above the level of this bone.

FIG. 1098.—Side of thorax, showing surface markings for bones, lungs (purple), pleura (blue), and spleen (green).

In order to mark out the **anterior borders** of the lungs a line is drawn from each apex point—2.5 cm. above the clavicle and rather nearer the anterior than the posterior border of Sternocleidomastoideus—downward and medialward across the sternoclavicular articulation and manubrium sterni until it meets, or almost meets, its fellow of the other side at the midpoint of the junction between the manubrium and body of the sternum. From this point the two lines run downward, practically along the midsternal line, as far as the level of the fourth costal cartilages. The continuation of the anterior border of the *right* lung is marked by a prolongation of its line vertically downward to the level of the sixth costal cartilage, and then it turns lateralward and downward. The line on the *left* side curves lateralward and downward across the fourth sternocostal articulation to reach the parasternal line at the fifth costal cartilage, and then turns medialward and downward to the sixth sternocostal articulation.

In the position of expiration the **lower border** of the lung may be marked by a slightly curved line with its convexity downward, from the sixth sternocostal junction to the tenth thoracic spinous process. This line crosses the mammary line at the sixth, and the midaxillary line at the eighth rib.

The **posterior borders** of the lungs are indicated by lines drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the vertebral column, across the costovertebral joints, as low as the spinous process of the tenth thoracic vertebra.

The position of the **oblique fissure** in either lung can be shown by a line drawn from the spinous process of the second thoracic vertebra around the side of the thorax to the sixth rib in the mammary line; this line corresponds roughly to the line of the vertebral border of the scapula when the hand is placed on the top of the head. The **horizontal fissure** in the right lung is indicated by a line drawn from the midpoint of the preceding, or from the point where it cuts the midaxillary line, to the midsternal line at the level of the fourth costal cartilage.

Trachea.—This may be marked out on the back by a line from the spinous process of the sixth cervical to that of the fourth thoracic vertebra where it bifurcates; from its bifurcation the two bronchi are directed downward and lateralward. In front, the point of bifurcation corresponds to the sternal angle.

Œsophagus.—The extent of the œsophagus may be indicated on the back by a line from the sixth cervical to the level of the ninth thoracic spinous process, 2.5 cm. to the left of the middle line.

Heart.—The outline of the heart in relation to the front of the thorax (Figs 1097, 1099) can be represented by a quadrangular figure. The apex of the heart is first determined, either by its pulsation or as a point in the fifth interspace, 9 cm. to the left of the midsternal line. The other three points are: (a) the seventh right sternocostal articulation; (b) a point on the upper border of the third right costal cartilage 1 cm. from the right lateral sternal line; (c) a point on the lower border of the second left costal cartilage 2.5 cm. from the left lateral sternal line. A line joining the apex to point (a) and traversing the junction of the body of the sternum with the xiphoid process represents the lowest limit of the heart—its acute margin. The right and left borders are represented respectively by lines joining (a) to (b) and the apex to (c); both lines are convex lateralward, but the convexity is more marked on the right where its summit is 4 cm. distant from the midsternal line opposite the fourth costal cartilage.

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder being overlapped by lung gives a more or less resonant note. The former is known as the area of superficial cardiac dulness, the latter as the area of deep cardiac dulness. The area of superficial cardiac dulness is somewhat triangular; from the apex of the heart two lines are drawn to the midsternal line, one to the level of the fourth costal cartilage, the other to the junction between the body and xiphoid process; the portion of the midsternal line between these points is the base of the triangle. Latham lays down the following rule as a sufficient practical guide for the definition of the area of superficial dulness. "Make a circle of two inches in diameter around a point midway between the nipple and the end of the sternum."

The **coronary sulcus** can be indicated by a line from the third left, to the sixth right, sternocostal joint. The **anterior longitudinal sulcus** is a finger's breadth to the right of the left margin of the heart.

The position of the various orifices is as follows: The **pulmonary orifice** is situated in the upper angle of the third left sternocostal articulation; the **aortic orifice** is a little below and medial to this, close to the articulation. The **left atrioventricular opening** is opposite the fourth costal cartilage, and rather to the left of the midsternal line; the **right atrioventricular opening** is a little lower, opposite

the fourth interspace of the right side. The lines indicating the atrioventricular openings are slightly below and parallel to the line of the coronary sulcus.

Arteries.—The line of the **ascending aorta** begins slightly to the left of the mid-sternal line opposite the third costal cartilage and extends upward and to the right to the upper border of the second right costal cartilage. The beginning of the **aortic arch** is indicated by a line from this latter point to the midsternal line about 2.5 cm. below the jugular notch. The point on the midsternal line is opposite the summit of the arch, and a line from it to the right sternoclavicular articulation represents the site of the **innominate artery**, while another line from a point slightly to the left of it and passing through the left sternoclavicular articulation indicates the position of the **left common carotid artery** in the thorax.

FIG. 1099.—Diagram showing relations of opened heart to front of thoracic wall. *Ant.* Anterior segment of tricuspid valve. *A.O.* Aorta. *A.P.* Anterior papillary muscle. *In.* Innominate artery. *L.C.C.* Left common carotid artery. *L.S.* Left subclavian artery. *L.V.* Left ventricle. *P.A.* Pulmonary artery. *R.A.* Right atrium. *R.V.* Right ventricle. *V.S.* Ventricular septum.

The **internal mammary artery** descends behind the first six costal cartilages about 1 cm. from the lateral sternal line.

Veins.—The line of the **right innominate vein** crosses the right sternoclavicular joint and the upper border of the first right costal cartilage about 1 cm. from the lateral sternal line; that of the **left innominate vein** extends from the left sternoclavicular articulation to meet the right at the upper border of the first right costal cartilage. The junction of the two lines indicates the origin of the **superior vena cava**, the line of which is continued vertically down to the level of the third right costal cartilage. The end of the **inferior vena cava** is situated opposite the upper margin of the sixth right costal cartilage about 2 cm. from the mid-sternal line.

SURFACE ANATOMY OF THE ABDOMEN.

Skin.—The skin of the front of the abdomen is thin. In the male it is often thickly hair-clad, especially toward the lower part of the middle line; in the female the hairs are confined to the pubes. Just below the line of the iliac crest, especially marked in fat subjects, is a shallow groove termed the **iliac furrow**, while in the site of the inguinal ligament a sharper fold known as the **fold of the groin** is easily distinguishable.

After distension of the abdomen from pregnancy or other causes the skin commonly presents transverse white lines which are quite smooth, being destitute of papillæ; these are known as **striae gravidarum** or **striae albicantes**. The **linea nigra** of pregnancy is often seen as a pigmented brown streak in the middle line between the umbilicus and symphysis pubis.

In the middle line of the front of the abdomen is a shallow furrow which extends from the junction between the body of the sternum with the xiphoid process to a short distance below the umbilicus; it corresponds to the **linea alba**. The umbilicus is situated in the middle line, but it varies in position as regards its height; in an adult subject it is always placed above the middle point of the body, and in a normal well-nourished subject is from 2 to 2.5 cm. above the level of the tubercles of the iliac crests.

Bones.—The bones in relation with the surface of the abdomen are (1) the lower part of the vertebral column and the lower ribs and (2) the pelvis; the former have already been described (page 1291), the latter will be considered with the lower limb.

Muscles (Fig. 1100).—The only muscles of the abdomen which have any considerable influence on surface form are the **Obliquus externus** and the **Rectus**. The upper digitations of origin of **Obliquus externus** are well-marked in a muscular subject, interdigitating with those of **Serratus anterior**; the lower digitations are covered by the border of **Latissimus dorsi** and are not visible. The attachment of the **Obliqui externus** and **internus** to the crest of the ilium forms a thick oblique roll which determines the iliac furrow. Sometimes on the front of the lateral region of the abdomen an undulating line marks the passing of the muscular fibres of the **Obliquus externus** into its aponeurosis. The lateral margin of the **Obliquus externus** is separated from that of the **Latissimus dorsi** by a small triangular interval—the **lumbar triangle**—the base of which is formed by the iliac crest, and its floor by **Obliquus internus**.

The lateral margin of **Rectus abdominis** is indicated by the **linea semilunaris**, which may be exactly defined by putting the muscle into action. The surface of the **Rectus** presents three transverse furrows, the **tendinous inscriptions**: the upper two of these, viz., one opposite, or a little below, the tip of the xiphoid process, and the other midway between this point and the umbilicus, are usually well-marked; the third, opposite the umbilicus, is not so distinct. Between the two **Recti** the **linea alba** can be palpated from the xiphoid process to a point just below the umbilicus; it is represented by a distinct dip between the muscles: beyond this the muscles are in apposition.

Vessels.—In thin subjects the pulsation of the **abdominal aorta** can be readily felt by making deep pressure in the middle line above the umbilicus.

Viscera.—Under normal conditions the various portions of the **digestive tube** cannot be identified by simple palpation. Peristalsis of the coils of small intestine can be observed in some persons with extremely thin abdominal walls when some degree of constipation exists. In cases of constipation it is sometimes possible to trace portions of the great intestine by feeling the fecal masses within the gut. In thin persons with relaxed abdominal walls the iliac colon can be felt in the left

iliac region—rolling under the fingers when empty and forming a distinct tumor when distended.

The greater part of the liver lies under cover of the lower ribs and their cartilages, but in the epigastric fossa it comes in contact with the abdominal wall. The

superior
ne

ligament

FIG. 1100.—Surface anatomy of the front of the thorax and abdomen.

position of the liver varies according to the posture of the body. In the erect posture in the adult male the edge of the liver projects about 1 cm. below the lower margin of the right costal cartilages, and its inferior margin can often be felt in this situation if the abdominal wall is thin. In the supine position the liver

recedes above the margin of the ribs and cannot then be detected by the finger; in the prone position it falls forward and is then generally palpable in a patient with loose and lax abdominal walls. Its position varies with the respiratory movements; during a deep inspiration it descends below the ribs; in expiration it is raised. Pressure from without, as in tight lacing, by compressing the lower part of the chest, displaces the liver considerably, its anterior edge frequently extending as low as the crest of the ilium. Again its position varies greatly with the state of the stomach and intestines; when these are empty the liver descends, when they are distended it is pushed upward.

The **pancreas** can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about 7 or 8 cm. above the umbilicus.

The **kidneys** being situated at the back of the abdominal cavity and deeply placed cannot be palpated unless enlarged or misplaced.

✓ SURFACE MARKINGS OF THE ABDOMEN.

Bony Landmarks.—Above, the chief bony markings are the xiphoid process, the lower six costal cartilages, and the anterior ends of the lower six ribs. The junction between the body of the sternum and the xiphoid process is on the level of the tenth thoracic vertebra. Below, the main landmarks are the symphysis pubis and the pubic crest and tubercle, the anterior superior iliac spine, and the iliac crest.

Muscles (Fig. 1106).—The Rectus lies between the linea alba and the linea semilunaris; the former is indicated by the middle line, the latter by a curved line, convex lateralward, from the tip of the cartilage of the ninth rib to the pubic tubercle; at the level of the umbilicus the linea semilunaris is about 7 cm. from the middle line. The line indicating the junction of the muscular fibres of Obliquus externus with its aponeurosis extends from the tip of the ninth costal cartilage to a point just medial to the anterior superior iliac spine.

The **umbilicus** is at the level of the fibrocartilage between the third and fourth lumbar vertebræ.

The **subcutaneous inguinal ring** is situated 1 cm. above and lateral to the pubic tubercle; the **abdominal inguinal ring** lies 1 to 2 cm. above the middle of the inguinal ligament. The position of the **inguinal canal** is indicated by a line joining these two points.

Surface Lines.—For convenience of description of the viscera and of reference to morbid conditions of the contained parts, the abdomen is divided into nine regions, by imaginary planes, two horizontal and two sagittal, the edges of the planes being indicated by lines drawn on the surface of the body (Fig. 1101). In the older method the upper, or subcostal, horizontal line encircles the body at the level of the lowest points of the tenth costal cartilages; the lower, or intertubercular, is a line carried through the highest points of the iliac crests seen from the front, *i. e.*, through the tubercles on the iliac crests about 5 cm. behind the anterior superior spines. An alternative method is that of Addison, who adopts the following lines:

(1) An upper transverse, the **transpyloric**, halfway between the jugular notch and the upper border of the symphysis pubis; this indicates the margin of the transpyloric plane, which in most cases cuts through the pylorus, the tips of the ninth costal cartilages and the lower border of the first lumbar vertebra; (2) a lower transverse line midway between the upper transverse and the upper border of the symphysis pubis; this is termed the **transtubercular**, since it practically corresponds to that passing through the iliac tubercles; behind, its plane cuts the body of the fifth lumbar vertebra.

By means of these horizontal planes the abdomen is divided into three zones named from above, the **subcostal**, **umbilical**, and **hypogastric zones**. Each of these is further subdivided into three regions by the two sagittal planes, which are indicated on the surface by a right and a left lateral line drawn vertically through points halfway between the anterior superior iliac spines and the middle line. The middle region of the upper zone is called the **epigastric**, and the two lateral regions

FIG. 1101.—Surface lines of the front of the thorax and abdomen.

the **right** and **left hypochondriac**. The central region of the middle zone is the **umbilical**, and the two lateral regions the **right** and **left lumbar**. The middle region of the lower zone is the **hypogastric** or **pubic**, and the lateral are the **right** and **left iliac** or **inguinal**. The middle regions, viz., **epigastric**, **umbilical**, and **pubic**, can each be divided into right and left portions by the middle line. In the following description of the viscera the regions marked out by Addison's lines are those referred to.

Stomach (Fig. 1103).—The shape of the stomach is constantly undergoing alteration; it is affected by the particular phase of the process of gastric digestion, by

FIG. 1102.—Radiographs of a moderately distended stomach, showing the influence of posture. (Modified from Herta.) *A.* With the patient in the erect posture. *B.* With the patient lying down.

the state of the surrounding viscera, and by the amount and character of its contents. Its position also varies with that of the body (Fig. 1102), so that it is

FIG. 1103.—Front of abdomen, showing surface markings for liver, stomach, and great intestine.

impossible to indicate it on the surface with any degree of accuracy. The measurements given refer to a moderately filled stomach with the body in the supine position.

The cardiac orifice is opposite the seventh left costal cartilage about 2.5 cm. from the side of the sternum; it corresponds to the level of the tenth thoracic vertebra. The pyloric orifice is on the transpyloric line about 1 cm. to the right of the middle line, or alternately 5 cm. below the seventh right sternocostal articulation; it is at the level of the first lumbar vertebra. A curved line, convex downward and to the left, joining these points indicates the lesser curvature. In the left lateral line the fundus of the stomach reaches as high as the fifth interspace or the sixth costal cartilage, a little below the apex of the heart. To indicate the greater curvature a curved line is drawn from the cardiac orifice to the summit of the fundus, thence downward and to the left, finally turning medialward to the pyloric orifice, but passing, on its way, through the intersection of the left lateral with the transpyloric line. The portion of the stomach which is in contact with the abdominal wall can be represented roughly by a triangular area the base of which is formed by a line drawn from the tip of the tenth left costal cartilage to the tip of the ninth right cartilage, and the sides by two lines drawn from the end of the eighth left costal cartilage to the ends of the base line.

FIG. 1104.—Front of abdomen, showing surface markings for duodenum, pancreas, and kidneys. *A A'*. Plane through joint between body and xiphoid process of sternum. *B B'*. Plane midway between *A A'* and transpyloric plane. *C C'*. Plane midway between transpyloric and transtubercular planes.

A space of some clinical importance—the **space of Traube**—overlies the stomach and may be thus indicated. It is semilunar in outline and lies within the following boundaries: the lower edge of the left lung, the anterior border of the spleen, the left costal margin and the inferior margin of the left lobe of the liver.

Duodenum (Fig. 1104).—The superior part is horizontal and extends from the pylorus to the right lateral line; the descending part is situated medial to the right lateral line, from the transpyloric line to a point midway between the transpyloric and transtubercular lines. The horizontal part runs with a slight upward slope from the end of the descending part to the left of the middle line; the ascending part is vertical, and reaches the transpyloric line, where it ends in the duodeno-jejunal flexure, about 2.5 cm. to the left of the middle line.

Small Intestine.—The coils of small intestine occupy the front of the abdomen. For the most part the coils of the jejunum are situated on the left side, *i. e.*, in the left lumbar and iliac regions, and in the left half of the umbilical region. The coils of the ileum lie toward the right in the right lumbar and iliac regions, in the right

half of the umbilical region, and in the hypogastric region; a portion of the ileum is within the pelvis. The end of the ileum, *i. e.*, the **ileocolic junction**, is slightly below and medial to the intersection of the right lateral and transtubercular lines.

Cecum and Vermiform Process.—The **cecum** is in the right iliac and hypogastric regions; its position varies with its degree of distension, but the midpoint of a line drawn from the right anterior superior iliac spine to the upper margin of the symphysis pubis will mark approximately the middle of its lower border.

The position of the base of the **vermiform process** is indicated by a point on the lateral line on a level with the anterior superior iliac spine.

Ascending Colon.—The ascending colon passes upward through the right lumbar region, lateral to the right lateral line. The **right colic flexure** is situated in the upper and right angle of intersection of the subcostal and right lateral lines.

Transverse Colon.—The transverse colon crosses the abdomen on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach.

Descending Colon.—The **left colic flexure** is situated in the upper left angle of the intersection between the left lateral and transpyloric lines. The descending colon courses down through the left lumbar region, lateral to the left lateral line, as far as the iliac crest (see footnote p. 1181).

Iliac Colon.—The line of the iliac colon is from the end of the descending colon to the left lateral line at the level of the anterior superior iliac spine.

Liver (Fig. 1103).—The upper limit of the right lobe of the liver, in the middle line, is at the level of the junction between the body of the sternum and the xiphoid process; on the right side the line must be carried upward as far as the fifth costal cartilage in the mammary line, and then downward to reach the seventh rib at the side of the thorax. The upper limit of the left lobe can be defined by continuing this line downward and to the left to the sixth costal cartilage, 5 cm. from the middle line. The lower limit can be indicated by a line drawn 1 cm. below the lower margin of the thorax on the right side as far as the ninth costal cartilage, thence obliquely upward to the eighth left costal cartilage, crossing the middle line just above the transpyloric plane and finally, with a slight left convexity, to the end of the line indicating the upper limit.

According to Birmingham the limits of the normal liver may be marked out on the surface of the body in the following manner. Take three points: (a) 1.25 cm. below the right nipple; (b) 1.25 cm. below the tip of the tenth rib; (c) 2.5 cm. below the left nipple. Join (a) and (c) by a line slightly convex upward; (a) and (b) by a line slightly convex lateralward; and (b) and (c) by a line slightly convex downward.

The fundus of the **gall-bladder** approaches the surface behind the anterior end of the ninth right costal cartilage close to the lateral margin of the Rectus abdominis.

Pancreas (Fig. 1104).—The pancreas lies in front of the second lumbar vertebra. Its head occupies the curve of the duodenum and is therefore indicated by the same lines as that viscus; its neck corresponds to the pylorus. Its body extends along the transpyloric line, the bulk of it lying above this line to the tail which is in the left hypochondriac region slightly to the left of the lateral line and above the transpyloric.

Spleen (Figs. 1098, 1105).—To map out the spleen the tenth rib is taken as representing its long axis; vertically it is situated between the upper border of the ninth and the lower border of the eleventh ribs. The highest point is 4 cm. from the middle line of the back at the level of the tip of the ninth thoracic spinous process; the lowest point is in the midaxillary line at the level of the first lumbar spinous process.

Kidneys (Figs. 1104, 1105).—The right kidney usually lies about 1 cm. lower than the left, but for practical purposes similar surface markings are taken for each.

On the front of the abdomen the upper pole lies midway between the plane of the lower end of the body of the sternum and the transpyloric plane, 5 cm. from

the middle line. The lower pole is situated midway between the transpyloric and intertubercular planes, 7 cm. from the middle line. The hilus is on the transpyloric plane, 5 cm. from the middle line. Round these three points a kidney-shaped figure 4 cm. to 5 cm. broad is drawn, two thirds of which lie medial to the lateral line. To indicate the position of the kidney from the back, the parallelogram of Morris is used; two vertical lines are drawn, the first 2.5 cm., the second 9.5 cm. from the middle line; the parallelogram is completed by two horizontal lines drawn respectively at the levels of the tips of the spinous process of the eleventh thoracic and the lower border of the spinous process of the

FIG. 1105.—Back of lumbar region, showing surface markings for kidneys, ureters, and spleen. The lower portions of the lung and pleura are shown on the right side.

third lumbar vertebra. The hilus is 5 cm. from the middle line at the level of the spinous process of the first lumbar vertebra.

FIG. 1106.—Front of abdomen, showing surface markings for arteries and inguinal canal.

Ureters.—On the front of the abdomen, the line of the ureter runs from the hilus of the kidney to the pubic tubercle; on the back, from the hilus vertically downward, passing practically through the posterior superior iliac spine (Fig. 1105).

Vessels (Fig. 1106).—The **inferior epigastric artery** can be marked out by a line from a point midway between the anterior superior iliac spine and the pubic symphysis to the umbilicus. This line also indicates the lateral boundary of **Hesselbach's triangle**—an area of importance in connection with inguinal hernia; the other boundaries are the lateral edge of Rectus abdominis, and the medial half of the inguinal ligament. The line of the **abdominal aorta** begins in the middle line about 4 cm. above the transpyloric line and extends to a point 2 cm. below and to the left of the umbilicus—or more accurately to a point 2 cm. to the left of the middle line on a line which passes through the highest points of the iliac crests (*AA'*, Fig. 1106). The point of termination of the abdominal aorta corresponds to the level of the fourth lumbar vertebra; a line drawn from it to a point midway between the anterior superior iliac spine and the symphysis pubis indicates the common and external iliac arteries. The **common iliac** is represented by the upper third of this line, the **external iliac** by the remaining two-thirds.

Of the larger branches of the abdominal aorta, the **celiac artery** is 4 cm., the **superior mesenteric** 2 cm. above the transpyloric line; the **renal arteries** are 2 cm. below the same line. The **inferior mesenteric** artery is 4 cm. above the bifurcation of the abdominal aorta.

Nerves.—The thoracic nerves on the anterior abdominal wall are represented by lines continuing those of the bony ribs. The termination of the seventh nerve is at the level of the xiphoid process, the tenth reaches the vicinity of the umbilicus, the twelfth ends about midway between the umbilicus and the upper border of the symphysis pubis. The first lumbar is parallel to the thoracic nerves; its iliohypogastric branch becomes cutaneous above the subcutaneous inguinal ring; its ilioinguinal branch at the ring.

SURFACE ANATOMY OF THE PERINEUM.

Skin.—In the middle line of the posterior part of the perineum and about 4 cm. in front of the tip of the coccyx is the anal orifice. The junction of the mucous membrane of the anal canal with the skin of the perineum is marked by a white line which indicates also the line of contact of the external and internal Sphincters. In the anterior part of the perineum the external genital organs are situated. The skin covering the scrotum is rough and corrugated, but over the penis it is smooth; extending forward from the anus on to the scrotum and penis is a median ridge which indicates the scrotal raphé. In the **female** are seen the skin reduplications forming the labia majora and minora laterally, the frenulum of the labia behind, and the prepuce of the clitoris in front; still more anteriorly is the mons pubis.

Bones.—In the antero-lateral boundaries of the perineum, the whole outline of the pubic arch can be readily traced ending in the ischial tuberosities. Behind in the middle line is the tip of the coccyx.

Muscles and Ligaments.—The margin of the **Gluteus maximus** forms the postero-lateral boundary, and in thin subjects, by pressing deeply, the sacrotuberous ligament can be felt through the muscle. The only other muscles influencing surface form are the **Ischiocavernosus** covering the crus penis, which lies on the side of the pubic arch, and the **Sphincter ani externus**, which, in action, closes the anal orifice and causes a puckering of the skin around it.

SURFACE MARKINGS OF THE PERINEUM.

A line drawn transversely across in front of the ischial tuberosities divides the perineum into a posterior or rectal, and an anterior or urogenital, triangle. This line passes through the central point of the perineum, which is situated about

2.5 cm. in front of the centre of the anal aperture or, in the male, midway between the anus and the reflection of the skin on to the scrotum.

Rectum and Anal Canal.—A finger inserted through the anal orifice is grasped by the Sphincter ani externus, passes into the region of the Sphincter ani internus, and higher up encounters the resistance of the Puborectalis; beyond this it may reach the lowest of the transverse rectal folds. In front, the urethral bulb and membranous part of the urethra are first identified, and then about 4 cm. above the anal orifice the prostate is felt; beyond this the vesiculæ seminales, if enlarged, and the fundus of the bladder, when distended, can be recognized. On either side is the ischiorectal fossa. Behind are the anococcygeal body, the pelvic surfaces of the coccyx and lower end of the sacrum, and the sacrospinous ligaments (Fig 1107).

FIG. 1107.—Median sagittal section of male pelvis.

In the female the posterior wall and fornix of the vagina, and the cervix and body of the uterus can be felt in front, while somewhat laterally the ovaries can just be reached.

Male Urogenital Organs.—The *corpora cavernosa penis* can be followed backward to the crura which are attached to the sides of the pubic arch. The *glans penis*, covered by the prepuce, and the external urethral orifice can be examined, and the course of the urethra traced along the under surface of the penis to the bulb which is situated immediately in front of the central point of the perineum. Through the wall of the *scrotum* on either side the *testis* can be palpated; it lies toward the back of the scrotum, and along its posterior border the *epididymis* can be felt; passing upward along the medial side of the epididymis is the *spermatic cord*, which can be traced upward to the subcutaneous inguinal ring.

By means of a sound the general topography of the urethra and bladder can

be investigated; with the urethroscope the interior of the urethra can be illuminated and viewed directly; with the cystoscope the interior of the bladder is in a similar manner illuminated for visual examination. In the bladder the main points to which attention is directed are the **trigone**, the **torus uretericus**, the **plicae uretericae**, and the openings of the **ureters** and **urethra** (see Fig. 1033).

Clitoris

Vestibule

*External urethral
orifice*

Vaginal orifice

Hymen

FIG. 1108.—External genital organs of female. The labia minora have been drawn apart.

Female Urogenital Organs.—In the **puddendal cleft** (Fig. 1108) between the **labia minora** are the openings of the **vagina** and **urethra**. In the virgin the vaginal opening is partly closed by the **hymen**—after coitus the remains of the hymen are represented by the **carunculae hymeneales**. Between the hymen and the **frenulum** of the labia is the **fossa navicularis**, while in the groove between the hymen and the **labium minus**, on either side, the small opening of the **greater vestibular (Bartholin's) gland** can be seen. These glands when enlarged can be felt on either side of the posterior part of the vaginal orifice. By inserting a finger into the vagina the following structures can be examined through its wall (Fig. 1109). Behind, from below upward, are the **anal canal**, the **rectum**, and the **rectouterine excavation**. Projecting into the roof of the vagina is the vaginal portion of the **cervix uteri** with the **external uterine orifice**; in front of and behind the cervix the anterior and posterior **vaginal fornices** respectively can be examined. With the finger in the vagina and the other hand on the abdominal wall the whole of the **cervix** and **body of the uterus**, the **uterine tubes**, and the **ovaries** can be palpated. If a speculum be introduced into the vagina, the walls of the passage, the vaginal portion of the cervix, and the external uterine orifice can all be exposed for visual examination.

The external urethral orifice lies in front of the vaginal opening; the angular gap in which it is situated between the two converging labia minora is termed the

vestibule. The urethral canal in the female is very dilatable and can be explored with the finger. About 2.5 cm. in front of the external orifice of the urethra are the **glans** and **prepuce of the clitoris**, and still farther forward is the **mons pubis**.

FIG. 1109.—Median sagittal section of female pelvis.

✓ SURFACE ANATOMY OF THE UPPER EXTREMITY.

Skin.—The skin covering the shoulder and arm is smooth and very movable on the underlying structures. In the axilla there are numerous hairs and many sudoriferous and sebaceous glands. Over the medial side and front of the forearm the skin is thin and smooth, and contains few hairs but many sudoriferous glands; over the lateral side and back of the arm and forearm it is thicker, denser, and contains more hairs but fewer sudoriferous glands. In the region of the olecranon it is thick and rough, and is very loosely connected to the underlying tissue so that it falls into transverse wrinkles when the forearm is extended. At the front of the wrist there are three transverse furrows in the skin; they correspond respectively from above downward to the positions of the styloid process of the ulna, the wrist-joint, and the midcarpal joint.

The skin of the palm of the hand differs considerably from that of the forearm. At the wrist it suddenly becomes hard and dense and covered with a thick layer of epidermis; on the thenar eminence these characteristics are less marked than elsewhere. In spite of its hardness and density the skin of the palm is exceedingly sensitive and very vascular, but it is destitute of hairs and sebaceous glands. It is tied down by fibrous bands along the lines of flexion of the digits, exhibiting certain furrows of a permanent character. One of these, starting in front of the

wrist at the tuberosity of the navicular bone, curves around the thenar eminence and ends on the radial border of the hand a little above the metacarpophalangeal joint of the index finger. A second line begins at the end of the first and extends obliquely across the palm to reach the ulnar border about the middle of the fifth metacarpal bone. A third line begins at the ulnar border about 2.5 cm. distal to the end of the second and extends across the heads of the fifth, fourth, and third metacarpal bones. The proximal segments of the fingers are joined to one another on the volar aspect by folds of skin constituting the "web" of the fingers; these folds extend across about the level of the centres of the proximal phalanges and their free margins are continuous with the transverse furrows at the roots of the fingers. Since the web is confined to the volar aspect the fingers appear shorter when viewed from in front than from behind.

Over the fingers and thumb the skin again becomes thinner, especially at the flexures of the joints (where it is crossed by transverse furrows) and over the terminal phalanges; it is disposed on numerous ridges in consequence of the arrangement of the papillæ in it. These ridges form, in different individuals, distinctive and permanent patterns which can be used for purposes of identification. The superficial fascia in the palm of the hand is made up of dense fibro-fatty tissue which binds the skin so firmly to the palmar aponeurosis that very little movement is permitted between the two.

On the back of the hand and fingers the subcutaneous tissue is lax, so that the skin is freely movable on the underlying parts. Over the interphalangeal joints the skin is very loose and is thrown into transverse wrinkles when the fingers are extended.

Bones.—The **clavicle** can be felt throughout its entire length. The enlarged sternal extremity projects above the upper margin of the sternum at the side of the jugular notch, and from this the body of the bone can be traced lateralward immediately under the skin. The medial part is convex forward, but the surface is partially obscured by the attachments of *Sternocleidomastoideus* and *Pectoralis major*; the lateral third is concave forward and ends at the acromion of the scapula in a slight enlargement. The clavicle is almost horizontal when the arm is lying by the side, although in muscular subjects it may incline a little upward at its acromial end, which is on a plane posterior to the sternal end.

The only parts of the **scapula** that are truly subcutaneous are the spine and acromion, but the coracoid process, the vertebral border, the inferior angle, and to a lesser extent the axillary border can also be readily defined. The acromion and spine are easily recognizable throughout their entire extent, forming with the clavicle the arch of the shoulder. The acromion forms the point of the shoulder; it joins the clavicle at an acute angle—the acromial angle—slightly medial to, and behind the tip of the acromion. The spine can be felt as a distinct ridge, marked on the surface as an oblique depression which becomes less distinct and ends in a slight dimple a little lateral to the spinous processes of the vertebræ. Below this point the vertebral border can be traced downward and lateralward to the inferior angle, which can be identified although covered by *Latissimus dorsi*. From the inferior angle the axillary border can usually be traced upward through its thick muscular covering, forming with its enveloping muscles the posterior fold of the axilla. The coracoid process is situated about 2 cm. below the junction of the intermediate and lateral thirds of the clavicle; it is covered by the anterior border of *Deltoides*, and thus lies a little lateral to the infraclavicular fossa or depression which marks the interval between the *Pectoralis major* and *Deltoides*.

The **humerus** is almost entirely surrounded by muscles, and the only parts which are strictly subcutaneous are small portions of the medial and lateral epicondyles; in addition to these, however, the tubercles and a part of the head of the bone can be felt under the skin and muscles by which they are covered. Of these,

the greater tubercle forms the most prominent bony point of the shoulder, extending beyond the acromion; it is best recognized when the arm is lying passive by the side, for if the arm be raised it recedes under the arch of the shoulder. The lesser tubercle, directed forward, is medial to the greater and separated from it by the intertubercular groove, which can be made out by deep pressure. When the arm is abducted the lower part of the head of the humerus can be examined by pressing deeply in the axilla. On either side of the elbow-joint and just above it are the medial and lateral epicondyles. Of these, the former is the more prominent, but the medial supracondylar ridge passing upward from it is much less marked than the lateral, and as a rule is not palpable; occasionally, however, the hook-shaped supracondylar process (page 312) is found on this border. The position of the lateral epicondyle is best seen during semiflexion of the forearm, and is indicated by a depression; from it the strongly marked lateral supracondylar ridge runs upward.

The most prominent part of the **ulna**, the olecranon, can always be identified at the back of the elbow-joint. When the forearm is flexed the upper quadrilateral surface is palpable, but during extension it recedes into the olecranon fossa. During extension the upper border of the olecranon is slightly above the level of the medial epicondyle and nearer to this than to the lateral; when the forearm is fully flexed the olecranon and the epicondyles form the angles of an equilateral triangle. On the back of the olecranon is a smooth triangular subcutaneous surface, and running down the back of the forearm from the apex of this triangle the prominent dorsal border of the ulna can be felt in its whole length: it has a sinuous outline, and is situated in the middle of the back of the limb above; but below, where it is rounded off, it can be traced to the small subcutaneous surface of the styloid process on the medial side of the wrist. The styloid process forms a prominent tubercle continuous above with the dorsal border and ending below in a blunt apex at the level of the wrist-joint; it is most evident when the hand is in a position midway between supination and pronation. When the forearm is pronated another prominence, the head of the ulna, appears behind and above the styloid process.

Below the lateral epicondyle of the humerus a portion of the head of the **radius** is palpable; its position is indicated on the surface by a little dimple, which is best seen when the arm is extended. If the finger be placed in this dimple and the semiflexed forearm be alternately pronated and supinated the head of the radius will be felt distinctly, rotating in the radial notch. The upper half of the body of the bone is obscured by muscles; the lower half, though not subcutaneous, can be readily examined, and if traced downward is found to end in a lozenge-shaped convex surface on the lateral side of the base of the styloid process; this is the only subcutaneous part of the bone, and from its lower end the apex of the styloid process bends medialward toward the wrist. About the middle of the dorsal surface of the lower end of the radius is the dorsal radial tubercle, best perceived when the wrist is slightly flexed; it forms the lateral boundary of the oblique groove for the tendon of *Extensor pollicis longus*.

On the front of the wrist are two subcutaneous eminences, one, on the radial side, the larger and flatter, produced by the tuberosity of the **navicular** and the ridge on the **greater multangular**; the other, on the ulnar side, by the **pisiform**. The tuberosity of the navicular is distal and medial to the styloid process of the radius, and is most clearly visible when the wrist-joint is extended; the ridge on the greater multangular is about 1 cm. distal to it. The pisiform is about 1 cm. distal to the lower end of the ulna and just distal to the level of the styloid process of the radius; it is crossed by the uppermost crease which separates the front of the forearm from the palm of the hand. The rest of the volar surface of the bony carpus is covered by tendons and the transverse carpal ligament, and is entirely concealed, with the exception of the hamulus of the **hamate bone**, which, however, is difficult to

define. On the dorsal surface of the carpus only the **triangular bone** can be clearly made out.

Distal to the carpus the dorsal surfaces of the **metacarpal bones**, covered by the Extensor tendons, except the fifth, are visible only in very thin hands; the dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length. Slightly lateral to the middle line of the hand is a prominence, frequently well-marked, but occasionally indistinct, formed by the styloid process of the third metacarpal bone; it is situated about 4 cm. distal to the dorsal radial tubercle. The heads of the metacarpal bones can be plainly seen and felt, rounded in contour and standing out in bold relief under the skin when the fist is clenched; the head of the third is the most prominent. In the palm of the hand the metacarpal bones are covered by muscles, tendons, and aponeuroses, so that only their heads can be distinguished. The base of the metacarpal bone of the thumb, however, is prominent dorsally, distal to the styloid process of the radius; the body of the bone is easily palpable, ending at the head in a flattened prominence, in front of which are the sesamoid bones.

The enlarged ends of the **phalanges** can be easily felt. When the digits are bent the proximal phalanges form prominences, which in the joints between the first and second phalanges are slightly hollow, but flattened and square-shaped in those between the second and third.

Articulations.—The **sternoclavicular joint** is subcutaneous, and its position is indicated by the enlarged sternal extremity of the clavicle, lateral to the long cord-like sternal head of Sternocleidomastoideus. If this muscle be relaxed a depression between the end of the clavicle and the sternum can be felt, defining the exact position of the joint.

The position of the **acromioclavicular joint** can generally be ascertained by determining the slightly enlarged acromial end of the clavicle which projects above the level of the acromion; sometimes this enlargement is so considerable as to form a rounded eminence.

The **shoulder-joint** is deeply seated and cannot be palpated. If the forearm be slightly flexed a curved crease or fold with its convexity downward is seen in front of the elbow, extending from one epicondyle to the other; the **elbow-joint** is slightly distal to the centre of the fold. The position of the **radiohumeral joint** can be ascertained by feeling for a slight groove or depression between the head of the radius and the capitulum of the humerus, at the back of the elbow-joint.

The position of the **proximal radioulnar joint** is marked on the surface at the back of the elbow by the dimple which indicates the position of the head of the radius. The site of the **distal radioulnar joint** can be defined by feeling for the slight groove at the back of the wrist between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

Of the three transverse skin furrows on the front of the wrist, the middle corresponds fairly accurately with the **wrist-joint**, while the most distal indicates the position of the **midcarpal articulation**.

The **metacarpophalangeal** and **interphalangeal joints** are readily available for surface examination; the former are situated just distal to the prominences of the knuckles, the latter are sufficiently indicated by the furrows on the volar, and the wrinkles on the dorsal surfaces.

Muscles (Figs. 1075, 1110, 1111).—The anterior border of the **Trapezius** presents as a slight ridge running downward and forward from the superior nuchal line of the occipital bone to the junction of the intermediate and lateral thirds of the clavicle. The inferior border of the muscle forms an undulating ridge passing downward and medialward from the root of the spine of the scapula to the spinous process of the twelfth thoracic vertebra.

the greater tubercle forms the most prominent bony point of the shoulder, extending beyond the acromion; it is best recognized when the arm is lying passive by the side, for if the arm be raised it recedes under the arch of the shoulder. The lesser tubercle, directed forward, is medial to the greater and separated from it by the intertubercular groove, which can be made out by deep pressure. When the arm is abducted the lower part of the head of the humerus can be examined by pressing deeply in the axilla. On either side of the elbow-joint and just above it are the medial and lateral epicondyles. Of these, the former is the more prominent, but the medial supracondylar ridge passing upward from it is much less marked than the lateral, and as a rule is not palpable; occasionally, however, the hook-shaped supracondylar process (page 312) is found on this border. The position of the lateral epicondyle is best seen during semiflexion of the forearm, and is indicated by a depression; from it the strongly marked lateral supracondylar ridge runs upward.

The most prominent part of the **ulna**, the olecranon, can always be identified at the back of the elbow-joint. When the forearm is flexed the upper quadrilateral surface is palpable, but during extension it recedes into the olecranon fossa. During extension the upper border of the olecranon is slightly above the level of the medial epicondyle and nearer to this than to the lateral; when the forearm is fully flexed the olecranon and the epicondyles form the angles of an equilateral triangle. On the back of the olecranon is a smooth triangular subcutaneous surface, and running down the back of the forearm from the apex of this triangle the prominent dorsal border of the ulna can be felt in its whole length: it has a sinuous outline, and is situated in the middle of the back of the limb above; but below, where it is rounded off, it can be traced to the small subcutaneous surface of the styloid process on the medial side of the wrist. The styloid process forms a prominent tubercle continuous above with the dorsal border and ending below in a blunt apex at the level of the wrist-joint; it is most evident when the hand is in a position midway between supination and pronation. When the forearm is pronated another prominence, the head of the ulna, appears behind and above the styloid process.

Below the lateral epicondyle of the humerus a portion of the head of the **radius** is palpable; its position is indicated on the surface by a little dimple, which is best seen when the arm is extended. If the finger be placed in this dimple and the semiflexed forearm be alternately pronated and supinated the head of the radius will be felt distinctly, rotating in the radial notch. The upper half of the body of the bone is obscured by muscles; the lower half, though not subcutaneous, can be readily examined, and if traced downward is found to end in a lozenge-shaped convex surface on the lateral side of the base of the styloid process; this is the only subcutaneous part of the bone, and from its lower end the apex of the styloid process bends medialward toward the wrist. About the middle of the dorsal surface of the lower end of the radius is the dorsal radial tubercle, best perceived when the wrist is slightly flexed; it forms the lateral boundary of the oblique groove for the tendon of *Extensor pollicis longus*.

On the front of the wrist are two subcutaneous eminences, one, on the radial side, the larger and flatter, produced by the tuberosity of the **navicular** and the ridge on the **greater multangular**; the other, on the ulnar side, by the **pisiform**. The tuberosity of the navicular is distal and medial to the styloid process of the radius, and is most clearly visible when the wrist-joint is extended; the ridge on the greater multangular is about 1 cm. distal to it. The pisiform is about 1 cm. distal to the lower end of the ulna and just distal to the level of the styloid process of the radius; it is crossed by the uppermost crease which separates the front of the forearm from the palm of the hand. The rest of the volar surface of the bony carpus is covered by tendons and the transverse carpal ligament, and is entirely concealed, with the exception of the hamulus of the **hamate bone**, which, however, is difficult to

where it presents a somewhat flattened form. Above, its anterior border presents a slightly curved eminence which forms the lateral boundary of the infraclavicular fossa; below, it is closely united with the *Pectoralis major*. Its posterior border is thin, flattened, and scarcely marked above, but is thicker and more prominent below. The insertion of *Deltoides* is marked by a depression on the lateral side of the middle of the arm.

Of the scapular muscles the only one which influences surface form is the *Teres major*; it assists the *Latissimus dorsi* in forming the thick, rounded, posterior axillary fold.

When the arm is raised the *Coracobrachialis* reveals itself as a narrow elevation emerging from under cover of the anterior axillary fold and running medial to the body of the humerus.

On the front and medial aspects of the arm is the prominence of the *Biceps brachii*, bounded on either side by an intermuscular depression. It determines the contour of the front of the arm and extends from the anterior axillary fold to the bend of the elbow; its upper tendons are concealed by the *Pectoralis major* and *Deltoides*, and its lower tendon sinks into the antecubital fossa. When the muscle is fully contracted it presents a globular form, and the *lacertus fibrosus* attached to its tendon of insertion becomes prominent as a sharp ridge running downward and medialward.

On either side of the *Biceps brachii* at the lower part of the arm the *Brachialis* is discernible. Laterally it forms a narrow eminence extending some distance up the arm; medially it exhibits only a little fulness above the elbow.

On the back of the arm the long head of the *Triceps brachii* may be seen as a longitudinal eminence, emerging from under cover of *Deltoides* and gradually passing into the flattened plane of the tendon of the muscle at the lower part of the back of the arm. When the muscle is in action the medial and lateral heads become prominent.

On the front of the elbow are two muscular elevations, one on either side, separate above but converging below so as to form the medial and lateral boundaries of the antecubital fossa. The medial elevation consists of the *Pronator teres* and the *Flexors*, and forms a fusiform mass, pointed above at the medial epicondyle and gradually tapering off below. The *Pronator teres* is the most lateral of the group, while the *Flexor carpi radialis*, lying to its medial side, is the most prominent and may be traced downward to its tendon, which is situated nearer to the radial than to the ulnar border of the front of the wrist and medial to the radial artery. The *Palmaris longus* presents no surface marking above, but below, its tendon stands out when the muscle is in action as a sharp, tense cord in front of the middle of the wrist. The *Flexor digitorum sublimis* does not directly influence surface form; the position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of *Palmaris longus* and *Flexor carpi ulnaris*. The *Flexor carpi ulnaris* determines the contour of the medial border of the forearm, and is separated from the *Extensor* group of muscles by the ulnar furrow produced by the subcutaneous dorsal border of the ulna; its tendon is evident along the ulnar border of the lower part of the forearm, and is most marked when the hand is flexed and adducted.

The elevation forming the lateral side of the antecubital fossa consists of the *Brachioradialis*, the *Extensors* and the *Supinator*; it occupies the lateral and a considerable part of the dorsal surface of the forearm in the region of the elbow, and forms a fusiform mass which is altogether on a higher level than that produced by the medial elevation. Its apex is between the *Triceps brachii* and *Brachialis* some distance above the elbow-joint; it acquires its greatest breadth opposite the lateral epicondyle, and below this shades off into a flattened surface. About the middle of the forearm it divides into two diverging longitudinal eminences. The

The lateral border of the *Latissimus dorsi* (Fig. 1096) may be traced, when the muscle is in action, as a rounded edge starting from the iliac crest and slanting obliquely forward and upward to the axilla, where it takes part with the *Teres major* in forming the posterior axillary fold.

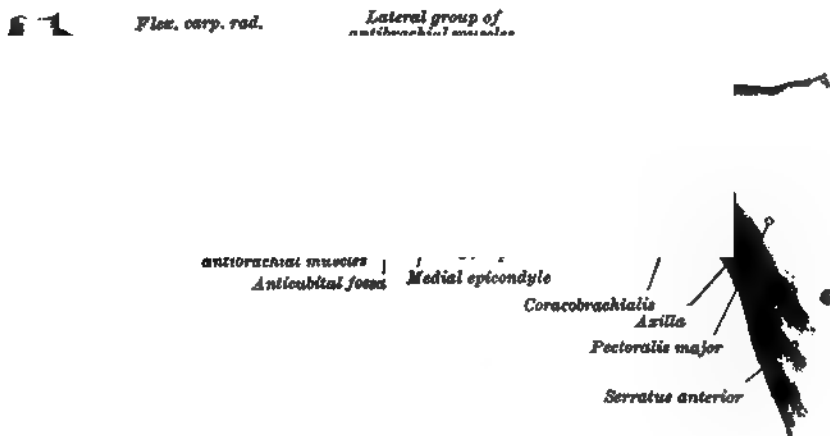

FIG. 1110.—Front of right upper extremity.

The *Pectoralis major* (Fig. 1100) conceals a considerable part of the thoracic wall in front. Its sternal origin presents a border which bounds, and determines the width of the sternal furrow. The upper margin is generally well-marked medially and forms the medial boundary of a triangular depression, the infraclavicular fossa, which separates the *Pectoralis major* from the *Deltoideus*; it gradually becomes less marked as it approaches the tendon of insertion and is closely blended with the *Deltoideus*. The lower border of *Pectoralis major* forms the rounded anterior axillary fold. Occasionally a gap is visible between the clavicular and sternal parts of the muscle.

FIG. 1111.—Back of right upper extremity

When the arm is raised the lowest slip of origin of *Pectoralis minor* produces a fulness just below the anterior axillary fold and serves to break the sharp outline of the lower border of *Pectoralis major*.

The origin of the *Serratus anterior* (Figs. 1096, 1100) causes a very characteristic surface marking. When the arm is abducted the lower five or six serrations form a zigzag line with a general convexity forward; when the arm is by the side the highest visible serration is that attached to the fifth rib.

The *Deltoideus* with the prominence of the upper end of the humerus produces the rounded contour of the shoulder; it is rounded and fuller in front than behind,

where it presents a somewhat flattened form. Above, its anterior border presents a slightly curved eminence which forms the lateral boundary of the infraclavicular fossa; below, it is closely united with the *Pectoralis major*. Its posterior border is thin, flattened, and scarcely marked above, but is thicker and more prominent below. The insertion of *Deltoides* is marked by a depression on the lateral side of the middle of the arm.

Of the scapular muscles the only one which influences surface form is the *Teres major*; it assists the *Latissimus dorsi* in forming the thick, rounded, posterior axillary fold.

When the arm is raised the *Coracobrachialis* reveals itself as a narrow elevation emerging from under cover of the anterior axillary fold and running medial to the body of the humerus.

On the front and medial aspects of the arm is the prominence of the *Biceps brachii*, bounded on either side by an intermuscular depression. It determines the contour of the front of the arm and extends from the anterior axillary fold to the bend of the elbow; its upper tendons are concealed by the *Pectoralis major* and *Deltoides*, and its lower tendon sinks into the antecubital fossa. When the muscle is fully contracted it presents a globular form, and the *lacertus fibrosus* attached to its tendon of insertion becomes prominent as a sharp ridge running downward and medialward.

On either side of the *Biceps brachii* at the lower part of the arm the *Brachialis* is discernible. Laterally it forms a narrow eminence extending some distance up the arm; medially it exhibits only a little fulness above the elbow.

On the back of the arm the long head of the *Triceps brachii* may be seen as a longitudinal eminence, emerging from under cover of *Deltoides* and gradually passing into the flattened plane of the tendon of the muscle at the lower part of the back of the arm. When the muscle is in action the medial and lateral heads become prominent.

On the front of the elbow are two muscular elevations, one on either side, separate above but converging below so as to form the medial and lateral boundaries of the antecubital fossa. The medial elevation consists of the *Pronator teres* and the *Flexors*, and forms a fusiform mass, pointed above at the medial epicondyle and gradually tapering off below. The *Pronator teres* is the most lateral of the group, while the *Flexor carpi radialis*, lying to its medial side, is the most prominent and may be traced downward to its tendon, which is situated nearer to the radial than to the ulnar border of the front of the wrist and medial to the radial artery. The *Palmaris longus* presents no surface marking above, but below, its tendon stands out when the muscle is in action as a sharp, tense cord in front of the middle of the wrist. The *Flexor digitorum sublimis* does not directly influence surface form; the position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendons of *Palmaris longus* and *Flexor carpi ulnaris*. The *Flexor carpi ulnaris* determines the contour of the medial border of the forearm, and is separated from the *Extensor* group of muscles by the ulnar furrow produced by the subcutaneous dorsal border of the ulna; its tendon is evident along the ulnar border of the lower part of the forearm, and is most marked when the hand is flexed and adducted.

The elevation forming the lateral side of the antecubital fossa consists of the *Brachioradialis*, the *Extensors* and the *Supinator*; it occupies the lateral and a considerable part of the dorsal surface of the forearm in the region of the elbow, and forms a fusiform mass which is altogether on a higher level than that produced by the medial elevation. Its apex is between the *Triceps brachii* and *Brachialis* some distance above the elbow-joint; it acquires its greatest breadth opposite the lateral epicondyle, and below this shades off into a flattened surface. About the middle of the forearm it divides into two diverging longitudinal eminences. The

lateral eminence consists of the **Brachioradialis** and the **Extensores carpi radiales longus** and **brevis**, and descends from the lateral supracondylar ridge in the direction of the styloid process of the radius. The medial eminence comprises the **Extensor digitorum communis**, **Extensor digiti quinti proprius**, and the **Extensor carpi ulnaris**; it begins at the lateral epicondyle of the humerus as a tapering mass which is separated above from the **Anconæus** by a well-marked furrow, and below from the **Pronator teres** and **Flexor** group by the ulnar furrow. The medial border of the **Brachioradialis** starts as a rounded elevation above the lateral epicondyle; lower down the muscle forms a prominent mass on the radial side of the upper part of the forearm; below it tapers to its tendon, which may be traced to the styloid process of the radius. The **Anconæus** presents as a triangular slightly elevated area, immediately lateral to the subcutaneous surface of the olecranon and differentiated from the **Extensor** group by an oblique depression; the upper angle of the triangle is at the dimple over the lateral epicondyle.

At the lower part of the back of the forearm in the interval between the two diverging eminences is an oblique elongated swelling; full above but flattened and partially subdivided below; it is caused by the **Abductor pollicis longus** and the **Extensor pollicis brevis**. It crosses the dorsal and lateral surfaces of the radius to the radial side of the wrist-joint, whence it is continued on to the dorsal surface of the thumb as a ridge best marked when the thumb is extended.

The tendons of most of the **Extensor** muscles can be seen and felt on the back of the wrist. Laterally is the oblique ridge produced by the **Extensor pollicis longus**. The **Extensor carpi radialis longus** is scarcely palpable, but the **Extensor carpi radialis brevis** can be identified as a vertical ridge emerging from under the ulnar border of the tendon of the **Extensor pollicis longus** when the wrist is extended. Medial to this the **Extensor** tendons of the fingers can be felt, the **Extensor digiti quinti proprius** being separated from the tendons of the **Extensor digitorum communis** by a slight furrow.

The muscles of the hand are principally concerned, as regards surface form, in producing the thenar and hypothenar eminences, and cannot be individually distinguished; the thenar eminence, on the radial side, is larger and rounder than the hypothenar, which is a long narrow elevation along the ulnar side of the palm. When the **Palmaris brevis** is in action it produces a wrinkling of the skin over the hypothenar eminence and a dimple on the ulnar border. On the back of the hand the **Interossei dorsales** give rise to elongated swellings between the metacarpal bones; the first forms a prominent fusiform bulging when the thumb is adducted, the others are not so marked.

Arteries.—Above the middle of the clavicle the pulsation of the **subclavian artery** can be detected by pressing downward, backward, and medialward against the first rib. The pulsation of the **axillary artery** as it crosses the second rib can be felt below the middle of the clavicle just medial to the coracoid process; along the lateral wall of the axilla the course of the artery can be easily followed close to the medial border of **Coracobrachialis**. The **brachial artery** can be recognized in practically the whole of its extent, along the medial margin of the **Biceps**; in the upper two-thirds of the arm it lies medial to the humerus, but in the lower third is more directly on the front of the bone. Over the lower end of the radius, between the styloid process and **Flexor carpi radialis**, a portion of the **radial artery** is superficial and is used clinically for observations on the pulse.

Veins.—The superficial veins of the upper extremity are easily rendered visible by compressing the proximal trunks; their arrangement is described on pages 747 to 749.

Nerves.—The uppermost trunks of the **brachial plexus** are palpable for a short distance above the clavicle as they emerge from under the lateral border of **Sterno-**

cleidomastoideus; the larger nerves derived from the plexus can be rolled under the finger against the lateral axillary wall but cannot be identified. The **ulnar nerve** can be detected in the groove behind the medial epicondyle of the humerus.

SURFACE MARKINGS OF THE UPPER EXTREMITY.

Bony Landmarks.—The bony landmarks as described above are so readily available for surface recognition that no special measurements are required to indicate them. It may be noted, however, that the medial angle of the scapula is applied to the second rib, while the inferior angle lies against the seventh. The intertubercular groove of the humerus is vertically below the acromioclavicular joint when the arm hangs by the side with the palm of the hand forward.

Articulations.—The **acromioclavicular joint** is situated in a plane passing sagittally through the middle line of the front of the arm. The line of the **elbow-joint** is not straight; the radiohumeral portion is practically at right angles to the long axis of the humerus and is situated about 2 cm. distal to the lateral epicondyle; the ulnohumeral portion is oblique, and its medial end is about 2.5 cm. distal to the medial epicondyle. The position of the **wrist-joint** can be indicated by drawing a curved line, with its convexity upward, between the styloid processes of the radius and ulna; the summit of the convexity is about 1 cm. above the centre of a straight line joining the two processes.

Muscles.—The only muscles of the upper extremity which occasionally require definition by surface lines are the Trapezius, the Latissimus dorsi, and the Pectorales major and minor. The antero-superior border of **Trapezius** is indicated by a line from the superior nuchal line about 3 cm. lateral to the external occipital protuberance to the junction of the intermediate and lateral thirds of the clavicle; the line of the lower border extends from the spinous process of the twelfth thoracic vertebra to the vertebral border of the scapula at the root of the spine. The upper border of **Latissimus dorsi** is almost horizontal, running from the spinous process of the seventh thoracic vertebra to the inferior angle of the scapula and thence somewhat obliquely to the intertubercular sulcus of the humerus; the lower border corresponds roughly to a line drawn from the iliac crest about 2 cm. from the lateral margin of the Sacrospinalis to the intertubercular sulcus. The upper margin of **Pectoralis major** extends from the middle of the clavicle to the surgical neck of the humerus; its lower border is practically in the line of the fifth rib and reaches from the fifth costochondral junction to the middle of the anterior border of Deltoideus. The two lines indicating the borders of **Pectoralis minor** begin at the coracoid process of the scapula and extend to the third and fifth ribs respectively, just lateral to the corresponding costal cartilages. On the front of the elbow-joint a triangular space—the **antecubital fossa**—is mapped out for convenience of reference. The base of the triangle is a line joining the medial and lateral epicondyles, while the sides are formed respectively by the salient margins of the Brachioradialis and Pronator teres.

Mucous Sheaths.—On the volar surfaces of the wrist and hand the mucous sheaths of the Flexor tendons (Fig. 1112) can be indicated as follows. The sheath for Flexor pollicis longus extends from about 3 cm. above the upper edge of the transverse carpal ligament to the terminal phalanx of the thumb. The common sheath for the Flexores digitorum reaches about 3.5 to 4 cm. above the upper edge of the transverse carpal ligament and extends on the palm of the hand to about the level of the centres of the metacarpal bones. The sheath for the tendons to the little finger is continued from the common sheath to the base of the terminal phalanx of this finger; the sheaths for the tendons of the other fingers are separated from the common sheath by an interval; they begin opposite the necks of the meta-

carpal bones and extend to the terminal phalanges. The mucous sheaths of the Extensor tendons are shown in Fig. 1113 (see also page 550).

FIG. 1112.—The mucous sheaths of the tendons on the front of the wrist and digits.

Arteries (Fig. 1114).—The course of the **axillary artery** can be marked out by abducting the arm to a right angle and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence of the Coracobrachialis. Of the branches of the axillary artery, the origin of the **thoracoacromial** corresponds to the point where the artery crosses the upper border of Pectoralis minor; the **lateral thoracic** takes practically the line of the lower border of Pectoralis minor; the **subscapular** is sufficiently indicated by

the axillary border of the scapula; the **scapular circumflex** is given off the subscapular opposite the midpoint of a line joining the tip of the acromion to the lower edge of the deltoid tuberosity, while the **humeral circumflex** arteries arise from the axillary about 2 cm. above this. The position of the **brachial artery** is

FIG. 1113.—The mucous sheaths of the tendons on the back of the wrist.

marked by a line drawn from the junction of the anterior and middle thirds of the distance between the anterior and posterior axillary folds to a point midway between the epicondyles of the humerus and continued distally for 2.5 cm., at which point the artery bifurcates. With regard to the branches of the brachial

artery—the **profunda** crosses the back of the humerus at the level of the insertion of *Deltoides*; the **nutrient** is given off opposite the middle of the body of the humerus; a line from this point to the back of the medial condyle represents the **superior ulnar collateral**; the **inferior ulnar collateral** is given off about 5 cm. above the fold of the elbow-joint and runs directly medialward.

FIG. 1114.—Front of right upper extremity, showing surface markings for bones, arteries, and nerves.

The position of the **radial artery** in the forearm is represented by a line from the lateral margin of the Biceps tendon in the centre of the antecubital fossa to the medial side of the front of the styloid process of the radius when the limb is in the position of supination. The situation of the distal portion of the artery is indicated by continuing this line around the radial side of the wrist to the proximal end of the first intermetacarpal space.

FIG. 1115.—Back of right upper extremity, showing surface markings for bones and nerves.

On account of the curved direction of the **ulnar artery**, two lines are required to indicate its course; one is drawn from the front of the medial epicondyle to the radial side of the pisiform bone; the lower two-thirds of this line represents two-thirds of the artery; the upper third is represented by a second line from the centre of the hollow in front of the elbow-joint to the junction of the upper and middle thirds of the first line.

The **superficial volar arch** (Fig. 1116) can be indicated by a line starting from the radial side of the pisiform bone and curving distalward and lateralward as far as the base of the thumb, with its convexity toward the fingers. The summit of the arch is usually on a level with the ulnar border of the outstretched thumb. The **deep volar arch** is practically transverse, and is situated about 1 cm. nearer to the carpus.

Nerves (Figs. 1114, 1115).—In the arm the line of the **median nerve** is practically the same as that for the brachial artery; at the bend of the elbow the nerve is medial to the artery. The course of the nerve in the forearm is marked by a line starting from a point just medial to the centre of one joining the epicondyles, and extending to the lateral margin of the tendon of *Palmaris longus* at the wrist.

The **ulnar nerve** follows the line of the brachial artery in the upper half of the arm, but at the middle of the arm it diverges and descends to the back of the medial epicondyle. In the forearm it is represented by a line from the front of the medial epicondyle to the radial side of the pisiform bone.

The course of the **radial nerve** can be indicated by a line from just below the posterior axillary fold, to the lateral side of the humerus at the junction of its middle and lower thirds; thence it passes vertically downward on the front of the arm to the level of the lateral epicondyle. The course of the **superficial radial nerve** is represented by a continuation of this line downward to the junction of the middle and lower thirds of the radial artery; it then crosses the radius and runs distalward to the dorsum of the base of the first metacarpal bone.

The **axillary nerve** crosses the humerus about 2 cm. above the centre of a line joining the tip of the acromion to the lower edge of the deltoid tuberosity.

FIG. 1116.—Palm of left hand, showing position of skin creases and bones, and surface markings for the volar arches.

SURFACE ANATOMY OF THE LOWER EXTREMITY.

Skin.—The skin of the thigh, especially in the hollow of the groin and on the medial side, is thin, smooth and elastic, and contains few hairs except on the neighborhood of the pubis. Laterally it is thicker and the hairs are more numerous. The junction of the skin of the thigh with that on the front of the abdomen is marked by a well-defined furrow which indicates the site of the inguinal ligament; the furrow presents a general convexity downward, but its medial half, which is the better marked, is nearly straight. The skin over the buttock is fairly thick and is characterized by its low sensibility and slight vascularity; as a rule it is destitute of conspicuous hairs except toward the post-anal furrow, where in some males they are abundantly developed. An almost transverse fold—the **gluteal fold**—crosses the lower part of the buttock; it practically bisects the lower margin of the *Glutaeus maximus* and is most evident during extension of the hip-joint. The skin over the front of the knee is covered by thickened epidermis; it is loose and thrown into transverse wrinkles when the leg is extended. The skin of the leg

is thin, especially on the medial side, and is covered with numerous large hairs. On the dorsum of the foot the skin is thin, loosely connected to subjacent parts, and contains few hairs, on the plantar surface, and especially over the heel, the epidermis is of great thickness, and here, as in the palm of the hand, there are neither hairs nor sebaceous glands.

Bones.—The hip bones are largely covered with muscles, so that only at a few points do they approach the surface. In front the anterior superior iliac spine is easily recognized, and in thin subjects stands out as a prominence at the lateral end of the fold of the groin; in fat subjects its position is indicated by an oblique depression, at the bottom of which the bony process can be felt. Proceeding upward and backward from this process the sinuously curved iliac crest can be traced to the posterior superior iliac spine, the site of which is indicated by a slight depression; on the outer lip of the crest, about 5 cm. behind the anterior superior spine, is the prominent iliac tubercle. In thin subjects the pubic tubercle is very apparent, but in the obese it is obscured by the pubic fat; it can, however, be detected by following up the tendon of origin of Adductor longus. Another part of the bony pelvis which is accessible to touch is the ischial tuberosity, situated beneath the Glutaeus maximus, and, when the hip is flexed, easily felt, as it is then uncovered by muscle.

The femur is enveloped by muscles, so that in fairly muscular subjects the only accessible parts are the lateral surface of the greater trochanter and the lower expanded end of the bone. The site of the greater trochanter is generally indicated by a depression, owing to the thickness of the Glutaei medius and minimus which project above it; when, however, the thigh is flexed, and especially if it be crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The lateral condyle is more easily felt than the medial; both epicondyles can be readily identified, and at the upper part of the medial condyle the sharp adductor tubercle can be recognized without difficulty. When the knee is flexed a portion of the patellar surface is uncovered and is palpable.

The anterior surface of the patella is subcutaneous. When the knee is extended the medial border of the bone is a little more prominent than the lateral, and if the Quadriceps femoris be relaxed the bone can be moved from side to side. When the joint is flexed the patella recedes into the hollow between the condyles of the femur and the upper end of the tibia, and becomes firmly applied to the femur.

A considerable portion of the tibia is subcutaneous. At the upper end the condyles can be felt just below the knee; the medial condyle is broad and smooth, and merges into the subcutaneous surface of the body below; the lateral is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, is the tubercle for the attachment of the iliotibial band. In front of the upper end of the bone, between the condyles, is an oval eminence, the tuberosity, which is continuous below with the anterior crest of the bone. This crest can be identified in the upper two-thirds of its extent as a flexuous ridge, but in the lower third it disappears and the bone is concealed by the tendons of the muscles on the front of the leg. Medial to the anterior crest is the broad surface, slightly encroached on by muscles in front and behind. The medial malleolus forms a broad prominence, situated at a higher level and somewhat farther forward than the lateral malleolus; it overhangs the medial border of the arch of the foot; its anterior border is nearly straight, its posterior presents a sharp edge which forms the medial margin of the groove for the tendon of Tibialis posterior.

The only subcutaneous parts of the fibula are the head, the lower part of the body, and the lateral malleolus. The head lies behind and lateral to the lateral condyle of the tibia, and presents as a small prominent pyramidal eminence slightly above the level of the tibial tuberosity; its position can be readily located by

following downward the tendon of *Biceps femoris*. The lateral malleolus is a narrow elongated prominence, from which the lower third or half of the lateral surface of the body of the bone can be traced upward.

On the dorsum of the tarsus the individual bones cannot be distinguished, with the exception of the head of the *talus*, which forms a rounded projection in front of the ankle-joint when the foot is forcibly extended. The whole dorsal surface of the foot has a smooth convex outline, the summit of which is the ridge formed by the head of the *talus*, the *navicular*, the second cuneiform, and the second metatarsal bone; from this it inclines gradually lateralward, and rapidly medialward. On the medial side of the foot the medial process of the tuberosity of the *calcaneus* and the ridge separating the posterior from the medial surface of the bone are distinguishable; in front of this, and below the medial malleolus, is the *sustentaculum tali*. The tuberosity of the *navicular* is palpable about 2.5 to 3 cm. in front of the medial malleolus.

Farther forward, the ridge formed by the base of the *first metatarsal bone* can be obscurely felt, and from this the body of the bone can be traced to the expanded head; beneath the base of the *first phalanx* is the medial sesamoid bone. On the lateral side of the foot, the most posterior bony point is the lateral process of the tuberosity of the *calcaneus*, with the ridge separating the posterior from the lateral surface of the bone. In front of this the greater part of the lateral surface of the *calcaneus* is subcutaneous; on it, below and in front of the lateral malleolus, the *trochlear process*, when present, can be felt. Farther forward the base of the *fifth metatarsal bone* is prominent, and from it the body and expanded head can be traced.

As in the case of the metacarpals, the dorsal surfaces of the *metatarsal bones* are easily defined, although their heads do not form prominences; the plantar surfaces are obscured by muscles. The *phalanges* in their whole extent are readily palpable.

Articulations.—The *hip-joint* is deeply seated and cannot be palpated.

The interval between the *tibia* and *femur* can always be easily felt; if the *knee-joint* be extended this interval is on a higher level than the apex of the *patella*, but if the joint be slightly flexed it is directly behind the apex. When the knee is semiflexed, the medial borders of the *patella* and of the medial condyle of the *femur*, and the upper border of the medial condyle of the *tibia*, bound a triangular depressed area which indicates the position of the joint.

The ankle-joint can be felt on either side of the Extensor tendons, and during extension of the joint the superior articular surface of the talus presents below the anterior border of the lower end of the tibia.

Muscles.—Of the muscles of the thigh, those of the anterior femoral region (Fig. 1117) contribute largely to surface form. The **Tensor fasciae latae** produces a broad elevation immediately below the anterior part of the iliac crest and behind the anterior superior iliac spine; from its lower border a groove caused by the iliotibial band extends downward to the lateral side of the knee-joint. The upper portion of **Sartorius** constitutes the lateral boundary of the femoral triangle, and, when the muscle is in action, forms a prominent oblique ridge which is continued below into a flattened plane and then gradually merges into a general fulness on the medial side of the knee-joint. When the Sartorius is not in action, a depression exists between the Quadriceps femoris and the Adductors, and extends obliquely downward and medialward from the apex of the femoral triangle to the side of the knee. In the angle formed by the divergence of Sartorius and Tensor fasciae latae, just below the anterior superior iliac spine, the **Rectus femoris** appears, and in a muscular subject its borders can be clearly defined when the muscle is in action. The **Vastus lateralis** forms a long flattened plane traversed by the groove of the iliotibial band. The **Vastus medialis** gives rise to a considerable

prominence on the medial side of the lower half of the thigh; this prominence increases toward the knee and ends somewhat abruptly with a full curved outline. The **Vastus intermedius** is completely hidden. The Adductores cannot be differentiated from one another, with the exception of the upper tendon of Adductor longus and the lower tendon of Adductor magnus. When the Adductor longus is in action its upper tendon stands out as a prominent ridge running obliquely downward and lateralward from the neighborhood of the pubic tubercle, and forming the medial border of the femoral triangle. The lower tendon of Adductor magnus can be distinctly felt as a short ridge extending downward between the Sartorius and Vastus medialis to the adductor tubercle. The adductores fill in the triangular space at the upper part of the thigh, between the femur and the pelvis, and to them is due the contour of the medial border of the thigh, the **Gracilis** contributing largely to the smoothness of the outline.

The **Glutæus maximus** (Fig. 1118) forms the full rounded outline of the buttock; it is more prominent behind, compressed in front, and ends at its tendinous insertion in a depression immediately behind the greater trochanter; its lower border crosses the gluteal fold obliquely downward and lateralward. The upper part of Glutæus medius is visible, but its lower part with Glutæus minimus and the external rotators are completely hidden. From beneath the lower margin of Glutæus maximus the hamstrings appear; at first they are narrow and not well-defined, but as they descend they become more prominent and eventually divide into two well-marked ridges formed by their tendons; these constitute the upper boundaries of the popliteal fossa. The tendon of **Biceps femoris** is a thick cord running to the head of the fibula; the tendons of the **Semimembranosus** and **Semitendinosus** as they run medialward to the tibia are separated by a slight furrow; the Semitendinosus is the more medial, and can be felt in certain positions of the limb as a sharp cord, while the Semimembranosus is thick and rounded. The Gracilis is situated a little in front of them.

The **Tibialis anterior** (Fig. 1119) presents a fusiform enlargement at the lateral side of the tibia and projects beyond the anterior crest of the bone; its tendon can be traced on the front of the tibia and ankle-joint and thence along the medial side of the foot to the base of the first metatarsal bone. The fleshy fibres of **Peronæus longus** are strongly marked at the upper part of the lateral side of the leg; it is separated by furrows from Extensor digitorum longus in front and Soleus behind. Below, the fleshy fibres end abruptly in a tendon which overlaps the more flattened

FIG. 1119.—Lateral aspect of right leg.

elevation of *Peronæus brevis*; below the lateral malleolus the tendon of *Peronæus brevis* is the more marked.

On the dorsum of the foot (Fig. 1120) the tendons emerging from beneath the transverse and cruciate crural ligaments spread out and can be distinguished as follows: the most medial and largest is *Tibialis anterior*, the next is *Extensor hallucis proprius*, then *Extensor digitorum longus* dividing into four tendons, to the second, third, fourth, and fifth toes, and lastly *Peronæus tertius*. The *Extensor digitorum brevis* produces a rounded outline on the dorsum of the foot and a fulness in front of the lateral malleolus. The *Interossei dorsales* bulge between the metatarsal bones.

Ten.

FIG. 1120.—The mucous sheaths of the tendons around the ankle. Lateral aspect.

At the back of the knee is the popliteal fossa, bounded above by the tendons of the hamstrings and below by the *Gastrocnemius*. Below this fossa is the prominent fleshy mass of the calf of the leg produced by *Gastrocnemius* and *Soleus* (Fig. 1118). When these muscles are in action the borders of *Gastrocnemius* form two well-defined curved lines which converge to the tendocalcaneus; the medial border is the more prominent. At the same time the edges of *Soleus* can be seen forming, on either side of *Gastrocnemius*, curved eminences, of which the lateral is the longer. The fleshy mass of the calf ends somewhat abruptly in the tendocalcaneus, which tapers in the upper three-fourths of its extent but widens out slightly below. Behind the medial border of the lower part of the tibia (Fig. 1121) a well-defined ridge is produced by the tendon of *Tibialis posterior* during contraction of the muscle.

On the sole of the foot the *Abductor digiti quinti* forms a narrow rounded elevation on the lateral side, and the *Abductor hallucis* a lesser elevation on the medial side. The *Flexor digitorum brevis*, bound down by the plantar aponeurosis, is not very apparent; it produces a flattened form, and the thickened skin underlying it is thrown into numerous wrinkles.

Arteries.—The *femoral artery* as it crosses the brim of the pelvis is readily felt; in its course down the thigh its pulsation becomes gradually more difficult of recognition. When the knee is flexed the pulsation of the *popliteal artery* can easily be detected in the popliteal fossa.

On the lower part of the front of the tibia the **anterior tibial artery** becomes superficial and can be traced over the ankle into the **dorsalis pedis**; the latter can be followed to the proximal end of the first intermetatarsal space. The pulsation of the **posterior tibial artery** becomes evident near the lower end of the back of the tibia, and is easily detected behind the medial malleolus.

FIG. 1121.—The mucous sheaths of the tendons around the ankle. Medial aspect.

Veins.—By compressing the proximal trunks, the venous arch on the dorsum of the foot, together with the great and small saphenous veins leading from it (see page 756), are rendered visible.

Nerves.—The only nerve of the lower extremity which can be located by palpation is the **common peroneal** as it winds around the lateral side of the neck of the fibula.

SURFACE MARKINGS OF THE LOWER EXTREMITY.

Bony Landmarks.—The anterior superior iliac spine is at the level of the sacral promontory—the posterior at the level of the spinous process of the second sacral vertebra. A horizontal line through the highest points of the iliac crests passes also through the spinous process of the fourth lumbar vertebra, while, as already pointed out (page 1303), the transtubercular plane through the tubercles on the iliac crests cuts the body of the fifth lumbar vertebra. The upper margin of the greater sciatic notch is opposite the spinous process of the third sacral vertebra, and slightly below this level is the posterior inferior iliac spine. The surface markings of the posterior inferior iliac spine and the ischial spine are both situated in a line which joins the posterior superior iliac spine to the outer part of the ischial tuberosity; the posterior inferior spine is 5 cm. and the ischial spine 10 cm. below the posterior superior spine; the ischial spine is opposite the first piece of the coccyx.

With the body in the erect posture the line joining the pubic tubercle to the top of the greater trochanter is practically horizontal; the middle of this line overlies the acetabulum and the head of the femur.

A line used for clinical purposes is that of Nélaton (Fig. 1122), which is drawn from the anterior superior iliac spine to the most prominent part of the ischial tuberosity; it crosses the centre of the acetabulum and the upper border of the

greater trochanter. Another surface marking of clinical importance is **Bryant's triangle**, which is mapped out thus: a line from the anterior superior iliac spine to the top of the greater trochanter forms the base of the triangle; its sides are formed respectively by a horizontal line from the anterior superior iliac spine and a vertical line from the top of the greater trochanter.

Sacrospinous lig.

Sacrospinous

*Greater trochanter
femur*

FIG. 1122.—Nélaton's line and Bryant's triangle

Articulations.—The posterior superior iliac spine overlies the centre of the **sacro-iliac articulations**.

The **hip-joint** may be indicated, as described above, by the centre of a horizontal line from the pubic tubercle to the top of the greater trochanter; or more generally, it is below and slightly lateral to the middle of the inguinal ligament. The **knee-joint** is superficial and requires no surface marking. The level of the **ankle-joint** is that of a transverse line about 1 cm. above the level of the tip of the medial malleolus. If the foot be forcibly extended, the head of the talus appears as a rounded prominence on the medial side of the dorsum; just in front of this prominence and behind the tuberosity of the navicular is the **talonavicular joint**. The **calcaneocuboid joint** is situated midway between the lateral malleolus and the prominent base of the fifth metatarsal bone; the line indicating it is parallel to that of the **talonavicular joint**. The line of the **fifth tarsometatarsal joint** is very oblique; it starts from the projection of the base of the fifth metatarsal bone, and if continued would pass through the head of the first metatarsal. The lines of the **fourth and third tarsometatarsal joints** are less oblique. The **first tarsometatarsal joint** corresponds to a groove which can be felt by making firm pressure on the medial border of the foot 2.5 cm. in front of the tuberosity of the navicular bone; the position of the **second tarsometatarsal joint** is 1.25 cm. behind this. The **metatarsophalangeal joints** are about 2.5 cm. behind the webs of the corresponding toes.

Muscles.—None of the muscles require any special surface lines to indicate them, but there are three intermuscular spaces which occasionally require definition, viz., the femoral triangle, the adductor canal, and the popliteal fossa.

The **femoral triangle** is bounded above by the inguinal ligament, laterally by the medial border of Sartorius, and medially by the medial border of Adductor longus. In the triangle is the fossa ovalis, through which the great saphenous vein dips to join the femoral; the centre of this fossa is about 4 cm. below and lateral to the pubic tubercle, its vertical diameter measures about 4 cm. and its transverse about 1.5 cm. The femoral ring is about 1.25 cm. lateral to the pubic tubercle.

The **adductor canal** occupies the medial part of the middle third of the thigh; it begins at the apex of the femoral triangle and lies deep to the vertical part of Sartorius. The **popliteal fossa** is bounded: above and medially by the tendons of Semimembranosus and Semitendinosus; above and laterally by the tendon of Biceps femoris; below and medially by the medial head of Gastrocnemius; below and laterally by the lateral head of Gastrocnemius and the Plantaris.

Mucous Sheaths.—The positions of the mucous sheaths around the tendons about the ankle-joints are sufficiently indicated in Figs. 1120, 1121 (see also page 586).

FIG. 1123.—Left gluteal region, showing surface markings for arteries and sciatic nerve.

Arteries.—The points of emergence of the three main arteries on the buttock, viz., the superior and inferior gluteals and the internal pudendal, may be indicated in the following manner (Fig. 1123). With the femur slightly flexed and rotated inward, a line is drawn from the posterior superior iliac spine to the posterior superior angle of the greater trochanter; the point of emergence of the **superior gluteal artery** from the upper part of the greater sciatic foramen corresponds to the junction of the upper and middle thirds of this line. A second line is drawn from the posterior superior iliac spine to the outer part of the ischial tuberosity; the junction of its lower with its middle third marks the point of emergence of the **inferior gluteal** and **internal pudendal arteries** from the lower part of the greater sciatic foramen. The course of the **femoral artery** (Fig. 1124) is represented by the upper two-thirds of a line from a point midway between the anterior superior iliac spine and the symphysis pubis to the adductor tubercle, with the thigh abducted and rotated outward; the **profunda femoris** arises from it about 1 to 5 cm. below the inguinal ligament. The course of the upper part of the **popliteal artery** (Fig. 1126) is indicated by a line from the lateral margin of Semimembranosus at the junction of the middle and lower thirds of the thigh, obliquely downward to the middle of

the popliteal fossa; from this point it runs vertically downward for about 2.5 cm. or to the level of a line through the lower part of the tibial tuberosity. The line indicating the **anterior tibial artery** (Fig. 1125) is drawn from the medial side of the head of the fibula to a point midway between the malleoli; the artery begins about 3 cm. below the head of the fibula. The **dorsalis pedis artery** is represented on the dorsum of the foot by a line from the centre of the interval between the malleoli to the proximal end of the first intermetatarsal space.

FIG. 1124.—Front of right thigh, showing surface markings for bones, femoral artery and femoral nerve.

FIG. 1125.—Lateral aspect of right leg, showing surface markings for bones, anterior tibial and dorsalis pedis arteries, and deep peroneal nerve.

The course of the **posterior tibial artery** (Fig. 1126) can be shown by a line from the end of the popliteal artery, *i. e.*, 2.5 cm. below the centre of the popliteal fossa, to midway between the tip of the medial malleolus and the centre of the convexity of the heel; its main branch, the **peroneal artery**, begins about 7 or 8 cm. below the level of the knee-joint and follows the line of the fibula to the back of the lateral malleolus. The **medial** and **lateral plantar arteries** begin from the end of the posterior tibial; the medial extends to the middle of the plantar surface of the ball of the great toe, the lateral to within a finger's breadth of the tuberosity of the fifth metatarsal bone; from this latter point the **plantar arch** crosses the foot transversely to the proximal end of the first intermetatarsal space.

Veins.—The line of the **great saphenous vein** is from the front of the medial malleolus to the centre of the fossa ovalis; the **small saphenous vein** runs from the back of the lateral malleolus to the centre of the popliteal fossa.

FIG. 1126.—Back of left lower extremity, showing surface markings for bones, vessels, and nerves.

Nerves.—The course of the **sciatic nerve** (Fig. 1126) can be indicated by a line from a point midway between the outer border of the ischial tuberosity and the posterior superior angle of the greater trochanter to the upper angle of the popliteal fossa. The continuation of this line vertically through the centre of the popliteal fossa represents the position of the **tibial nerve**, while the **common peroneal nerve** follows the line of the tendon of Biceps femoris. The lines for the **deep peroneal nerve** and the continuation of the **tibial nerve** corresponds respectively to those for the anterior and posterior tibial arteries.

Ball-and-socket joints

Gliding joints

TERMINOLOGY ADOPTED IN TEXT	BASLE TERMINOLOGY	OLD TERMINOLOGY
Articulations of the vertebral column and cranium	Ligamenta columnae vertebralis et cranii	Articulations of the spine and cranium
Anterior longitudinal ligament	Lig. longitudinale anterius	Anterior common ligament
Posterior longitudinal ligament	Lig. longitudinale posterius	Posterior common ligament
Intervertebral fibrocartilages	Fibrocartilagines intervertebrales	Intervertebral disks
Ligamenta flava	Ligg. flava	Ligamenta subflava
Supraspinal ligament	Lig. supraspinale	Supraspinous ligament
Interspinal ligaments	Ligg. interspinalia	Interspinal ligaments
Cruciate ligament of the atlas	Lig. cruciatum atlantis	Cruciform ligament
Anterior atlantoöccipital membrane	Membrana atlantoöccipitalis anterior	Anterior atlantoöccipital ligament
Posterior atlantoöccipital membrane	Membrana atlantoöccipitalis posterior	Posterior atlantoöccipital ligament
Membrana tectoria	Membrana tectoria	Occipitoaxial ligament
Alar ligaments	Ligg. alaria	Odontoid or check ligaments
Articulation of the mandible	Articulatio mandibularis	Temporomandibular articulation
Temporomandibular ligament	Lig. temporomandibulare	External lateral ligament
Sphenomandibular ligament	Lig. sphenomandibulare	Internal lateral ligament
Articular disk	Discus articularis	Articular meniscus
Stylomandibular ligament	Lig. stylomandibulare	Stylomaxillary ligament
Articulations of the heads of the ribs	Articulationes capitulorum	Costocentral articulations
Radiate ligament	Lig. capituli costae radiatum	Anterior costovertebral or stellate ligament
Interarticular ligament	Lig. capituli costae interarticularare	Intraarticular ligament
Costotransverse articulations	Articulationes costotransversariae	Costotransverse articulations
Anterior costotransverse ligament	Lig. costotransversarium anterius	Anterior superior ligament
Ligament of the neck of the rib	Lig. colli costae	Middle costotransverse ligament
Ligament of the tubercle of the rib	Lig. tuberculi costae	Posterior costotransverse ligament
Sternocostal articulations	Articulationes sternocostales	Chondrosternal articulations
Radiate sternocostal ligaments	Ligg. sternocostalia radiata	Chondrosternal or sternocostal ligaments
Interarticular sternocostal ligament	Lig. sternocostale interarticularare	Intraarticular chondrosternal ligament
Costoxiphoid ligaments	Ligg. costoxiphoidea	Chondroxiphoid ligaments
Interchondral articulations	Articulationes interchondrales	Articulations of the cartilages of the ribs with each other
Articulations of the pelvis	Ligg. cinguli extremitatis inferioris	Articulations of the pelvis
Sacroteruberous ligament	Lig. sacrotuberosum	Great or posterior sacrosclatic ligament
Sacrospinous ligament	Lig. sacrospinosum	Small or anterior sacrosclatic ligament
Sacrococcygeal symphysis	Symphysis sacrococcygea	Articulation of the sacrum and coccyx
Lateral sacrococcygeal ligament	Lig. sacrococcygeum laterale	Intertransverse ligament
Pubic symphysis	Symphysis ossium pubis	Articulation of the pubic bones
Greater sciatic foramen	Foramen ischiadicum majus	Great sacrosclatic foramen
Lesser sciatic foramen	Foramen ischiadicum minus	Small sacrosclatic foramen
Pubic arcuate ligament	Lig. arcuatum pubis	Subpubic ligament
Interpubic fibrocartilaginous lamina	Lamina fibrocartilaginea interpubica	Interpubic disk
Sternoclavicular articulation	Articulatio sternoclaviculare	Sternoclavicular articulation
Costoclavicular ligament	Lig. costoclaviculare	Rhomboid ligament
Articular disk	Discus articularis	Interarticular fibrocartilage
Acromioclavicular articulation	Articulatio acromioclavicularis	Scapuloclavicular articulation
Ligaments of the scapula	Ligg. cinguli extremitatis superioris	Ligaments of the scapula
Superior transverse ligament	Lig. transversum scapulae superioris	Suprascapular ligament
Inferior transverse ligament	Lig. transversum scapulae inferioris	Spinoglenoid ligament
Humeral articulation	Articulatio humeri	Shoulder-joint
Glenoidal labrum	Labrum glenoidale	Glenoid ligament
Elbow-joint	Articulatio cubiti	Elbow-joint
Ulnar collateral ligament	Lig. collaterale ulnare	Internal lateral ligament
Radial collateral ligament	Lig. collaterale radiale	External lateral ligament

TERMINOLOGY ADOPTED IN TEXT	BASLE TERMINOLOGY	OLD TERMINOLOGY
Proximal radioulnar articulation	Articulatio radioulnaris proximalis	Superior radioulnar joint
Annular ligament	Lig. annulare radii	Orbicular ligament
Oblique cord	Chorda obliqua	Oblique ligament
Distal radioulnar articulation	Articulatio radioulnaris distalis	Inferior radioulnar joint
Articular disk	Discus articularis	Triangular articular disk
Radiocarpal articulation	Articulatio radiocarpea	Wrist-joint
Volar radiocarpal ligament	Lig. radiocarpeum volare	Anterior ligament of the radiocarpal joint
Dorsal radiocarpal ligament	Lig. radiocarpeum dorsale	Posterior ligament of the radiocarpal joint
Ulnar collateral ligament	Lig. collaterale carpi ulnare	Internal lateral ligament
Radial collateral ligament	Lig. collaterale carpi radiale	External lateral ligament
Intercarpal articulations	Articulationes intercarpeae	Carpal joints
Volar ligaments	Ligg. intercarpea volaria	Palmar ligaments
Intermetacarpal articulations	Articulationes intermetacarpeae	Articulations of metacarpal bones with each other
Transverse metacarpal ligament	Lig. capitulum (oss. metacarpium) transversa	Transverse metacarpal ligament
Metacarpophalangeal articulations	Articulationes metacarpophalangeae	Metacarpophalangeal joints
Volar ligaments	Ligg. metacarpophalangeae volaria	Glenoid ligament of Cruveilhier; palmar or vaginal ligaments
Collateral ligaments	Ligg. collateralia	Lateral ligaments
Articulation of the digits	Articulationes digitorum manus	Articulation of the phalanges
Coxal articulation	Articulatio coxae	Hip-joint
Articular capsule	Capsula articularis	Capsular ligament
Iliofemoral ligament	Lig. iliofemorale	Y-ligament; ligament of Bigelow
Pubocapsular ligament	Lig. pubocapsulare	Pubofemoral band
Ischiocapsular ligament	Lig. ischiocapsulare	Ligament of Bertin
Glenoidal labrum	Labrum glenoidale	Cotyloid ligament
Transverse acetabular ligament	Lig. transversum acetabuli	Transverse ligament
Knee-joint	Articulatio genu	Knee-joint
Articular capsule	Capsula articularis	Capsular ligament
Patellar retinacula	Retinacula patellae	Lateral patellar ligaments
Oblique popliteal ligament	Lig. popliteum obliquum	Posterior ligament
Tibial collateral ligament	Lig. collaterale tibiale	Internal lateral ligament
Fibular collateral ligament	Lig. collaterale fibulare	External lateral or long external lateral ligament
Cruciate ligaments	Ligg. cruciata genu	Crucial ligaments
Anterior cruciate ligament	Lig. cruciatum anterius	External crucial ligament
Posterior cruciate ligament	Lig. cruciatum posterius	Internal crucial ligament
Menisci	Menisci	Semilunar fibrocartilages
Medial meniscus	Meniscus medialis	Internal semilunar cartilage
Lateral meniscus	Meniscus lateralis	External semilunar cartilage
Alar folds	Plicae alares	Ligamenta alaria
Patellar fold	Plica synovialis patellaris	Ligamentum mucosum
Tibiofibular articulation	Articulatio tibiofibularis	Superior tibiofibular articulation
Articular capsule	Capsula articularis	Capsular ligament
Ligaments of head of fibula	Ligg. capituli fibulae	Anterior and posterior superior tibiofibular ligaments
Interosseous membrane	Membrana interossea cruris	Middle tibiofibular ligament
Tibiofibular syndesmosis	Syndesmosis tibiofibulare	Inferior tibiofibular articulation
Anterior ligament	Lig. malleoli lateralis anterius	Anterior inferior ligament
Posterior ligament	Lig. malleoli lateralis posterius	Posterior inferior ligament
Talocrural articulation	Articulatio talocruralis	Ankle-joint; tibiotarsal articulation
Articular capsule	Capsula articularis	Capsular ligament
Deltoid ligament	Lig. deltoideum	Internal lateral ligament
Anterior talofibular ligament	Lig. talofibulare anterius	Anterior fasciculus } of external
Posterior talofibular ligament	Lig. talofibulare posterius	Posterior fasciculus } lateral
Calcaneofibular ligament	Lig. calcaneofibulare	Middle fasciculus } ligament
Intertarsal articulations	Articulationes intertarsae	Articulations of the tarsus

TERMINOLOGY ADOPTED IN TEXT	BASLE TERMINOLOGY	OLD TERMINOLOGY
Talocalcaneal articulation	Articulatio talocalcanes	Articulation of calcaneus and astragalus; calcaneo-astragaloid articulation
Articular capsule	Capsula articularis	Capsular ligament
Anterior talocalcaneal ligament	Lig. talocalcaneum anterius	Anterior calcaneo-astragaloid ligament
Posterior talocalcaneal ligament	Lig. talocalcaneum posterius	Posterior calcaneo-astragaloid ligament
Lateral talocalcaneal ligament	Lig. talocalcaneum laterale	External calcaneo-astragaloid ligament
Medial talocalcaneal ligament	Lig. talocalcaneum mediale	Internal calcaneo-astragaloid ligament
Talocalcaneonavicular articulation	Articulatio talocalcaneonavicularis	Talocalcaneonavicular articulation
Articular capsule	Capsula articularis	Capsular ligament
Dorsal talonavicular ligament	Lig. talonaviculare dorsale	Superior astragalonavicular ligament
Calcaneocuboid articulation	Articulatio calcaneocuboides	Articulation of calcaneus with cuboid
Articular capsule	Capsula articularis	Capsular ligament
Dorsal calcaneocuboid ligament	Lig. calcaneocuboidum dorsale	Superior calcaneocuboid ligament
Bifurcated ligament	Lig. bifurcatum	
Calcaneonavicular part of	Pars calcaneonavicularis	Superior calcaneonavicular ligament
Calcaneocuboid part of	Pars calcaneocuboid	Internal calcaneocuboid ligament
Long plantar ligament	Lig. plantare longum	Long calcaneocuboid or superficial long plantar ligament
Plantar calcaneocuboid ligament	Lig. calcaneocuboidum plantare	Short plantar ligament
Plantar calcaneonavicular ligament	Lig. calcaneonaviculare plantare	Inferior calcaneonavicular ligament
Cuneonavicular articulation	Articulatio cuneonavicularis	Articulation of navicular with cuneiform bone
Articulation of the digits	Articulationes digitorum pedis	Articulations of the phalanges

MYOLOGY.

Epicranius	Epicranius	Occipitofrontalis
Galea aponeurotica	Galea aponeurotica	Epicranial aponeurosis
Orbicularis oculi	Orbicularis oculi	Orbicularis palpebrarum
Lacrimal part	Pars lacrimalis	Tensor tarsi
Corrugator	Corrugator	Corrugator supercilii
Procerus	Procerus	Pyramidalis nasi
Nasalis	Nasalis	Compressor naris
Depressor septi	Depressor septi	Depressor alae nasi
Quadratus labii superioris	Quadratus labii superioris	Zygomaticus minor
Zygomatic head	Caput zygomaticum	Levator labii superioris
Infraorbital head	Caput infraorbitale	Levator labii superioris alaeque nasi
Angular head	Caput angulare	Levator anguli oris
Caninus	Caninus	Zygomaticus major
Zygomaticus	Zygomaticus	Levator menti
Mentalis	Mentalis	Depressor labii inferioris; Quadratus menti
Quadratus labii inferioris	Quadratus labii inferioris	Depressor anguli oris
Triangularis	Triangularis	Pterygomandibular ligament
Pterygomandibular raphé		Masseteric fascia
Parotidomasseteric fascia	Fascia parotidomasseterica	Temporal
Temporalis	Temporalis	External pterygoid
Pterygoideus externus	Pterygoideus externus	Internal pterygoid
Pterygoideus internus	Pterygoideus internus	Deep cervical fascia
Fascia colli	Fascia colli	Sternomastoid
Sternocleidomastoideus	Sternocleidomastoideus	Digastric
Digastricus	Digastricus	Stylohyoid
Stylohyoideus	Stylohyoideus	Mylohyoid
Mylohyoideus	Mylohyoideus	Geniohyoid
Geniohyoideus	Geniohyoideus	Sternohyoid
Sternohyoideus	Sternohyoideus	Omohyoid
Omohyoides	Omohyoides	Sternothyroid
Sternothyroideus	Sternothyroideus	Thyrohyoid
Thyrohyoideus	Thyrohyoideus	Rectus capitis anticus major
Longus capitis	Longus capitis	Rectus capitis anticus minor
Rectus capitis anterior	Rectus capitis anterior

NEUROLOGY.

Medulla spinalis

Funiculi of medulla spinalis
Columns of gray substance
Anterior column
Lateral column
Posterior column
Dorsal nucleus

Anterior cerebrospinal fasciculus
Anterior proper fasciculus

Lateral cerebrospinal fasciculus
Cerebellospinal fasciculus
Superficial antero-lateral fasciculus
Lateral proper fasciculus

Fasciculus gracilis
Fasciculus cuneatus

Rhombencephalon

Medulla oblongata
Anterior median fissure
Posterior median fissure
Olive
Tubercle of Rolando
Spinal tract of trigeminal nerve
Lemniscus
Decussation of lemniscus
Cerebellospinal fasciculus
Medial longitudinal fasciculus

Horizontal sulcus [of cerebellum]
Quadrangular lobule
Folium vermis

Medulla spinalis

Funiculi medullae spinalis
Columnae griseae
Columna anterior
Columna lateralis
Columna posterior
Nucleus dorsalis [Stillingi, Clarkii]
Fasciculus cerebrospinalis anterior
Fasciculus anterior proprius [Flechsigi]
Fasciculus cerebrospinalis lateralis
Fasciculus cerebellospinalis
Fasciculus anterolateralis superficialis [Gowersi]
Fasciculus lateralis proprius [Flechsigi]
Fasciculus gracilis [Golli]
Fasciculus cuneatus [Burdachi]

Rhombencephalon

Medulla oblongata
Fissura mediana anterior
Fissura mediana posterior
Olive
Tuber cinereum
Tractus spinalis n. trigemini
Lemniscus
Decussatio lemniscorum
Fasciculus cerebellospinalis
Fasciculus longitudinalis medialis
Sulcus horizontalis [cerebelli]

Lobulus quadrangularis
Folium vermis

Spinal cord

Columns of spinal cord
Horns of gray matter
Anterior cornu
Lateral cornu
Posterior cornu
Clarke's column

Direct pyramidal tract
Anterior basis bundle

Crossed pyramidal tract
Direct cerebellar tract
Gowers' tract.

Lateral basis bundle

Column of Goll
Column of Burdach

Hind-brain

Spinal bulb
Ventral or ventromedian fissure
Dorsal or dorsomedian fissure
Olivary body
Tubercle of Rolando
Spinal root of fifth cranial nerve
Fillet
Sensory decussation
Direct cerebellar tract
Posterior longitudinal bundle

Great horizontal fissure

Ant. and post. crescentic lobes
Folium cacuminis; cacuminal lobe

TERMINOLOGY ADOPTED IN TEXT

Rhombencephalon (*continued*)

Superior semilunar lobule
Nodule
Uvula
Tonsillae
Tuber vermis
Inferior semilunar lobule

Brachia conjunctiva
Brachia pontis
Restiform bodies
Anterior medullary velum

Posterior medullary velum
Tænia of fourth ventricle
Rhomboid fossa
Medial eminence

OLD TERMINOLOGY

Hind-brain (*continued*)

Postero-superior lobule
Nodular lobe
Uvular lobe
Amygdaline nucleus
Tuber valvulae
Slender and postero-inferior lobules
Superior cerebellar peduncles
Middle cerebellar peduncles
Inferior cerebellar peduncles
Valve of Vieussens; superior medullary velum
Inferior medullary velum
Ligula
Floor of fourth ventricle
Fasciculus teres
Eminentia teres
Trigonum acusticum
Striae acusticae
Trigonum vagi

Mid-brain

Crus cerebri
Crusta or pes
Intercalatum
Inferior quadrigeminal body
Superior quadrigeminal body
Aqueduct of Sylvius

Fore-brain

Optic thalamus
Middle commissure
Internal geniculate body; post-geniculatum
External geniculate body; pre-geniculatum
Epiphysis
Nucleus of Luys
Corpus albicans
Pituitary body
Optic commissure

Cerebral hemisphere

Great longitudinal fissure
Fissure of Sylvius
Fissure of Rolando
Callosomarginal fissure
Ascending frontal convolution; precentral gyre
Suprafrontal gyre
Medifrontal gyre
Subfrontal gyre
Intraparietal fissure
Ascending parietal convolution; postcentral gyre
Subparietal district or lobule
Occipitotemporal convolution
Gyri of Heschl
Island of Reil
Callosal convolution
Callosal sulcus
Dentate fissure
Peduncle of corpus callosum
Gyrus epicallous
Gyrus dentatus
Body of corpus callosum
Hippocampus minor
Anterior horn; precornu

Posticornu

Descending horn; medicornu

Hippocampus major
Caudatum
Lenticular nucleus
Anterior limb of internal capsule
Posterior limb of internal capsule
Taenia semicircularis

TERMINOLOGY ADOPTED IN TEXT	BASLE TERMINOLOGY	OLD TERMINOLOGY
Prosencephalon (continued)	Prosencephalon (continued)	Fore-brain (continued)
<i>Cerebral hemisphere</i>	<i>Hemisphaerium</i>	<i>Cerebral hemisphere</i>
Optic radiation	Radiatio occipitothalamica	Optic radiation
Column of fornix	Columna fornicis	Anterior pillar of fornix
Thalamomamillary fasciculus	Fasciculus thalamomamillaris	Bundle of Vicq d'Asyr
Crura of fornix	Crus fornicis	Posterior pillar of fornix
Septum pellucidum	Septum pellucidum	Septum lucidum
Cavity of septum pellucidum	Cavum septi pellucidi	Pseudocole; fifth ventricle
Tela chorioidea of third ventricle	Tela chorioidea ventriculi tertii	Velum interpositum
Tela chorioidea of fourth ventricle	Tela chorioidea ventriculi quarti	Tela chorioidea inferior
Choroid plexus of lateral ventricle	Plexus chorioideus ventriculus lateralis	Paraplexus
Meninges	Meninges	Meninges
Cerebral dura mater	Dura mater encephali	Dura of brain
Spinal dura mater	Dura mater spinalis	Spinal dura
Subarachnoid cavity	Cavum subarachnoideale	Subarachnoid space
Cisterna cerebellomedullaris	Cisterna cerebellomedullaris	Cisterna magna
Cisterna interpeduncularis	Cisterna interpeduncularis	Cisterna basalis
Arachnoid granulations	Granulationes arachnoidales	Pachionian bodies
Cerebral pia mater	Pia mater encephali	Pia of brain
Spinal pia mater	Pia mater spinalis	Pia of cord
Cerebral nerves	Nervi cerebrales	Cranial nerves
Olfactory nerves	Nn. olfactorii	First nerve
Optic nerve	N. opticus	Second nerve
Oculomotor nerve	N. oculomotorius	Third nerve
Trochlear nerve	N. trochlearis	Fourth nerve
Trigeminal nerve	N. trigeminus	Fifth nerve
Semilunar ganglion	Ganglion semilunare [Gasseri]	Gasserian ganglion
Nasociliary nerve	N. nasociliaris	Nasal nerve
Ciliary ganglion	Ganglion ciliare	Ophthalmic or lenticular ganglion
Maxillary nerve	N. maxillaris	Superior maxillary nerve
Middle meningeal nerve	N. meningeus medius	Meningeal or dural branch
Zygomatic nerve	N. zygomaticus	Temporomalar nerve
Zygomaticotemporal branch	Ramus zygomaticotemporalis	Temporal branch; orbital nerve
Zygomaticofacial branch	Ramus zygomaticofacialis	Malar branch
Posterior superior alveolar branches	Rami alveolares superiores posteriores	Posterior superior dental branches
Middle superior alveolar branch	Ramus alveolaris superior medius	Middle superior dental branch
Anterior superior alveolar branch	Ramus alveolaris superior anteriores	Anterior superior dental branch
Inferior palpebral branches	Rami palpebrales inferiores	Palpebral branches
Superior labial branches	Rami labiales superiores	Labial branches
Sphenopalatine ganglion	Ganglion sphenopalatinum	Ganglion of Meckel
Greater superficial petrosal nerve	N. petrosus superficialis major	Large superficial petrosal nerve
Deep petrosal nerve	N. petrosus profundus	Large deep petrosal nerve
Nerve of pterygoid canal	N. canalis pterygoidei [Vidii]	Vidian nerve
Orbital branches	Rami orbitales	Ascending branches
Palatine nerves	Nn. palatini	Descending branches
Mandibular nerve	N. mandibularis	Inferior maxillary nerve
Nervus spinosus	N. spinosus	Recurrent or meningeal branch
Buccinator nerve	N. buccinatorius	Long buccal nerve
Inferior alveolar nerve	N. alveolaris inferior	Inferior dental nerve
Abducent nerve	N. abducens	Sixth nerve
Facial nerve	N. facialis	Seventh nerve
Sensory part of facial nerve	N. intermedius	Pars intermedia of Wrisberg
Genicular ganglion	Ganglion geniculi	Geniculate ganglion
Nerve to Stapedius	N. stapedius	Tympanic branch
Zygomatic branches	Rami zygomatici	Malar branches
Buccal branches	Rami buccales	Infraorbital branches
Acoustic nerve	N. acusticus	Eighth nerve; auditory nerve
Vestibular root	Radix vestibularis	Vestibular nerve
Cochlear root	Radix cochlearis	Cochlear nerve
Glossopharyngeal nerve	N. glossopharyngeus	Ninth nerve
Superior ganglion	Ganglion superius	Jugular ganglion
Petrous ganglion	Ganglion petrosum	Inferior ganglion
Tympanic nerve	N. tympanicus	Nerve of Jacobson
Vagus nerve	N. vagus	Tenth nerve; pneumogastric nerve
Jugular ganglion	Ganglion jugulare	Ganglion of root
Ganglion nodosum	Ganglion nodosum	Ganglion of trunk; inferior ganglion
Meningeal branch	Ramus meningeus	Dural branch
Auricular branch	Ramus auricularis	Nerve of Arnold

TERMINOLOGY ADOPTED IN TEXT

BASIS TERMINOLOGY

OLD TERMINOLOGY

Cerebral nerves (continued)**Nervi cerebrales (continued)****Cranial nerves (continued)**

Vagus nerve

N. vagus

Tenth nerve; pneumogastric nerve

Recurrent nerve

N. recurrens

Inferior or recurrent laryngeal nerve

Superior cardiac branches

Rami cardiaci superiores

Cervical cardiac branches

Inferior cardiac branches

Rami cardiaci inferiores

Thoracic cardiac branches

Anterior bronchial branches

Rami bronchiales anteriores

Anterior or ventral pulmonary branches

Posterior bronchial branches

Rami bronchiales posteriores

Posterior or dorsal pulmonary branches

Esophageal plexus

{ Plexus oesophageus anterior
Plexus oesophageus posterior }

Plexus gulæ

Accessory nerve

N. accessorius

Eleventh nerve; spinal accessory nerve

Cerebral part

Ramus internus

Accessory portion

Spinal part

Ramus externus

Spinal portion

Hypoglossal nerve

N. hypoglossi

Twelfth nerve

Spinal nerves**Nervi spinales****Spinal nerves**

Posterior divisions

Rami posteriores

Posterior divisions

Medial branch

Ramus medialis

Internal branch

Lateral branch

Ramus lateralis

External branch

Greater occipital nerve

N. occipitalis major

Great occipital nerve

Anterior divisions

Rami anteriores

Anterior divisions

Smaller occipital nerve

N. occipitalis minor

Small occipital nerve

Anterior branch

Ramus anterior

Facial branch

Posterior branch

Ramus posterior

Mastoid branch

Cutaneous cervical nerve

N. cutaneus colli

Superficial or transverse cervical nerve

Supraclavicular nerves

Nn. supraclaviculares

Descending branches

Anterior supraclavicular nerves

Nn. supraclaviculares anteriores

Suprasternal nerves

Middle supraclavicular nerves

Nn. supraclaviculares medii

Supraclavicular nerves

Posterior supraclavicular nerves

Nn. supraclaviculares posteriores

Supra-acromial nerves

Brachial plexus

Plexus brachialis

Brachial plexus

Lateral cord

Fasciculus lateralis

Outer cord

Medial cord

Fasciculus medialis

Inner cord

Posterior cord

Fasciculus posterior

Posterior cord

Dorsal scapular nerve

N. dorsalis scapulae

Nerve to Rhomboidei; posterior scapular nerve

Long thoracic nerve

N. thoracalis longus

External respiratory nerve of Bell

Lateral and medial anterior thoracic nerves

Nn. thoracales anteriores

Internal and external anterior thoracic nerves

Thoracodorsal nerve

N. thoracodorsalis

Long subscapular nerve

Axillary nerve

N. axillaris

Circumflex nerve

Lateral brachial cutaneous nerve

N. cutaneus brachii lateralis

Cutaneous branch of circumflex nerve

Lateral antibrachial cutaneous nerve

N. cutaneus antibrachii lateralis

Cutaneous branch of musculo-cutaneous nerve

Volar branch

Ramus volaris

Anterior branch

Dorsal branch

Ramus dorsalis

Posterior branch

Medial antibrachial cutaneous nerve

N. cutaneus antibrachii medialis

Internal cutaneous nerve

Volar branch

Ramus volaris

Anterior branch

Ulnar branch

Ramus ulnaris

Posterior branch

Medial brachial cutaneous nerve

N. cutaneus brachii medialis

Lesser internal cutaneous nerve

Volar interosseous nerve

N. interosseus volaris

Anterior interosseous nerve

Proper volar digital nerves

Nn. digitales volares proprii

Collateral branches of digital nerves

Radial nerve

N. radialis

Musculospiral nerve

Posterior brachial cutaneous nerve

N. cutaneus brachii posterior

Internal cutaneous branch of musculospiral nerve

Dorsal antibrachial cutaneous nerve

N. cutaneus antibrachii dorsalis

External cutaneous branches of musculospiral nerve

Superficial branch of radial nerve

Ramus superficialis

Radial nerve

Deep branch of radial nerve

Ramus profundus

Posterior interosseous nerve

Dorsal interosseous nerve

N. interosseus dorsalis

Iliohypogastric nerve

Lumbosacral trunk

Truncus lumbosacralis

Iliac branch

Iliohypogastric nerve

N. iliohypogastricus

Hypogastric branch

Lateral cutaneous branch

Ramus cutaneus lateralis

Genitocrural nerve

Anterior cutaneous branch

Ramus cutaneus anterior

Genital branch

Genitofemoral nerve

N. genitofemoralis

Femoral or crural branch

External spermatic nerve

N. spermaticus externus

External cutaneous nerve

Lumboinguinal nerve

N. lumboinguinalis

Anterior crural nerve

Lateral femoral cutaneous nerve

N. cutaneus femoralis lateralis

Middle cutaneous nerve

Femoral nerve

N. femoralis

Long or internal saphenous nerve

Intermediate cutaneous nerve

Ramus cutaneus anterior

Patellar branch

Saphenous nerve

N. saphenus

Infrapatellar branch

Ramus infrapatellaris

TERMINOLOGY ADOPTED IN TEXT	BASLE TERMINOLOGY	OLD TERMINOLOGY
Spinal nerves (<i>continued</i>)	Nervi spinales (<i>continued</i>)	Spinal nerves (<i>continued</i>)
Posterior femoral cutaneous nerve	N. cutaneus femoralis posterior	Small sciatic nerve
Sciatic nerve	N. ischiadicus	Great sciatic nerve
Tibial nerve	N. tibialis	Internal popliteal nerve
Medial sural cutaneous nerve	N. cutaneus surae medialis	Nervus communicans tibialis
Sural nerve	N. suralis	Short saphenous nerve
Medial plantar nerve	N. plantaris medialis	Internal plantar nerve
Lateral plantar nerve	N. plantaris lateralis	External plantar nerve
Common peroneal nerve	N. peroneus communis	External popliteal nerve
Lateral sural cutaneous nerve	N. cutaneus surae lateralis	Lateral cutaneous branch
Peroneal anastomotie branch	Ramus anastomotieus peroneus	Nervus communicans fibularis
Deep peroneal nerve	N. peroneus profundus	Anterior tibial nerve
Superficial peroneal nerve	N. peroneus superficialis	Musculocutaneous nerve
Medial dorsal cutaneous nerve	N. cutaneus dorsalis medialis	Internal dorsal cutaneous branch
Intermediate dorsal cutaneous nerve	N. cutaneus dorsalis intermedius	External dorsal cutaneous branch
Pudendal nerve	N. pudendus	Internal pudic nerve
Posterior scrotal nerves	Nn. scrotales posteriores	Superficial peroneal nerves
Sympathetic system	Systema nervorum sympathicum	Sympathetic system
Sympathetic trunks	Truncus sympathicus	Gangliated cord
Internal carotid plexus	Plexus caroticus internus	Carotid plexus
Ansa subclavia [Vieussenii]	Ansa subclavia [Vieussenii]	Ansa Vieussenii
Middle cardiac nerve	N. cardiacus medius	Great cardiac nerve
Greater splanchnic nerve	N. splanchnicus major	Great splanchnic nerve
Lowest splanchnic nerve	N. splanchnicus imus	Least splanchnic nerve
Cardiac plexus	Plexus cardiacus	Superficial and deep cardiac plexuses
Posterior coronary plexus	Plexus coronarius posterior	Left coronary plexus
Anterior coronary plexus	Plexus coronarius anterior	Right coronary plexus
Coeliac plexus	Plexus coeliacus	Solar plexus
Coeliac ganglia	Ganglia coeliaca	Semilunar ganglia
Superior gastric plexus	Plexus gastricus superior	Gastric or coronary plexus
Abdominal aortic plexus	Plexus aorticus abdominis	Aortic plexus
Lesser cavernous nerves	Nn. cavernosi penis minores	Small cavernous nerves
Greater cavernous nerve	N. cavernosus penis major	Large cavernous plexus

PERIPHERAL ORGANS OF THE SPECIAL SENSES.

Organ of Taste	Organon gustus	Organs of taste
Gustatory calyculi	Calyculi gustatorii	Taste-buds
Organ of smell	Organon olfactus	The nose
External nose	Nasus externus	Outer nose
Lateral cartilage	Cartilago nasi lateralis	Upper lateral cartilage
Greater alar cartilage	Cartilago alaris major	Lower lateral cartilage
Lesser alar cartilages	Cartilagine alares minores	Sesamoid cartilages
Nasal cavity	Cavum nasi	Nasal fossa
Choanæ	Choanae	Posterior nares
Accessory sinuses of nose	Sinus paranasales	Accessory sinuses of nose
Maxillary sinus	Sinus maxillaris	Antrum of Highmore
Organ of sight	Organon visus	The eye
Bulb of eye	Bulbus oculi	Eyeball
Sinus venosus sclerae	Sinus venosus sclerae	Canal of Schlemm
Corneal epithelium	Epithelium corneae	Anterior layer
Anterior elastic lamina	Lamina elastica anterior	Anterior limiting layer; Bowman's membrane
Posterior elastic lamina	Lamina elastica posterior	Membrane of Descemet; membrane of Demours
Spaces of the angle of the iris	Spatia anguli iridis	Spaces of Fontana
Endothelium of the anterior chamber	Endothelium camerae anterioris	Posterior layer; corneal endothelium
Zonula ciliaris	Zonula ciliaris [Zinni]	Zonule of Zinn
Spatia zonularis	Spatia zonularis	Canal of Petit
Rectus medialis	M. rectus medialis	Rectus internus
Rectus lateralis	M. rectus lateralis	Rectus externus
Ligament or tendon of Zinn	Annulus tendineus communis [Zinni]	Ligament or tendon of Zinn
Fascia bulbi	Fascia bulbi [Tenoni]	Capsule of Ténon
Lateral palpebral commissure	Commissura palpebrarum lateralis	External canthus
Medial palpebral commissure	Commissura palpebrarum medialis	Internal canthus

TERMINOLOGY ADOPTED IN TEXT	BASLE TERMINOLOGY	OLD TERMINOLOGY
Organ of sight (<i>continued</i>)	Organon visus (<i>continued</i>)	The eye (<i>continued</i>)
Superior tarsus	Tarsus superior	Superior tarsal plate
Inferior tarsus	Tarsus inferior	Inferior tarsal plate
Orbital septum	Septum orbitale	Palpebral ligaments
Medial palpebral ligament	Lig. palpebrale mediale	Internal tarsal ligament
Lateral palpebral raphé	Raphe palpebralis lateralis	External tarsal ligament
Tarsal glands	Glandulae tarsales [Meibomi]	Meibomian glands
Lacrimal ducts	Ductus lacrimales	Lacrimal canals
Nasolacrimal duct	Ductus nasolacrimalis	Nasal duct
Organ of hearing	Organon auditus	The ear
Auricula	Auricula	Pinna
Fossa triangularis	Fossa triangularis	Fossa of antihelix
Scapha	Scapha	Fossa of helix
Auricularis anterior	M. auricularis anterior	Attrahens aurem
Auricularis superior	M. auricularis superior	Attollens aurem
Auricularis posterior	M. auricularis posterior	Retrahens aurem
External acoustic meatus	Meatus acusticus externus	External auditory meatus
Tegmental wall	Paries tegmentalis	Roof of tympanic cavity
Jugular wall	Paries jugularis	Floor of tympanic cavity
Membranous wall	Paries membranacea	Outer wall
Petrotympenic fissure	Fissura petrotympenicus	Glaserian fissure
Labyrinthic wall	Paries labyrinthica	Inner wall
Fenestra vestibuli	Fenestra vestibuli	Fenestra ovalis
Fenestra cochleae	Fenestra cochleae	Fenestra rotunda
Prominence of facial canal	Prominentia canalis facialis	Prominence of aqueduct of Fallopius
Mastoid wall	Paries mastoidea	Posterior wall
Tympanic antrum	Antrum tympanicum	Mastoid antrum
Pyramidal eminence	Eminentia pyramidalis	Pyramid
Carotid wall	Paries carotica	Anterior wall
Auditory tube	Tuba auditiva	Eustachian tube
Anterior process [of malleus]	Processus anterior [Folii]	Processus gracilis
Lateral process [of malleus]	Processus lateralis	Processus brevis
Short crus [of incus]	Crus breve	Short process
Long crus [of incus]	Crus longum	Long process
Lenticular process [of incus]	Processus lenticularis	Os orbiculare
Recessus sphaericus	Recessus sphaericus	Recessus hemisphericus
Recessus ellipticus	Recessus ellipticus	Recessus hemiellipticus
Lateral semicircular canal	Canalis semicircularis lateralis	External semicircular canal
Ductus reuniens	Ductus reuniens	Canalis reuniens
Semicircular ducts	Ductus semicirculares	Membranous semicircular canals
Ductus cochlearis	Ductus cochlearis	Membranous cochlea or scala media
Vestibular membrane	Membrana vestibularis [Reissneri]	Reissner's membrane
• Spiral organ of Corti	Organon spirale [Corti]	Organ of Corti
• Vestibular ganglion	Ganglion vestibulare	Ganglion of Scarpa
Spiral ganglion of cochlea	Ganglion spirale cochleae	Ganglion of Corti
Common integument	Integumentum commune	Skin

SPLANCHNOLOGY.

Respiratory apparatus	Apparatus respiratorius	Respiratory system
Laryngeal prominence	Prominentia laryngea	Pomum Adami
Corniculate cartilages	Cartilagine corniculatae [Santorini]	Cartilages of Santorini
Cuneiform cartilages	Cartilagine cuneiformes	Cartilages of Wrisberg
Tubercle of epiglottis	Tuberculum epiglotticum	Cushion of epiglottis
Hyothyroid membrane	Membrana hyothyreoida	Thyrohyoid membrane
Lateral hyothyroid ligament	Lig. hyothyreoidae laterale	Lateral thyrohyoid ligament
Conus elasticus	Conus elasticus	Cricothyroid membrane
Middle cricothyroid ligament	Lig. cricothyreoidae medium	Central part of cricothyroid membrane
Ventricular folds	Plicae ventriculares	Superior or false vocal cords
Ventricular ligament	Lig. ventriculare	Superior thyroarytenoid ligament
Vocal folds	Plicae vocales	Inferior or true vocal cords
Vocal ligament	Lig. vocale	Inferior thyroarytenoid ligament
Ventricle of the larynx	Ventriculus laryngis [Morgagni]	Laryngeal sinus
Appendix of laryngeal ventricle	Appendix ventriculi laryngis	Laryngeal sacculae
Rima glottidis	Rima glottidis	Rima glottidis
Intermembranous part	Pars intermembranacea	Glottis vocalis
Intercartilaginous part	Pars intercartilaginea	Glottis respiratoria
Vocalis muscle	M. vocalis	Inner portion of Thyroarytenoid

TERMINOLOGY ADOPTED IN TEXT

BASLE TERMINOLOGY

OLD TERMINOLOGY

Respiratory apparatus (*continued*)

Cricothyreoides
Cricoarytenoideus posterior
Cricoarytenoideus lateralis
Thyreothyreoides
Cupula of pleura
Pulmonary ligament
Costal surface
Mediastinal surface

Apparatus respiratorius (*continued*)

M. cricothyreoides
M. cricoarytenoideus posterior
M. cricoarytenoideus lateralis
M. thyreothyreoides
Cupula pleurae
Lig. pulmonale
Facies costalis
Facies mediastinalis

Respiratory system (*continued*)

Cricothyroid
Posterior cricoarytenoid
Lateral cricoarytenoid
Thyroarytenoid
Cervical pleura
Ligamentum latum pulmonis
External or thoracic surface
Inner surface

Digestive apparatus

Mouth
Glossopalatine arch
Pharyngopalatine arch
Levator veli palatini
Tensor veli palatini
Musculus uvulae
Glossopalatinus
Pharyngopalatinus
Incisor teeth
Premolar teeth
Dens serotinus
Deciduous teeth
Dentin
Crusta petrosa
Root of tongue
Papillae vallatae
Apex of tongue
Inferior surface of tongue
Genioglossus
Longitudinalis linguae superior
Longitudinalis linguae inferior
Transversus linguae
Verticalis linguae
Anterior lingual gland

Apparatus digestorius

Cavum oris
Arcus glossopalatinus
Arcus pharyngopalatinus
M. levator veli palatini
M. tensor veli palatini
M. uvulae
M. glossopalatinus
M. pharyngopalatinus
Dentes incisivi
Dentes praemolares
Dens serotinus
Dentes decidui
Substantia eburnea
Substantia ossea
Radix linguae
Papillae vallatae
Apex linguae
Facies inferior linguae
M. genioglossus
M. longitudinalis linguae superior
M. longitudinalis linguae inferior
M. transversus linguae
M. verticalis linguae
Gl. lingualis anterior [Blandini, Nuhn]

Organs of digestion

Oral or buccal cavity
Anterior pillar of fauces
Posterior pillar of fauces
Levator palati
Tensor palati
Azygos uvulae
Palatoglossus
Palatopharyngeus
Incisive or cutting teeth
Bicuspid teeth
Wisdom tooth
Temporary or milk-teeth
Ivory of teeth
Cement of teeth
Base of tongue
Circumvallate papillae
Tip of tongue
Under surface of tongue
Geniohyoglossus
Superior lingualis
Inferior lingualis
Transverse lingualis
Vertical lingualis
Gland of Nuhn

Accessory parotid gland
Parotid duct
Submaxillary duct
Smaller sublingual duct
Larger sublingual ducts
Nasal part of pharynx
Pharyngeal recess

Glandula parotis accessoria
Ductus parotideus [Stenonis]
Ductus submaxillaris
Ductus sublingualis major
Ductus sublinguales minores
Pars nasalis pharyngis
Recessus pharyngeus [Rosenmüller]

Socia parotidis
Stensen's duct
Wharton's duct
Bartholin's duct
Ducts of Rivinus
Nasopharynx
Fossa of Rosenmüller

Palatine tonsil
Pterygomandibular raphé
Constrictor pharyngis inferior

Tonsilla palatina
Raphe pterygomandibularis
M. constrictor pharyngis inferior

Tonsil
Pterygomandibular ligament
Inferior constrictor

Constrictor pharyngis medius

M. constrictor pharyngis medius

Middle constrictor

Constrictor pharyngis superior

M. constrictor pharyngis superior

Superior constrictor

Peritoneum

Omental bursa
Rectouterine excavation

Peritoneum

Bursa omentalis
Excavatio rectouterina [cavum Douglasi]

Peritoneum

Lesser peritoneal sac
Pouch of Douglas

Epiploic foramen
Lesser omentum

Foramen epiploicum [Winslow]
Omentum minus

Foramen of Winslow
Small omentum; gastrohepatic omentum

Greater omentum

Omentum majus

Great omentum; gastrocolic omentum

Vesicouterine excavation
Gastrolenal ligament
Phrenicolienal ligament
Phrenicocolic ligament
Mesenteriole of vermiform process

Excavatio vesicouterina
Lig. gastrolienale
Lig. phrenicolienale
Lig. phrenicocolicum
Mesenteriolum processus vermiformis

Uterovesical pouch
Gastrosplenic omentum
Lienorenal ligament
Phreno- or costocolic ligament
Mesoappendix

Digestive tube

Stomach
Circular folds
Intestinal glands
Duodenal glands
Solitary lymphatic nodules
Aggregated lymphatic nodules
Vermiform process

Tubus digestorius

Ventriculus
Plicae circulares
Glandulae intestinales [Lieberkühn]
Glandulae duodenales (Brunneri)
Noduli lymphatici solitarii
Noduli lymphatici aggregati [Peyer]
Processus vermiformis

Alimentary canal

Stomach; Gaster
Valvulae conniventes; valves of Kerkring
Crypts of Lieberkühn
Brunner's glands
Solitary glands
Peyer's patches or glands
Vermiform appendix

TERMINOLOGY ADOPTED IN TEXT

Digestive apparatus (*continued*)*Digestive tube*

Colic valve
 Right colic flexure
 Left colic flexure
 Descending colon }
 Iliac colon }
 Sigmoid colon
 Transverse rectal folds
 Anal canal
 Rectal columns
 Liver
 Inferior surface
 Left sagittal fossa
 Porta hepatis
 Caudate lobe
 Caudate process
 Fibrous coat
 Pancreatic duct
 Accessory pancreatic duct

Urogenital apparatus

Kidneys
 Urinary bladder
 Urethral crest
 Prostatic utricle
 Urethral glands
 Head of epididymis
 Tail of epididymis
 Sinus of epididymis
 Appendix of testis
 Appendix of epididymis
 Ductus deferens
 Corpus cavernosum urethrae
 Prostate
 Bulbourethral gland

*Epoöphoron**Vesicular ovarian follicles*

Uterine tube
 Internal uterine orifice
 External uterine orifice
 Pudendum
 Mons pubis
 Labia minora
 External urethral orifice
 Bulb of the vestibule
 Greater vestibular gland

*Mammæ**Ductless glands*

Thyroid gland
 Thymus
 Spleen
 Suprarenal glands
 Carotid sheaths
 Coccygeal sheath

BASLE TERMINOLOGY

Apparatus digestorius (*continued*)*Tubus digestorius*

Valvula coli
 Flexura colica dextra
 Flexura colica sinistra
 Colon descendens
 Colon sigmoideum
 Plicae transversales recti
 Pars analis recti
 Columnae rectales [Morgagni]
 Hepar
 Facies inferior
 Fossa sagittalis sinistra
 Porta hepatis
 Lobus caudatus
 Processus caudatus
 Capsula fibrosa [Glissoni]
 Ductus pancreaticus [Wirsungi]
 Ductus pancreaticus accessorius [Santorini]

Apparatus urogenitalis

Renes
 Vesica urinaria
 Crista urethralis
 Utriculus prostaticus
 Glandulae urethrales
 Caput epididymis
 Cauda epididymis
 Sinus epididymis
 Appendix testis [Morgagni]
 Appendix epididymis
 Ductus deferens
 Corpus cavernosum urethrae
 Prostata
 Glandula bulbourethralis [Cowperi]
 Epoöphoron

Folliculi oophori vesiculosi [Graafii]

Tuba uterina [Fallopia]
 Orificium internum uteri
 Orificium externum uteri
 Pudendum muliebre
 Mons pubis
 Labia minora pudendi
 Orificium urethrae externum
 Bulbus vestibuli
 Glandula vestibularis major [Bartholini]
 Mammæ

Glandula thyreoidea
 Thymus
 Lien
 Glandulae suprarenales
 Glomera carotica
 Glomus coccygeum

OLD TERMINOLOGY

Organs of digestion (*continued*)*Alimentary canal*

Ileocecal valve
 Hepatic flexure
 Splenic flexure
 Descending colon
 Iliac colon
 Pelvic colon
 Houston's valves
 Anal canal
 Columns of Morgagni
 Liver
 Visceral surface
 Longitudinal fissure
 Transverse fissure of liver
 Spigelian lobe
 Caudate lobe
 Areolar coat
 Duct of Wirsung
 Duct of Santorini

Urogenital organs

Kidneys
 Bladder
 Verumontanum
 Sinus pocularis
 Glands of Littre
 Globulus major
 Globus minor
 Digital fossa
 Hydatid of Morgagni
 Pedunculated hydatid
 Vas deferens; seminal duct
 Corpus spongiosum
 Prostate gland
 Cowper's gland

Parovarium; organ of Rosenmüller
Graafian follicles

Fallopian tube; oviduct
 Internal os
 External os
 Vulva
 Mons Veneris
 Nymphæ
 Urinary meatus
 Vaginal bulb
 Bartholin's gland; commissura labiorum anterior
 Mammary glands; breasts

Ductless glands

Thyroid body
 Thymus gland
 Spleen
 Adrenal capsule
 Carotid body or glands
 Coccygeal gland or body; Luschka's gland

INDEX.

A

- ABDOMEN**, 1140
 apertures in walls of, 1147
 boundaries of, 1147
 fascia of, 498
 triangular, 502
 lymph glands of, 785
 muscles of, 498
 dissection of, 498, 503, 504, 505
 regions of, 1147
 surface anatomy of, 1301
 markings of, 1303
Abdominal aorta, 686
 applied anatomy of, 687
 branches of, 689, 690
 surface markings of, 1309
aortic plexus, 1004
 muscles, 498
 ring, deep, 508
 external, 500
 inguinal, 508
 internal, 508
 wall, lymphatic vessels of, 787
Abducent nerve, 927
 applied anatomy of, 929
Abductor digiti quinti muscle
 (foot), 588
 (hand), 554
